Hydrops fetalis with Hb Bart occurs almost exclusively in Asians, especially Chinese, Cambodians, Thais, and Filipinos. Affected fetuses usually are born prematurely and either are stillborn or die shortly after birth.[1-4] Marked anasarca and enlargement of the liver and spleen are present. Severe anemia usually is present, with hemoglobin levels of 3 to 10 g/dL. The RBCs are markedly microcytic and hypochromic and include target cells and large numbers of circulating nucleated RBCs. These morphologic abnormalities and a negative Coombs test result exclude hemolytic diseases caused by blood group incompatibility. Hemoglobin electrophoresis reveals predominantly Hb Bart, with a smaller amount of Hb H. A minor component identified as Hb Portland ($\zeta_2\gamma_2$) migrating in the position of Hb A is also seen. Normal Hb A and Hb F are totally absent.[598]

Hydropic infants have massive hepatosplenomegaly. Extreme extramedullary erythropoiesis occurs in response to the profound hypoxia and hemolytic anemia characteristic of this disease. The universal edema characteristic of the hydrops fetalis syndrome is a reflection of severe congestive heart failure and hypoalbuminemia in utero. This is partly a consequence of anemia, but the strikingly abnormal oxygen affinity of the tetrameric Hb Bart is probably the most important determinant of the severe tissue hypoxia. The oxygen dissociation curve of Hb Bart lacks the normal sigmoid form because of noncooperativity during oxygen loading and unloading and is markedly shifted to the left. The shift is so great that little oxygen is released under conditions of low oxygen concentration in the tissues.

Infants with this syndrome do not die in an earlier trimester of pregnancy because of the presence of Hb Portland ($\zeta_2\gamma_2$). This hemoglobin does display cooperativity in a manner similar to that of Hb F and therefore has a much more favorable oxygen dissociation pattern than that of Hb Bart. A high incidence of toxemia of pregnancy has been described in women carrying severely affected infants, providing an increased rationale for prenatal diagnosis of this condition.

Prenatal Diagnosis of α-Thalassemia

Using molecular hybridization technology, Dozy and associates[599] detected the complete absence of α-globin genes in fetal fibroblasts obtained by amniocentesis in a pregnancy at risk of homozygous α°-thalassemia and the hydrops fetalis syndrome. A quantitative PCR method provides similar information rapidly and accurately.[600] The presence of hydrops can also be detected by ultrasonography. DNA studies or globin synthesis evaluation may be used to confirm the diagnosis in utero. PCR-based assays are available for the detection of the common α-thalassemia deletions.[600-603]

Therapy

Fetuses with homozygous α°-thalassemia usually die in utero because of severe hydrops fetalis and are stillborn. However, some infants have had successful blood exchange transfusion immediately after birth.[604-608] It is also possible to salvage affected fetuses by in utero blood transfusions.[609,610] Limb and urogenital defects are present in a substantial portion of infants with homozygous α°-thalassemia who are rescued by these measures, and some infants have developmental delay or other neurologic abnormalities. Management after the perinatal period is similar to the management of patients with thalassemia major and includes transfusion and chelation therapy as well as the possibility of BMT.[611]

Many patients with Hb H disease do not require RBC transfusions. For patients with more severe disease, characterized by lower hemoglobin levels or frequent exacerbations of the anemia, splenectomy can be helpful. Oxidant drugs can accelerate precipitation of Hb H and exacerbate hemolysis; they should therefore be avoided.

Infants with heterozygous α°-thalassemia trait lose their Hb Bart during the first few months of life and are left with the hematologic findings of α-thalassemia trait, a mild hypochromic microcytosis that persists throughout life.[1] The degree of morphologic abnormality varies greatly among different individuals. That α-thalassemia can be easily diagnosed by hemoglobin electrophoresis at birth gives some impetus to cord blood screening studies. Confusion between heterozygous α°-thalassemia trait and iron deficiency may lead to unnecessary evaluations for possible blood loss or unnecessary supplementation with iron unless the overlap in hematologic findings is recognized and more specific diagnostic studies are performed.

De Novo and Acquired Forms of α-Thalassemia

Two distinct α-thalassemia syndromes have been described that are attributable to acquired or de novo mutations: (1) α-thalassemia associated with mental retardation and (2) Hb H disease associated with MDS.

α-Thalassemia Associated With Mental Retardation

α-Thalassemia or Hb H disease can occur as a de novo abnormality in a rare disorder called the α-thalassemia with mental retardation syndrome (ATR).[596,597] In this disorder, affected patients have mental retardation and a number of other developmental abnormalities in association with α-thalassemia trait or Hb H disease that is inherited in a nontraditional manner. Two distinct types of the ATR syndrome have been identified. In some cases, there is the de novo appearance of large (2000 kb or so) deletions involving the entire α-globin gene cluster and adjacent DNA at the tip of chromosome 16, the so-called ATR-16 syndrome. In some of these patients, the deletion produces detectable cytogenetic abnormalities of chromosome 16, indicating

that a very large segment of the chromosome is deleted, sometimes because of unbalanced chromosomal translocations involving the telomeres of the affected chromosomes. In some cases, one parent is heterozygous for α^+-thalassemia by various criteria and the other parent is completely normal; in such cases, the child has Hb H disease (- -/- α). In other cases, both parents are normal and the affected child has the hematologic phenotype of heterozygous α^o-thalassemia (- -/- α) without Hb H disease. In this form of ATR, the clinical findings, such as the degree of mental retardation and associated congenital abnormalities, are variable.

The second type of ATR syndrome is not associated with detectable deletions of the α-globin gene complex. The molecular basis of the disorder consists of mutations of a gene on the X chromosome, and the condition has been called the ATR-X syndrome.[612] In contrast to patients with the ATR-16 syndrome who have a varied phenotype of developmental abnormalities, patients with the ATR-X syndrome have a more uniform or consistent phenotype, particularly severe mental retardation (with IQs of 50-70) and a characteristic dysmorphic facial appearance.[597]

The affected gene in this syndrome encodes a *trans*-acting factor, called ATRX, that is thought to influence the expression of the α-globin genes as well as that of other genes.[613,614] The structure of this large (280 kd) DNA-binding protein is complex and contains two major functional domains: an *N*-terminal cysteine-rich zinc finger–containing domain, called the ADD domain, that has structural features similar to those of DNA methyl transferases, and a C-terminal helicase/ATPase domain. The majority of the mutations associated with the ATR-X syndrome are located in the ADD domain or the helicase domain. The ATRX protein is widely expressed in many different tissues and its intracellular localization is within three different nuclear subcompartments: heterochromatin, ribosomal DNA arrays, and PML bodies. It has been shown to interact with other proteins such as the heterochromatin-associated protein HP1 and Daxx, one of the proteins localized in PML bodies. The prevailing opinion is that the ATRX protein is part of a large chromatin-remodeling complex of the SWI2/SNF2 family. It also has ATPase activity and has translocase activity, that is, it can move along DNA as a "molecular motor." The precise mechanism(s) by which ATRX influences the expression of α-globin (and other) genes remains unknown.

Acquired Hb H Disease Associated With Myelodysplastic Syndrome or ATMDS

Hb H disease has occasionally been observed to develop during the course of different types of MDS and more rarely in patients with other hematologic malignancies.[615] The disorder usually affects elderly men older than the age of 60 years. The degree of imbalance of globin chain synthesis and of α-globin mRNA deficiency in erythroid cells of affected patients is greater than that observed in the hereditary type of Hb H disease. It is conceivable that erythroid cells of the abnormal clone synthesize no α-globin chains at all and that the expression of all four α-globin genes is suppressed or silenced,[616] but this phenomenon is difficult to document in total blood as long as some normal erythroid cells are being produced.

Until recently, the molecular basis of this fascinating disorder remained unknown. Cytogenetic, gene mapping, gene sequencing, and gene or chromosome transfer studies failed to detect any deletion or mutation in the α-globin gene cluster or functional abnormality of α-globin gene of affected patients. The results of all of these prior studies suggested that the defect responsible for this disorder probably involved the abnormal expression or function of a *trans*-acting factor capable of influencing α-globin gene expression and, indeed, such a factor was recently identified. The discovery of the factor responsible for Hb H disease in MDS results from cDNA microarray analysis of RNA isolated from granulocytes of an affected patient. One of the genes that was found to be markedly underexpressed, compared with results obtained with RNA of normal granulocytes, was the *ATRX* gene,[617] the same gene that is mutated in the α-thalassemia with mental retardation syndrome of the ATR-X type. Sequence analysis of the *ATRX* gene in the DNA of blood cells of affected individuals has identified a number of different mutations. It is noteworthy that the mutations of the *ATRX* gene associated with acquired Hb H disease associated with MDS (ATMDS) occur in the same regions of the gene as the mutations associated with the ATR-X syndrome, that is, in the ADD or helicase domains. In fact, some of the *ATRX* gene mutations identified in ATMDS are identical or similar in expected functional consequences to various mutations found in the ATR-X syndrome.

The hematologic features in the syndrome are characterized by the presence on blood smear of a dimorphic RBC population, one of which is hypochromic, microcytic, hypochromic, and poikilocytic. Incubation of the blood with the supravital stain brilliant cresyl blue results in the detection of typical Hb H inclusions. Hemoglobin electrophoresis or HPLC detects the presence of Hb H, usually in greater quantities than that typically observed in inherited Hb H disease. In typical MDS, the MCV of the erythrocytes is normal or elevated, frequently higher than 100 fL. However, in ATMDS, the MCV and mean corpuscular hemoglobin (MCH) are low: MCV usually less than 80 fL and MCH usually less than 26 pg.[615] The amount of Hb H usually remains stable but may actually decrease during the course of the disease and no longer persists after transformation of MDS to acute leukemia. This finding suggests that the Hb H–producing clone does not have a selective survival or growth advantage.

The hematologic phenotype, as reflected by the amount of Hb H present in blood, of ATMDS is much more severe than that of the ATR-X syndrome.[613] Some of this difference in severity may be due to the nature of the ATMDS mutations, some of which are null mutations that are likely to be lethal when present in germline DNA of ATR-X embryos. However, the difference in severity is also observed in the case of mutations found in both syndromes that are identical or similar in expected functional consequences. This finding suggests that additional abnormalities in gene expression in ATMDS contribute to the severity of the deficit in α-globin gene expression observed in this syndrome. Perhaps the responsible defective cofactor(s) is one or more of the proteins that interact with the ATRX protein to produce a fully functional macromolecular complex that can act as a transcriptional cofactor or that can influence the epigenetic control of α-globin gene expression.

THALASSEMIC STRUCTURAL VARIANTS

Certain structural hemoglobin variants are characterized by the presence of a biosynthetic defect as well as abnormal structure.[6] Thalassemic hemoglobinopathies are unusual forms of thalassemia caused by such structural variants.

Hb Lepore

Hb Lepore ($\alpha_2\beta\delta$) is the prototype of a group of hemoglobinopathies characterized by fused globin chains.[1-4] The chains begin with a normal δ-chain sequence at their N-terminus and end with the normal β-chain sequence at their C-terminus. These hemoglobinopathies arise by unequal or nonhomologous crossover or recombination events that fuse the proximal end of one gene with the distal end of a closely linked structurally homologous gene (Fig. 38-18). During meiosis, mispairing and crossover of the highly homologous δ- and β-globin genes can occur, resulting in a Lepore chromosome, which contains (in addition to γ-globin genes) only the fused δβ gene, and an anti-Lepore chromosome, which contains the reciprocal fusion product (δβ), as well as intact δ- and β-globin genes.[1]

Lepore globin is synthesized in low amounts, presumably because it is under the control of the δ-globin gene promoter, which normally sustains transcription at only 2.5% the level of the β-globin gene.[618] Patients with Hb Lepore have the phenotype of β-thalassemia, distinguished by the added presence of 5% to 15% Hb Lepore. In

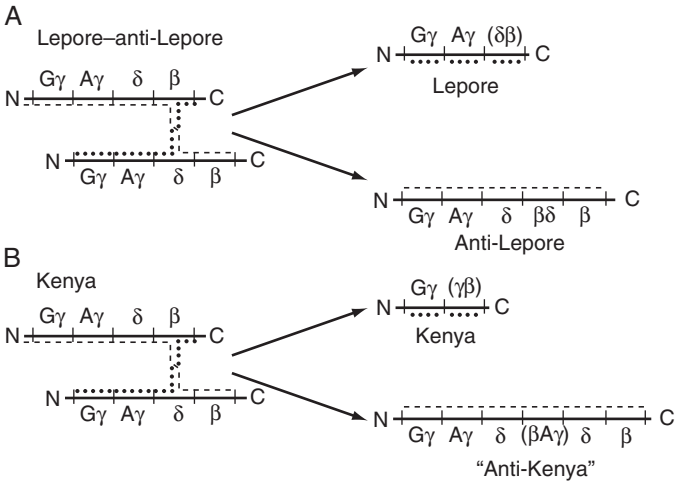

Figure 38-18 GENETIC ORIGINS OF HEMOGLOBIN (HB) LEPORE, ANTI-LEPORE HB, AND HB KENYA. *(Adapted from Benz EJ Jr: The hemoglobinopathies. In Kelly WN, DeVita VT, editors:* Textbook of internal medicine, *Philadelphia, 1988, JB Lippincott, p 1423.)*

contrast, the anti-Lepore globin (Miyada) is not associated with a β-thalassemia phenotype because of the presence of an intact and functionally normal β-globin gene on the same chromosome.

Heterozygotes for Hb Lepore have the clinical phenotype of β-thalassemia trait; homozygotes are usually similar to patients with homozygous β-thalassemia. Compound heterozygotes for Hb Lepore and a "classic" β-thalassemia allele usually have severe thalassemia. Hb Lepore thus interacts with thalassemia in the same way that a severe β-thalassemia gene does, although occasional cases have a milder phenotype of the thalassemia intermedia variety, perhaps because of an associated higher than usual level of γ-globin gene expression. The presence of Hb Lepore should be suspected in individuals with a microcytic, hypochromic anemia who also have a small amount of an abnormal hemoglobin migrating in the position of Hb S on routine hemoglobin electrophoresis. Hb Lepore accounts for 5% to 10% of the β-thalassemias seen in Greek and Italian populations. Several forms of Hb Lepore have been described that differ in the position at which the transition from δ to β DNA and amino acid sequence occurs.

An analogous but rare variant, Hb Kenya [$\alpha_2(^{A}\gamma\beta)_2$], arises from nonhomologous crossing over between the $^{A}\gamma$- and β-globin genes[619] (see Fig. 38-14) and is associated with the phenotype of $^{G}\gamma$ hereditary persistence of fetal hemoglobin (HPFH). A DNA sequence approximately 600 bases downstream from the β-globin gene acts as a strong enhancer, promoting the erythroid-specific expression of the β-globin genes in adult cells.[3,4,21] The fused $^{A}\gamma$ β gene as well as the linked upstream $^{G}\gamma$ gene are believed to come under the influence of the enhancer because of its abnormal proximity and thus are expressed at high levels in adult life.

Hb E

Hb E ($\alpha_2\beta_2^{26Glu\rightarrow Lys}$) is a common variant (15%-30% of the population) in Cambodia, Thailand, parts of China, and Vietnam. Hb E is very mildly unstable, but this instability does not significantly alter the life span of RBCs. Hb E trait resembles very mild β-thalassemia trait. Homozygotes exhibit more microcytosis but are still asymptomatic.[620] Compound heterozygotes for Hb E and a β-thalassemia gene (Hb E-β-thalassemia) resemble patients with β-thalassemia intermedia or β-thalassemia major. However, some problems such as infection and pulmonary hypertension may occur more commonly in Hb E-β-thalassemia than in homozygous β-thalassemia.[621]

The only nucleotide sequence abnormality found in the β^{E}-gene is a base change in codon 26 that causes the amino acid substitution. This mutation, which occurs in a potential cryptic RNA splice region, alters the consensus sequence surrounding a potential GT donor splice site and thus activates the cryptic site. Alternative splicing at this position occurs approximately 40% to 50% of the time, generating a structurally abnormal globin mRNA that cannot be translated appropriately.[622] The other mRNA precursors are spliced at the normal site, generating functionally normal mRNA, which is translated into β^{E}-globin because the mature mRNA retains the base change that encodes lysine at codon 26.

Hb E is important because it is so common in Southeast Asian populations. With increased emigration of Southeast Asians to North America, Hb E syndromes are being seen there with increased frequency.[623,624] Genetic counseling of these individuals should emphasize the potential consequences of the interaction of Hb E with β-thalassemia. Hb E is also an instructive example of the pleiotropic effects that point mutations can have on the amounts and types of gene products derived from a single mutant gene.

Hb Constant Spring

Hb Constant Spring (see Fig. 38-16) is an elongated α-globin variant resulting from a mutation that alters the normal translation termination codon.[625] Polyribosomes read through the usual translation stop site and incorporate an additional 31 amino acids until another in-phase termination codon is reached within the 3′ untranslated sequence. The amount of α^{cs} mRNA is markedly reduced, and α^{cs}-globin is synthesized in only minute amounts.[587,626] Six possible mutations of the normal translation termination codon (UAA) in α-globin mRNA could result in the generation of a "sense" codon.[627] Of these, five variants have been identified, each having a markedly underproduced abnormal variant, indicating that disruption of normal translation termination is in some way associated with abnormal mRNA accumulation, presumably because of instability of the mRNA.[587] The output of α-globin from the α^{cs} allele is only approximately 1% of normal, and the gene is thus rendered α-thalassemic. The α^{cs} allele has been identified only on chromosomes containing a *cis*-linked functionally normal α-globin gene.[1-4] Thus, α^{+}-thalassemia trait and Hb H disease–(- /$\alpha^{cs}\alpha$) associated with Hb Constant Spring are common, but hydrops fetalis caused by four abnormal α-globin genes cannot occur in association with this variant. Homozygosity for the variant is associated with a relatively mild form of Hb H disease.[1]

EXTRAORDINARILY UNSTABLE HEMOGLOBINS

Rare cases of α-thalassemia (e.g., Hb Quong Sze)[583] and β-thalassemia (e.g., Hb Indianapolis, recently renamed Hb Terre Haute)[628,629] arise from mutations that produce extremely labile globin chains. The chains fail to pair with the complementary chain, or they precipitate and are degraded so rapidly that they never form tetramers. These posttranslational lesions have the same pathophysiologic effects on hemoglobin biogenesis as reduction of globin mRNA production or function. Another group of β-globin chain variants, usually caused by mutations in exon 3 of the β-globin gene, are associated with inclusion body formation and a phenotype of dominant β-thalassemia intermedia.[16,17,630]

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN

Hereditary persistence of fetal hemoglobin consists of a group of rare conditions characterized by continued synthesis of high levels of Hb F in adult life.[1,631-633] No deleterious effects on patients are observed even when 100% of the hemoglobin produced in HPFH homozygotes is Hb F. These patients thus demonstrate convincingly that prevention or reversal of the Hb F–to–Hb A switch would provide efficacious therapy for β-thalassemia.

Two major types of HPFH have been described. Very high levels of fetal hemoglobin synthesis and uniform distribution of Hb F among all RBCs characterize pancellular HPFH. Heterocellular HPFH results from inherited increases in the number of F cells.

HPFH shows ethnic differences. In black patients with heterozygous pancellular deletional HPFH, the Hb F is within a range of 15% to 35% and contains $^{G}\gamma$ and $^{A}\gamma$ chains in a ratio of two to three. In Greeks with pancellular nondeletional HPFH, Hb F levels are lower, 10% to 20%, and the Hb F is 90% of the $^{A}\gamma$ type. Hb A_2 levels are lower than normal. There are usually no other hematologic abnormalities in these persons, although β/α-globin chain synthesis ratios may be lower in some black heterozygotes.

A few black patients have been described with homozygous HPFH. All hemoglobin within the RBCs of these patients is Hb F. Mild microcytosis and hypochromia of the RBCs are present without anemia. In fact, hemoglobin levels are mildly elevated, presumably because of increased erythropoiesis stimulated by the left-shifted oxygen dissociation curve of RBCs rich in Hb F. Globin chain synthesis reveals a γ/α synthetic ratio of approximately 0.5.

Pancellular HPFH can be divided into two classes. The deletional forms arise from large deletions within the β-globin gene cluster that remove the δ- and β-globin genes, part of the γδ intergenic DNA, and DNA downstream (to the 3′ side) from the β-globin genes.[1,631-633] The deletions appear to bring enhancer sequences into the proximity of the remaining γ-globin genes, promoting their high expression. Homozygotes for this condition produce only Hb F. In nondeletional HPFH, the β- and δ-globin genes are present. Single-base changes have been shown to occur in the promoter regions of either the $^{A}\gamma$- or $^{G}\gamma$-globin gene, resulting in overexpression of that form of Hb F.[1,631-633] In these individuals, Hb F levels rarely account for more than 20% of total hemoglobin.

A case of HPFH/β-thalassemia resembles β-thalassemia trait except for a higher proportion and regular distribution of Hb F in the RBCs.[1]

In δβ-thalassemia and HPFH patients, persistence of Hb F after the period of perinatal Hb F to Hb A switching is more marked than in patients with the "classic" (high Hb A_2) forms of thalassemia. Indeed, δβ-thalassemia and HPFH represent various degrees of the same genetic phenomenon. Both conditions frequently arise from deletions of DNA that remove or inactivate the β-globin gene.[1,631-633]

Heterocellular HPFH appears to result in many cases from mutations outside the β-globin gene cluster.[633] One controlling locus resides on the X chromosome.[634,635] Patients with these conditions probably represent the extreme end of a distribution of polymorphic capacities to produce F cells in adult life. Hb F levels are usually much lower than those in the pancellular forms. In some situations, elevated levels of Hb F are seen in otherwise normal individuals. In others, the high levels of Hb F become apparent only when other factors producing erythroid stress are present.

CHAPTER 39

PATHOBIOLOGY OF SICKLE CELL DISEASE

Robert P. Hebbel

Since it was recognized as the "first molecular disease," sickle cell anemia caused by homozygosity for the mutant sickle hemoglobin (HbS) has provided the classic paradigm for single-gene disorders. Predominant clinical features include hemolytic anemia, episodic painful events, chronic organ deterioration, disparate acute complications, and a foreshortened life span. However, the genesis of clinical sickle cell disease is complicated, and an understanding of its pathophysiology integrates concepts from multiple disciplines, includes contributions from the red blood cell (RBC) membrane and the vascular wall endothelium, and recognizes the likely participation of multiple genetic influences. This chapter addresses the pathophysiology that underlies the sickle cell disease syndromes described in Chapter 40.

EARLY YEARS OF SICKLE CELL DISEASE RESEARCH

Sickle cell disease syndromes were known in folk medicine for centuries in parts of Africa, but the disease was first reported in the medical literature in 1910 when Herrick described a young Grenadan man with recurrent pain, anemia, and sickle-shaped red corpuscles in the blood (Fig. 39-1, *A*). Early milestones in elucidating this disorder included discovery that deoxygenation induces reversible RBC sickling (Fig. 39-1, *B* to *E*) and recognition of genetic transmission. In 1940, Ham and Castle described a pO_2 threshold for concomitant induction of sickling and hyperviscosity, postulating that sickle cell pathophysiology resulted from a "vicious cycle of erythrostasis" involving mutually promotive sickling and viscosity changes. In 1949, Neel validated the Mendelian autosomal dominant inheritance of sickle cell anemia, and Pauling demonstrated presence of an abnormal hemoglobin in patients and carriers. This was followed by observation of the reversible sol-gel transformation of Hb solutions and the poor solubility of deoxygenated HbS, and in 1957 Ingram identified the underlying amino acid substitution. Thereafter, increasingly detailed investigations began to reveal the striking complexities of sickle cell disease pathobiology.

GENETIC CONSIDERATIONS

Molecular Context

The sickle mutation in the *HBB* gene is a GAG→GTG conversion that creates a $\beta^{6Glu\rightarrow Val}$ substitution and thereby forms β^S globin chains. Genes for other β-globin variants are allelic to the β^S gene and have a codominant impact on the hemoglobin phenotype. Examples include genes for the normal β chain (β^A), β mutants (e.g., β^C, β^0 or β^+ thalassemia), and deletional hereditary persistence of fetal hemoglobin (HPFH). Compound heterozygosity for β^S and each one of these results in well-defined clinical syndromes, such as HbAS (i.e., sickle trait), HbSC disease, HbS–β-thalassemia, and HbS-HPFH. Eight percent of African Americans have a β^S gene, 3% have β^C, 1.5% have β-thalassemia, and 0.1% have HPFH. Among African Americans, about one in 600 births results in the homozygous state, sickle cell anemia (HbSS), and about one in 400 results in some form of "sickle cell disease," which additionally includes the compound heterozygous variants other than sickle trait.

The *HBB* gene resides in a cluster of β-like genes within which are various nonexonic polymorphic sites. Different combinations of these define discrete β-locus background haplotypes, referred to as the Senegal, Benin, Bantu, Cameroon, and Arab–India haplotypes (Fig. 39-2). Each designation refers to an ethnographic region in which the sickle gene arose and achieved high frequency (typically peaking at 0.10-0.15 and perhaps even 0.20 in West Africa), which diminishes as distance from the regional center increases. The proportion of individuals having the mutation is about twice the gene frequency. In most cases, the sickle gene resides on one of these five major haplotypes, but there are other less common ones.

Origin, Selection, and Dispersion of the Sickle Gene

The residence of both β^A and β^S alleles on the distinct regional β cluster haplotype suggests that the sickle mutation arose independently in the five regions. The β^C mutation arose only once. Historical and biologic data argue that frequency of the β^S gene greatly expanded in Africa about 3000 years ago and in Asia about 4000 years ago. Its high prevalence suggests positive selection that is believed to have occurred after the introduction of iron tools. This led to adoption of an agricultural system that promoted both increased human habitation density and favorable breeding conditions for the mosquito vector, *Anopheles,* which in turn allowed development of endemic *Plasmodium falciparum*. In this context, high fixed β^S gene frequencies were reached because of a balanced polymorphism, such that heterozygotes (HbAS) have an adaptive advantage over either homozygote. Thus the Old World geographic distributions of the sickle gene and historical endemic malaria are notably concordant (see Fig. 39-2), suggesting that the sickle gene represents "a biologic solution to a cultural problem."

In hyperendemic areas, falciparum malaria uniformly infects the young and is the primary killer of children with sickle cell anemia. However, those with sickle trait are less likely to develop high-level parasitemia, to have severe malaria, or to die, an effect exerted early in childhood. At the level of the RBC, this protection probably reflects steps after initial parasite invasion. A mechanism that seems particularly plausible links protection to the instability of HbS, immune status, and splenic function. Infection of sickle trait RBCs with *P. falciparum* leads to augmented hemoglobin denaturation, clustering of membrane protein band 3, attraction of band 3 autoantibody, complement binding, and enhanced erythrophagocytosis, even of the early ring forms. This should result in accelerated clearance by the spleen. Indeed, in mice, the protective effect of HbS is lost after splenectomy, possibly suggesting that the "autosplenectomized" state may contribute to malarial virulence in HbS homozygotes. However, the timing of this scenario vis à vis appearance of immune mechanisms of protection is not yet defined.

Eventually, the sickle gene spread geographically by means of commerce, migration, and the Atlantic slave trade. This dispersion has

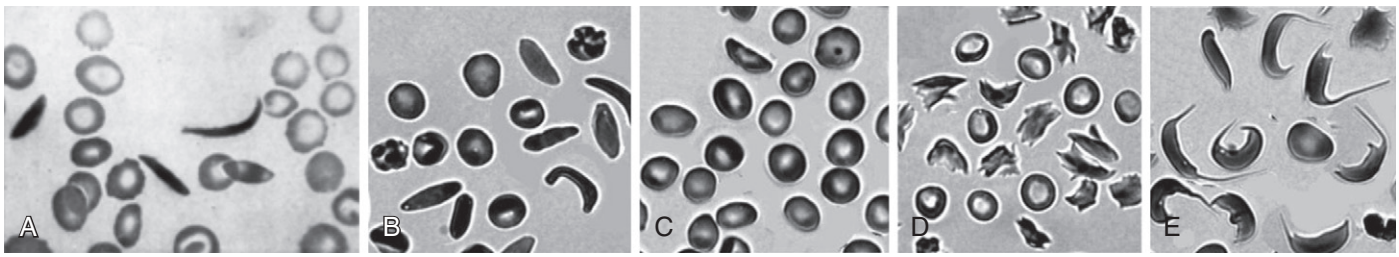

Figure 39-1 SICKLE RED BLOOD CELL (RBC) MORPHOLOGIES. **A,** Blood smear from the first patient report on sickle cell disease. **B** to **E,** Blood smears prepared under differing conditions from the same sickle cell anemia patient. **B,** Antecubital venous blood was fixed immediately at a pO_2 of approximately 40 mm Hg to document RBC shapes in vivo. Several RBC morphologies are evident, including two granular (raisinlike) cells, five somewhat elongated cells, and two highly elongated and curved cells. **C,** The mixed venous blood **(B)** was then fully oxygenated. Most cells have resumed normal shape, but one irreversibly sickled cell is present. **D,** The oxygenated cells **(C)** were then partially deoxygenated and assumed classical holly-leaf forms typical of rapid deoxygenation. **E,** The already partially deoxygenated mixed venous cells **(B)** were then fully deoxygenated ($pO_2 = 0$ mm Hg) and display the more elongated shape having fewer spikes that is assumed by slowly deoxygenated sickle RBC. The physical–chemical basis for these shapes is presented in Fig. 39-5. *(**B** to **E** from Obata K, Mattiello J, Asakura K, et al: Exposure of blood from patients with sickle cell disease to air changes the morphological, oxygen-binding, and sickling properties of sickled erythrocytes.* Am J Hematol *81:26, 2006. **A** from Herrick JB. Peculiar elongated and sickle-shaped red blood corpuscles in a case of severe anemia.* Arch Intern Med *5:517, 1910).*

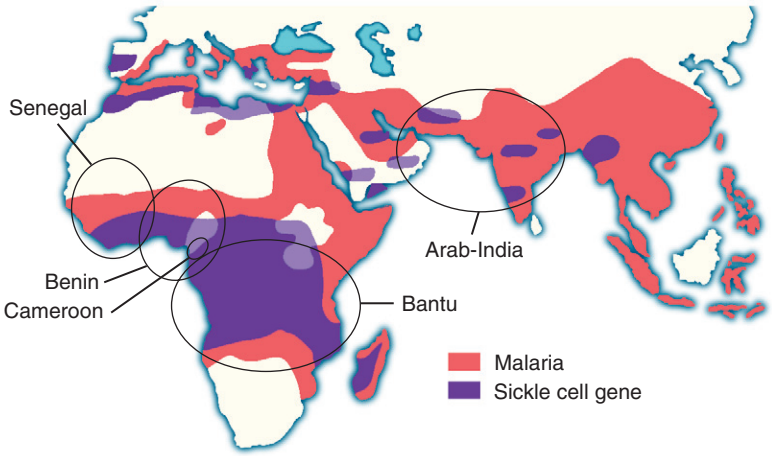

Figure 39-2 SICKLE GENE AND MALARIA. The five regions in which the sickle gene achieved high allelic frequency are superimposed on shading that identifies the Old World distribution of the sickle gene and of historical, endemic malaria. *(Adapted from Friedman MJ, Trager W: The biochemistry of resistance to malaria.* Sci Am *244:154, 1981 and from Nagel RL, Steinberg MH: Genetics of the β^S gene: Origins, epidemiology, and epistasis in sickle cell anemia. In Steinberg MH: Forget BG, Higgs DR, Nagel RL, eds:* Disorders of hemoglobin: Genetics, pathophysiology, and clinical management, *Cambridge, 2001, Cambridge University Press, p 711.)*

been tracked by analyses of regional β haplotypes, a biologic marker that largely corroborates predictions of gene flow derived from historical records. As a generalization, it spread on the Benin haplotype to North Africa and then across the Mediterranean. All three major African haplotypes are present in the western Arabian Peninsula, but on the eastern side, the sickle gene tends to be on the Arab-India haplotype, as it is in south Asia. In the Americas, the β^S gene is mostly found on the Benin, Senegal, and Bantu haplotypes.

ABNORMAL MOLECULAR BEHAVIORS OF SICKLE HEMOGLOBIN

Because the $\beta^{6Glu \rightarrow Val}$ substitution entails a loss of negative charge and gain in hydrophobicity, HbS exhibits three abnormal molecular behaviors of direct relevance to pathophysiology.

Hemoglobin S Charge and Tetramer Assembly

Formation of hemoglobin tetramers requires proximate assembly of stable dimers from unlike monomers (e.g., $\alpha + \beta \rightarrow \alpha\beta$), an event governed by electrostatic attraction. The normal α and β chains are positively and negatively charged, respectively. In heterozygous states for β-globin mutants, β-chain competition for dimer assembly is a determinant of the relative proportions of the hemoglobin variants.[1] Mutant β chains with lowered negative charge form αβ dimers more slowly; the relative rates for dimer association are $\alpha\beta^A > \alpha\beta^S > \alpha\beta^C$, with $\alpha\beta^A$ dimers formed about twice as rapidly as $\alpha\beta^S$ dimers. This explains why those with sickle trait typically have only 40% HbS and why the proportion of HbS is higher in HbSC disease than in HbAS. It also explains the effect of concurrent α-thalassemia on the proportion of HbS in sickle trait; as availability of α chains becomes limiting, the percentage of HbS typically drops from 40% to 35% (one α deletion), 30% (two α deletions), or less than 25% (three α deletions).

Hemoglobin S Stability and Oxidant Formation

HbS is modestly unstable, observed in vitro as instability to various applied stresses. Two stresses that are most clearly physiologic involve hemoglobin oxidation.[2] HbS has an abnormal redox potential compared with HbA that may underlie its modestly (≈40%) increased auto-oxidation rate. On the other hand, HbS exhibits markedly (≈340%) augmented instability upon interaction with aminophospholipids characteristic of the membrane's inner leaflet. Although the

Relationship of HbS Molecular Behaviors to Disease Features

Dimer assembly → RBC Hb composition

- Polymerization risk

HbS instability → Membrane defects
- Sickling
- Hemolysis
- Malaria resistance

HbS polymerization → Sickling
- Vasoocclusion
- Hemolysis

physical-chemical mechanism of the destabilizing role of the β^6 valine in HbS is not known, this instability leads to accumulation of various hemoglobin and iron forms at the cytosol–membrane interface.[2]

Hemoglobin S Solubility and Hemoglobin S Polymerization

Oxy-HbS, oxy-HbA, and deoxy-HbA have very high solubilities, but deoxy-HbS aggregates into densely packed polymers, a process that is fully reversible on reoxygenation.[3,4] This abnormal property causes the eponymous RBC shape change from polymer-mediated distortion, the fundamental basis for disease promotion in sickling disorders.

Polymer Structure

Deoxygenation causes transformation of soluble HbS to a highly viscous and semisolid gel that behaves thermodynamically similar to a crystal in equilibrium with a solution of individual tetrameric Hb molecules. Even complete deoxygenation does not convert all deoxy-HbS to polymer. The insoluble phase is a collection of domains of aligned polymers, the basic unit of which is a double strand in which two strings of deoxy-Hb tetramers make multiple contacts with each other (Fig. 39-3). In the physiologic form of the polymer, the component strings of hemoglobin molecules in a double strand are half-staggered and have a slight twist, creating a fiber that is approximately 21 nM in diameter and is composed of one central and six peripheral double strands. The crystal formed in vitro lacks the twist, but its molecular structure is known in great detail.

Each HbS tetramer has two β chains, the β_1 and β_2 subunits. Deoxy-HbS undergoes a slight structural shift so that the A helix β^{6Val} "donor" site of the β_2 subunit in one tetramer can contact an EF helix "acceptor" site (formed mainly by β^{85Phe}, β^{88Leu}, and β^{70Ala}) in the β_1 subunit of a tetramer in the neighboring single string. This critical, lateral association can be made only when HbS is in its deoxy conformation; the EF helix hydrophobic pocket is not a favorable acceptor site for the charged β^{6Glu} of HbA. The β^{6Val} in the β_1 subunit is located so it cannot participate in such contacts. However, the β_2 subunit of the second single string can form chemically similar β^{6Val}-dependent contacts with the β_1 subunit of the first single string. There are multiple additional axial and lateral contacts, but these are largely the same for deoxy-HbA and deoxy-HbS and are not themselves sufficient to stabilize a polymeric structure.

Role of Hemoglobin S Solubility

The RBC's hydration state dominates the physical-chemical behavior of HbS. The solubility of deoxy-HbS, approximately 16 g/dL, is so much lower than the mean cell hemoglobin concentration (MCHC) that deoxy-HbS polymerization can occur even during partial cellular deoxygenation, which can raise the deoxy-HbS concentration above its solubility limit. The biophysical effect of macromolecular crowding (boosting activity far above that predicted from concentration alone) confers non-ideal behavior on cytoplasmic constituents, augmenting likelihood for polymerization.

In vitro studies carried out under (nonphysiologic) equilibrium conditions of stable oxygen tension and long time scale corroborate crystallographic data on critical amino acids involved in atomic contacts by revealing the effect of other hemoglobins on HbS solubility (Fig. 39-4).[3] When different hemoglobins are mixed together, the tetramers dissociate into dimers that intermix and randomly assemble in a binomial distribution to reform tetramers. This clarifies the impact of naturally occurring, intracellular hemoglobin mixtures. In mixtures of HbS and HbA, overall solubility is improved because the hybrid $\alpha\beta^S/\alpha\beta^A$ tetramer integrates into polymer only one half as well as the $\alpha\beta^S/\alpha\beta^S$ tetramer (Fig. 39-4, A). Addition of HbF to HbS has an even greater sparing effect because neither the $\alpha\gamma/\alpha\gamma$ nor the hybrid $\alpha\beta^S/\alpha\gamma$ tetramer can be incorporated into polymer. In this regard, HbC has the same effect as HbA, and HbA_2 has the same effect as HbF (Fig. 39-5, A). This sparing effect of HbA is such that much lower hemoglobin oxygen saturation is required for polymer to form in HbAS than in HbSS RBCs (Fig. 39-5, *B*).

A curiosity is that the oxygen dissociation curve of sickle RBCs is right shifted, which increases in proportion to the MCHC. This is

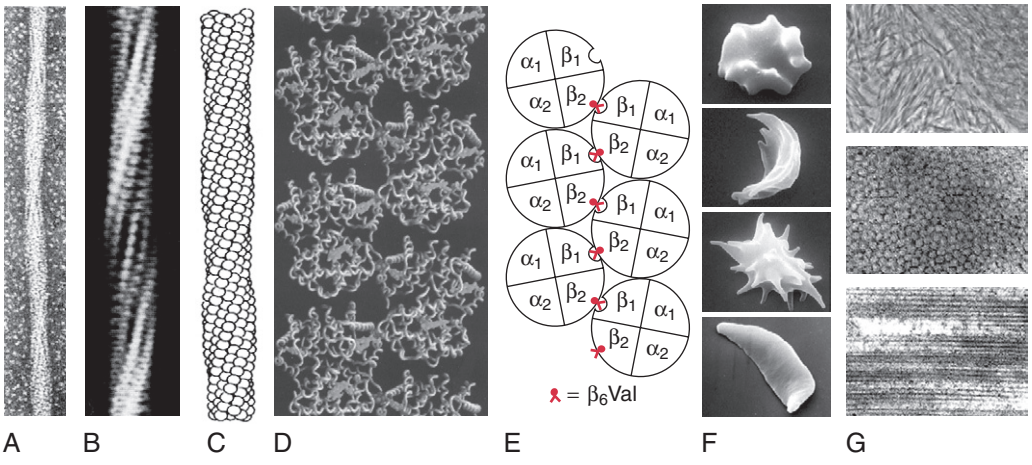

Figure 39-3 DEOXYGENATED HEMOGLOBIN S (HbS) POLYMER. **A,** Electron micrograph of a fiber of polymerized HbS obtained from a sickled red blood cell. **B,** Electron density surface map, modeled from authentic HbS fibers, shows pairings that create double strands plus a helical twist. **C,** Model of the HbS fiber, with Hb tetramers rendered as solid spheres. **D,** Protein backbone shows tetramer staggering in the HbS crystal. **E,** Schematic, two-dimensional representation of a double strand, demonstrating that only one of the two β^6 valine residues in each given tetramer participates in critical lateral contacts. **F,** Sickled red blood cells, showing various morphologies *(top to bottom):* granular, holly leaf shaped, classically sickled, and smoother and irreversibly sickled. **G,** Electron microscopy of sickled red blood cells reveals highly ordered polymer domains, as seen from the side *(bottom)* and on end *(middle),* or highly disorganized domains *(top). caused by the vanishingly low oxygen affinity of extant deoxy-HbS polymer, and it should promote neither hemoglobin polymerization (it results from it) nor tissue oxygenation (polymer is nonfunctional in oxygen delivery).

Kinetics of Polymerization

In vitro measurements of polymerization kinetics, allowed by inducing (nonphysiologic) instantaneous and complete conversion of HbS from R (oxy) to T (deoxy) state, reveal a delay before onset of polymerization, which then occurs explosively.[4] Under in vitro conditions, this delay time is inversely related to an extremely high power of the initial Hb concentration; it is approximately 10 msec at Hb of 40 g/dL, but it is 100,000 seconds at 20 g/dL (Fig. 39-4, *A*). HbS solutions and sickle RBCs behave similarly in this regard. Delay times must then vary enormously from cell to cell because they are dominated by marked heterogeneity in MCHC (i.e., shorter delay for more dehydrated cells) and are influenced by the presence of any non-S Hb (i.e., longer delay for presence of HbA, C, or F) (Fig. 39-4, *E*). Admixture of 20% to 30% HbA with HbS (simulating HbS-β^+-thalassemia) increases the delay time 10^1- to 10^2-fold, and admixture of 20% to 30% HbF with HbS increases it by 10^3- to 10^4-fold.

Actual polymer formation is hypothesized to proceed by a two-step, double-nucleation mechanism (Fig 39-4, *F*). Accordingly, the initial homogeneous nucleation takes place in bulk solution, during which small numbers of tetramers associate, with accumulation not favored until a critical nucleus size develops (estimated to be 30-50 tetramers). Then new tetramers can be added lengthwise to form a very large polymer. After this occurs, heterogeneous nucleation of new fibers takes place on the surface of the preexisting polymers, resulting in explosive, autocatalytic polymer formation. It is believed that the striking irreproducibility of long delay times (Fig. 39-4, *B*) reflects stochastic formation of a single (or at least very few) homogeneous nucleation event(s) in cells that slowly polymerize and that very short delay times (Fig. 39-4, *D*) reflect simultaneous formation of multiple nucleation sites in cells that polymerize rapidly.

The two central features of the polymerization process, governance by MCHC and the delay time, are highly dependent on the RBC membrane's control of cellular hydration. Whether the RBC membrane itself has any influence on polymerization remains under investigation. The good qualitative correspondence between polymerization in solution and in RBCs argues that the fundamental mechanism (Fig. 39-4, F) is not altered by membranes. Yet emerging evidence suggests that the abnormal sickle RBC membrane may even be able to contribute nucleation sites, thereby shortening delay times.

Polymerization Under (Patho)physiologic Conditions

Under physiologic conditions, sickle RBCs are not at equilibrium with a constant oxygen tension, and venous blood typically contains

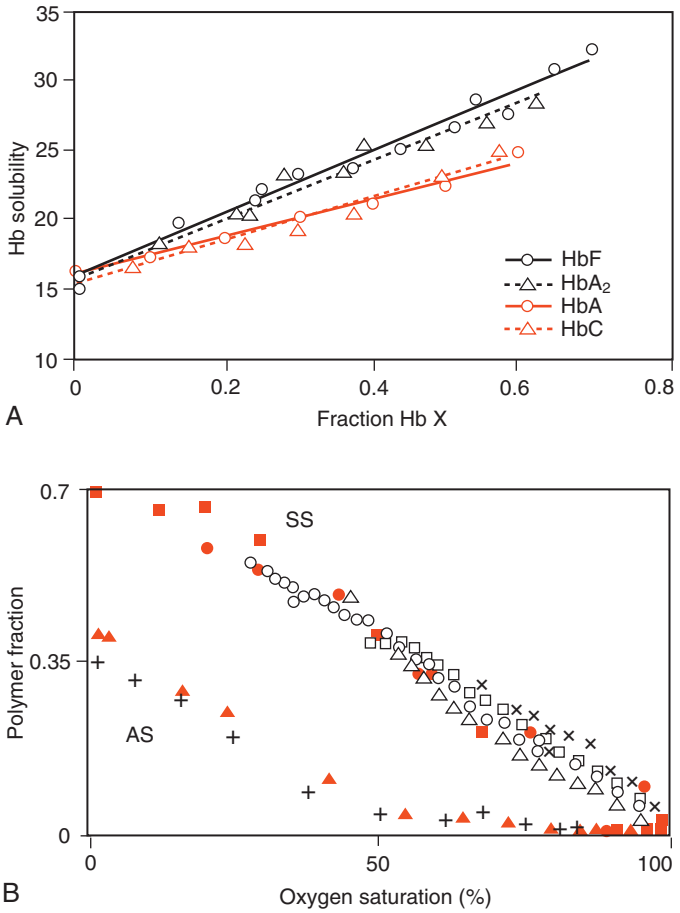

Figure 39-5 DEOXYHEMOGLOBIN S SOLUBILITY, DEFINED BY STUDIES UNDER EQUILIBRIUM CONDITIONS. **A,** Admixture of other hemoglobins with hemoglobin S raises overall solubility in absence of oxygen. **B,** The hemoglobin oxygen saturation required to initiate intracellular polymer formation (i.e., polymer fraction) is much lower for sickle trait than for normal red blood cells. *(**A,** Data from Poillon WN, Kim BC, Rodgers GP, et al: Sparing effect of hemoglobin F and hemoglobin A_2 on the polymerization of hemoglobin S at physiologic ligand saturations.* Proc Natl Acad Sci U S A *90:5039, 1993; **B,** Data from Schechter AN, Noguchi CT: Sickle hemoglobin polymer: Structure-function correlates. only about 20% sickled cells instead of the 90% predicted by equilibrium studies. Likewise, pathophysiologic deoxygenation is neither instantaneous nor complete. Indeed, HbS polymerization in vivo would be limited by the finite rate of physiologic RBC deoxygenation, and this effectively imposes a limit on what delay times are likely to be relevant in vivo: only those 1 second or longer (Fig. 39-4, G).[4] In aggregate, kinetic considerations argue that most RBCs in patients with sickle cell anemia are unlikely to sickle during their passage through the microcirculation unless something such as RBC–endothelial adhesion slows their transit time. Predictability, however, is complicated by the marked heterogeneity among RBCs in MCHC and HbF content, such that individual RBCs vary enormously in their likelihood of sickling.

The presence in RBCs of any preexisting polymer that did not completely melt during pulmonary transit would eliminate the delay time requirement because nucleation is already completed. Given the expected rapid RBC transit time through the lung (<1 second), fewer than 1% of RBCs should reach the arterial circulation still containing polymer. Despite it being critical to understanding in vivo pathophysiology, the practical balance of these considerations in the patient, particularly in those having arterial desaturation caused by lung disease or nocturnal disordered breathing, has not been directly examined.

A consequence of polymerization is alteration in RBC shape, which in vitro can become classically sickled or assume holly leaf or granular forms, depending on deoxygenation rate (slow to rapid, respectively), which determines the number of nucleation domains created (Fig. 39-4, *B* to *D*). However, physiologic oxygen transits are rapid relative to those typically used in vitro, so that granular cells may be most likely to develop in vivo. The RBC shape per se is not particularly important (shape is not a determinant of RBC deformability), but the underlying presence of polymer causes cells to lose their deformability, a feature critical for unimpeded RBC passage through the microvasculature.

Alternative Ligands: Nitric Oxide and Carbon Monoxide

Red blood cells and Hb appear to participate in nitric oxide (NO) transport to the microcirculation, although both magnitude of the effect and mechanisms involved are debated. NO is reported to improve RBC deformability and impair HbS polymerization, via undefined mechanisms, although both observations require confirmatory studies. Reaction of NO with oxy-Hb causes Hb oxidation to met-Hb plus consumption of NO.

Hemoglobin that is partially liganded with carbon monoxide (CO) is shifted to the R state but has lost a portion of the oxygen carrying capacity, thus simulating combined effects of anemia and a high-affinity Hb on oxygen delivery. Patients with sickle cell anemia can have nontrivial elevations of CO-Hb levels (reportedly as high as 7.6% in children) because of hemolysis.

ABNORMALITIES OF SICKLE RED BLOOD CELLS

Even oxygenated sickle RBCs exhibit a variety of membrane abnormalities that contribute to pathophysiology. Some are the consequence of proximate polymer formation, and others result from oxidative biochemistry. The integrated pathogenic context in which these abnormalities reside is presented below in sections on hemolysis and vascular biological disturbances.

Membrane Iron and Oxidant Generation

An abnormal oxidative biochemistry takes place at the cytosol–membrane interface of the sickle RBC.[2] The modest oxidation of HbS in solution and especially its avidity for bilayer lipid result in formation of superoxide and met-Hb, the proximate step in hemoglobin denaturation. Denatured hemoglobin can lose its heme to the lipid bilayer, where it is easily destroyed to liberate "free" iron. Membrane-associated iron is catalytically active, using cytosolic reducing substances (e.g., ascorbate, superoxide) to redox cycle and generate highly reactive oxidants. Also, it can form a redox couple with soluble oxy-Hb to promote further hemoglobin oxidation and denaturation. It is probable that this scenario underlies the various iron forms found at the cytosol–membrane interface of sickle RBC: hemoglobin, denatured hemichrome, free heme, and nonheme iron.

These processes may lead sickle RBCs to spontaneously generate excessive oxidant. Most importantly, however, the membrane location of catalytic iron establishes unique oxidant risk because it effectively targets oxidative damage to membrane components. In sickle RBCs, this is evidenced by oxidation of membrane protein thiols and peroxidation of membrane lipids. The unique juxtaposition of heme and iron with bilayer lipid is a critical feature because it effectively bypasses vitamin E, allowing reinitiation of peroxidative chain reactions. It is likely that deficient levels of RBC antioxidants (e.g., vitamin E, glutathione, ascorbic acid) caused by oxidative consumption or dietary

insufficiencies contribute to this oxidative stress state. Among the many sickle membrane defects, evidence for an oxidative origin or contribution is strongest for band 3 clustering, abnormal membrane microrheology, irreversibly sickled cell (ISC) formation, aberrant cation homeostasis, microvesiculation tendency, abnormal mechanosensitivity, and erythrophagocytosis.[2]

Cation Homeostasis and Dehydrated Cells

For normal RBCs, the MCHC averages about 32 g/dL and varies from 27 to 38 g/dL, with fewer than 1% of cells having an MCHC greater than 38 g/dL. In contrast, the MCHC of sickle RBCs averages about 34 g/dL and varies from 23 to 50 g/dL, with up to 40% of cells having an MCHC greater than 38 g/dL. This extreme density heterogeneity results from reticulocytosis (low-density, low-MCHC cells) and dehydrating mechanisms (higher density, high-MCHC cells) (Fig. 39-6).[5,6]

The most dramatic ion-handling abnormality of the sickle RBC is sickling-induced permeabilization of the RBC membrane to cations (Na^+, K^+, Ca^{2+}). This depends on cell deformation, so it probably partly reflects the sickle RBCs' exaggerated leak susceptibility to deformation (mechanosensitivity).[7] Sickling induces calcium influx and a slight acidification, occurring stochastically and only in some cells at any one time. This results in net potassium and water loss mediated mostly by activation of a Ca^{2+} activated (Gardos) K^+ channel and K^-Cl cotransport. The latter can be activated by lowered pH, endothelin-1, thiol oxidation, and a membrane interaction effect of hemoglobins that are relatively positively charged (HbC >HbS). It is influenced by macromolecular crowding of cytosolic proteins caused by the high MCHC. Even at steady state, sickle RBCs contain increased Ca^{2+} because it is sequestered in cytoplasmic inside-out membrane vesicles, providing evidence of prior cytosolic Ca^{2+} transients.

These aberrancies lead to decremental changes in RBC hydration and deformability. However, hyper-dense RBCs—mostly ISCs—are not older cells with longer histories of sickling and unsickling but rather can develop via a rapid reticulocyte-to-ISC transformation, with the RBC having lower HbF levels being particularly susceptible. Dehydrated RBCs have very diminished deformability and increased propensity for polymerization, the mutually promotive effects of dehydration and sickling comprising a vicious cycle. RBC dehydration is particularly likely to be exaggerated by the hypoxic and acidotic renal medullary environment, the greatest focus of disease in persons with sickle trait, and very probably by nocturnal arterial desaturation.

Deformability, Fragility, and Vesiculation

Even oxygenated sickle RBCs are poorly deformable.[8] The dominant cause of this is the high MCHC that imposes increased cytoplasmic viscosity and a poorly understood, hemoglobin-induced effect on membrane stiffness. There may also be a smaller oxidation-related component to membrane stiffness. Upon RBC deoxygenation in vitro, there is a temporal correspondence between appearance of polymer-induced shape change and deterioration of deformability, as measured by micropipette and laser diffractometer. On the other hand, filtration studies found decreased deformability before morphologic change, and viscometry reveals a large deterioration in bulk viscosity caused by deoxygenated dense discocytes that show little shape change.

Sickle RBCs are somewhat mechanically fragile, which may be a consequence of dehydration and a weakening of critical skeletal associations caused by oxidative protein damage. The tendency of sickled RBCs to lose membrane microvesicles reflects separation of the bilayer from the underlying skeleton by spicules of polymerized hemoglobin, with enhanced susceptibility caused by protein thiol oxidation and dysfunction.

Membrane Proteins and Lipids

Sickle RBC membrane protein function is adversely affected by thiol oxidation and possibly other oxidative protein modifications.[2] Ankyrin interactions with spectrin and band 3 are abnormal, glycophorin and band 3 exhibit decreased mobility, and thiol-oxidized β-actin displays abnormal associations in the spectrin–actin-4.1

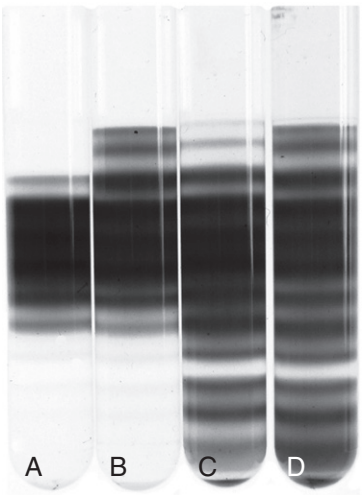

Figure 39-6 MARKED HETEROGENEITY IN SICKLE RED BLOOD CELL (RBC) HYDRATION. Compared with normal RBCs **(A)** studied by discontinuous density-gradient centrifugation, RBCs from a sickle subject with four α genes **(D)** include cells of unusually low density (usually reticulocytes) and abnormally high density (dehydrated cells). Sickle subjects with three and two α genes are shown in **C** and **B,** respectively. *(From Embury SH, Clark MR, Monroy G, Mohandas N: Concurrent sickle cell anemia and a-thalassemia.* J Clin Invest *73:116, 1984.)*

Major Sickle RBC Membrane Defects

- Membrane iron deposits →
 - Band 3 clumping → Ig attraction → erythrophagocytosis
 - Oxidative reactions targeted at membrane →
 - Thiol oxidation →
 - ISC formation
 - ↓ Deformability and ↑ fragility
 - Cation leak
 - Microvesiculation
 - Lipid peroxidation →
 - Enhanced mechanosensitivity
 - Erythrophagocytosis
- Abnormal cation homeostasis →
 - RBC dehydration → ↓ deformability
- Abnormal microrheology →
 - ↓ Deformability
- PS externalization →
 - Coagulation acceleration
 - Erythrophagocytosis
- Enhanced mechanosensitivity → ↑ deformability responses →
 - Cation loss
 - Microvesiculation → PS-positive microparticles
 - Fragility
 - PS externalization
- Abnormal RBC adhesion to endothelium
- Abnormal RBC adhesion to monocytes and macrophages

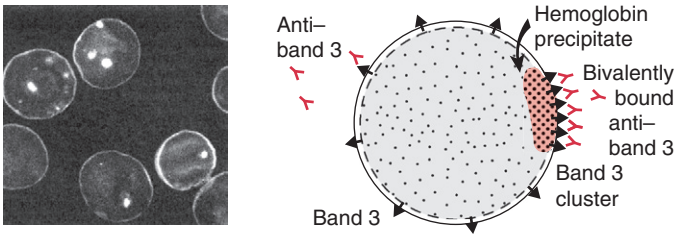

Figure 39-7 BAND 3 AND IMMUNOGLOBULIN COCLUSTERING. Denatured hemoglobin on the RBC membrane, is associated with clumping of band 3, and opsonization by naturally occurring anti-band 3 antibody. Clusters of band 3 are colocalized with immunoglobulin on the membranes of sickle red blood cells *(left)*. The drawing shows the colocalization scheme *(right)*. *(From Schluter K, Drenckhahn D: Co-clustering of denatured hemoglobin with band 3: Its role in binding of autoantibodies against band 3 to abnormal and aged erythrocytes.* Proc Natl Acad Sci U S A *83:6137, 1986.)*

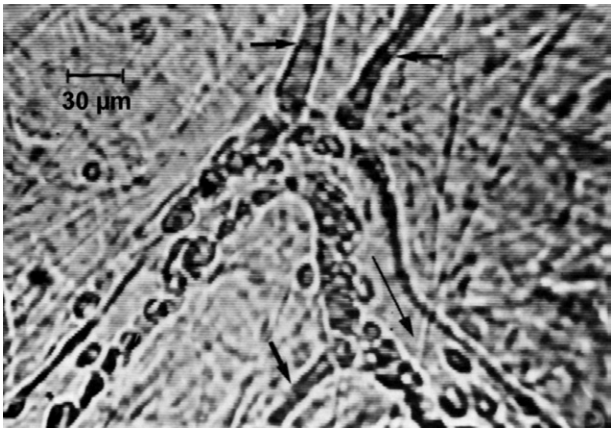

Figure 39-8 RBC ADHESION TO ENDOTHELIUM. RBCs adhere to the vascular wall endothelium under flow conditions in the microcirculation of a rat infused with human cells. Immobile RBCs are on walls of the postcapillary venule, and the smaller feeder microvessels *(small arrows)* have no flow because of the logjam of RBC. *(From Kaul DK, Fabry ME, Nagel RL: Microvascular sites and characteristics of sickle cell adhesion to vascular endothelium in shear flow conditions: Pathophysiological implications.* Proc Natl Acad Sci U S A *86:3356, 1989.)*

complex. Band 3 is abnormally clumped because of binding of denatured HbS to its cytosolic portion, which causes binding of naturally occurring anti–band 3 immunoglobulin (Fig. 39-7).

The processes that normally enforce bilayer phospholipid asymmetry are impaired in sickle RBCs: a scramblase that moves phosphatidylserine (PS) outward and is activated by calcium transits, and a translocase that moves PS inward can be inhibited by thiol oxidation. RBC sickling promotes PS externalization, a permanent feature of ISCs, but a substantial portion of reticulocytes also exhibits this because of impaired translocase activity. Other changes include presence of peroxidation byproducts such as malondialdehyde that can crosslink proteins and thereby promote erythrophagocytosis.

Notably, the increased presence of bilayer lipid hydroperoxides appears to account for the sickle RBC membranes' enhanced responsiveness to deformation-induced cation loss[7] and possibly other features promoted by the deformation of sickling.

Irreversibly Sickled Cells

The sickled RBCs seen on a typically-obtained blood smear are mostly ISCs (see Fig 39-1). Their permanent shape abnormality is caused not by retained polymer but rather by membrane retention of an elongated shape. This is explained by thiol oxidation of β-actin such that the spectrin–actin-4.1 complex exhibits abnormally slow dissociation and hence retention of elongation. Otherwise, ISCs are similar to other equally dense RBC: high MCHC, poor deformability, externalized PS, and low HbF content. ISC counts on average are higher in male patients, perhaps reflecting their average lower levels of HbF. The fundamental requirements for ISC formation seem to be RBC dehydration, prolonged deoxygenation, and assumption of a fixed membrane shape. This perhaps implies a prior "conditioning" residence in the microcirculation.

The clinical importance of ISCs lies in their ability to prompt diagnosis of a sickling disorder when seen on blood smear and in their short life span that contributes to overall hemolytic rate. They presumably would contribute to the RBC logjam involved in occlusion, but it is unclear whether ISC count correlates with vasoocclusive manifestations. Although still adhesive to endothelium, ISCs are less so than other sickle subpopulations, but they exhibit greater adherence to macrophages.

Endothelial Adhesivity

Oxygenated sickle RBCs are abnormally adhesive to vascular endothelial cells (Fig. 39-8). In vitro studies have identified about 20 candidate mechanisms involving adhesion molecules on endothelium, adhesive structures restricted to reticulocytes or present on all RBCs, with or without involvement of bridging by adhesogenic plasma proteins.[9] A central, unanswered question is whether in vivo this process occurs via a single, dominant mechanism. Alternatively, there may be mechanistic heterogeneity, with multiple mechanisms varying over time, in different vascular regions, among individuals, or even associated with different clinical contexts. For example, platelet activation releases α granule thrombospondin (TSP), a plausible adhesogenic intermediary bridge, so variation in the former could affect TSP-mediated RBC/endothelial adhesion. Likewise, adhesion mediated by endothelial vascular cell adhesion molecule 1 (VCAM1) (pairs with RBC $\alpha_4\beta_1$), $\alpha_v\beta_3$ (pairs with intercellular adhesion molecule 4 [ICAM4] and plasma TSP), and P-selectin (binds to sialylated RBC structures) are activated by tumor necrosis factor (TNF), platelet activating factor (PAF), and thrombin, respectively. Each of these stimulants is elevated in sickle blood. Only the $\alpha_v\beta_3$ and P-selectin mechanisms have been studied and verified in vivo so far.

Most of the candidate mechanisms are high affinity and demonstrable under flowing conditions, and they involve adhesive reticulocytes. Yet in the biologic context of the microcirculation where spatial constraints create enhanced opportunities for receptor–ligand contacts, even the low-affinity adhesive mechanisms observable for more dense RBC probably are relevant. This pathophysiology undoubtedly is governed by the plethora of biologic modifiers of endothelial activation state. Indeed, some adhesion mechanisms are relevant only if the endothelium is activated. Others become relevant if internal RBC signaling is triggered. Additional governing factors include the reticulocyte count, flow and shear rates, vessel diameter and geometry, and disturbances of flow regimens because of marginated white blood cells (WBCs). It also is quite possible that pathobiologic RBC adhesivity involves mixed blood cell interactions with endothelium.

Macrophage Interaction

Sickle RBCs are readily phagocytosed by macrophages because of RBC membrane modifications by malondialdehyde, PS externalization, and opsonization by immunoglobulin. The latter process probably is triggered mainly by clustering of membrane protein band 3 caused by denatured hemoglobin at the cytosol–membrane interface (see Fig. 39-7). The most dense cells have the most surface

immunoglobulin and higher PS externalization, and they exhibit the greatest interaction with macrophages and potential for erythrophagocytosis.

THE ROLE OF SICKLE RED BLOOD CELLS IN DISEASE PATHOGENESIS

Vascular Occlusion

Notwithstanding the conceptual simplicity of the sickling phenomenon, it is likely that development of microvascular occlusion is a complex process having an evolving genesis. Insofar as sickling is responsible, risk factors would comprise anything that would increase MCHC and RBC dehydration (e.g., insufficient clinical hydration, injudicious use of diuretics), foster arterial oxygen desaturation (e.g., lung disease, sleep-disordered breathing), prolong microvascular transit time (e.g., inflammation), increase blood viscosity (e.g., transfusion, clinical dehydration), right shift the oxygen binding curve (e.g., acidosis), disturb vascular dynamics (e.g., cold, aberrant neurochemical responses, abnormal vasomotive rhythms), or reduce HbF level. The latter is complicated, however, because in sickle RBCs, HbF is located mostly in a subpopulation of F cells. Variations in the percentage of F cells, therefore, have a large impact on the overall HbF level.[10] Yet RBCs pass through the microcirculation single file, and behavior of every individual RBC depends on its specific HbF content. This inherent contrariety has not been adequately studied, defined, or reconciled vis à vis mechanisms of vasoocclusion. Nonetheless, at the sensitivity of epidemiology, HbF level is inversely related to frequency of vasoocclusive painful crises.[11]

Sickle RBC adhesion to endothelium can slow microvascular flow, thus overcoming the delay time requirement for HbS polymerization. Indeed, experimental studies in sickle mice revealed that occlusion is a two-step process.[9] The current (although not necessarily definitive) model holds that adhesion of less dense (reticulocyte-enriched) sickle RBCs in the postcapillary venule initiate vasoocclusion, after which logjamming by dense and poorly deformable cells provides retrograde propagation (see Fig. 39-8). This predicts that determinants of RBC adhesivity and endothelial activation or dysfunction would help govern pathobiology. Consistent with this, clinical vasoocclusive severity does correlate with the endothelial adhesivity of sickle RBCs in vitro.

Diminished RBC deformability can additionally impair microvascular flow, and dense sickle RBC (especially ISC) appear to have difficulty entering the microvasculature (e.g., at bifurcations). Within the smaller vessels, RBC adhesivity and deformability would be predicted to exert combined—possibly synergistic—effects, although this has not been sufficiently studied. However, in humans with sickle disease, clinical vasoocclusive severity correlates with preservation of RBC deformability rather than degradation thereof.

Consequences of Vasoocclusion

Microvascular vasoocclusion has long been assumed to underlie the acute painful episode and chronic organ deterioration in sickle cell disease, although there are associated enigmas.[12] However, both microvascular and macrovascular disease are features of sickle pathobiology. These may well be linked because localized vasoocclusion can exert adverse systemic effects on vascular biology.[13] In addition, a new concept has questioned whether occlusive disease really underlies all complications of this disease.

Hemolytic Anemia

RBC life span in SCA averages about 15 days but with marked interindividual variability (from ≈7 to ≈30 days); in HbSC disease, the average is about 30 days.[14] All four fundamental mechanisms that can underlie RBC removal in hematologic disease—erythrophagocytosis, fragmentation, trapping, and osmotic lysis probably contribute (Fig. 39-9, *bottom*). These are consequences of the proximate aberrancies of the sickle RBC discussed earlier (Fig. 39-9, *middle*) that result from the specific molecular behaviors of the mutant HbS (Fig. 39-9, *top*). This integrated synthesis of research data presents the most plausible mechanistic blueprint.[14]

Although complex, the routes to accelerated RBC removal resolve into two basic pathogenic cascades: one from polymer formation that underlies the three mechanisms (trapping, fragmentation, osmotic lysis) that cause intravascular hemolysis and one from HbS instability that leads to erythrophagocytosis and extravascular hemolysis. Notably, intravascular hemolysis accounts for only one-third of overall sickle hemolysis; two-thirds is explained by extravascular hemolysis.[14]

Because these distinct destructive processes would contribute differentially to appearance of serum lactate dehydrogenase (LDH), it is unlikely to be a *quantitative* biomarker of hemolytic rate in the sickle context. The only biomarkers that have been documented to correlate strongly and quantitatively with measured RBC life span in sickle cell anemia are the (uncorrected) reticulocyte percentage and HbF level.[14]

The shortest survival is exhibited by the sickle RBC that are most dehydrated and that have the lowest amounts of HbF.[15,16] This is consistent with the polymerization-based cascade of abnormalities (see Fig. 39-9). Whether these two features fully explain the very wide range of hemolytic rates is not known; the precise mechanism by which sickling leads to direct lysis is also unknown. Presumably, the sickle RBCs' fragility is related, and sickled RBCs lose Hb via microvesiculation when sickling is reversed in vivo. Improved RBC hydration caused by concurrent α-globin gene deletion improves RBC survival,[17] as does the increment in HbF level in patients taking hydroxyurea.[10] The reason that sickle RBC survival drops substantially in association with acute vasoocclusive crises[14] has not been defined, nor is it known whether this precedes or follows crisis onset.

The influence of the instability-based cascade is evident in enhanced erythrophagocytosis of sickle RBC, promoted by denatured Hb causing band 3 clumping and attraction of immunoglobulin, membrane modification by the lipid oxidation product malondialdehyde, and PS externalization.

Consequences of Hemolysis

The presence of hemolysis-derived cell-free oxy-Hb in sickle plasma can consume NO,[18] but how substantially this contributes to the overall diminished bioavailability of NO is not known.[14] Hemolysis causing this precise consumptive process has been asserted to be the proximate cause of certain specific clinical complications,[19] but supporting data are only correlative (e.g., association of stroke with elevated LDH). In fact, hemolytic release of free Hb in sickle disease would be paralleled by several additional potentially injurious products that presumably would also correlate with the same clinical events. Two are perhaps most notable.[14] Sickle hemolysis causes robust generation of PS-positive microparticles that can adversely impact endothelium; these also accelerate coagulation activation,[20] thrombin being an additional potential perturbant. Also, the likely release of free heme caused by HbS instability in the context of severely depleted levels of haptoglobin and hemopexin would exert toxic effects on endothelium. Heme also would stimulate monocyte production of TNF, yet another endothelial perturbant. Thus hemolysis as a proximate cause of events seems perfectly plausible, but this has not been unambiguously demonstrated and its mechanism is debatable.

INFLAMMATION AND ENDOTHELIAL DYSFUNCTION

Sickle cell disease is a chronic, systemic inflammatory state.[13,14] Characteristic features include elevated leukocyte counts; activation of granulocytes and monocytes; elevation of proximate inflammatory mediators, acute-phase reactants, and soluble adhesion molecules; activation of hemostatic systems; and excess oxidant generation.

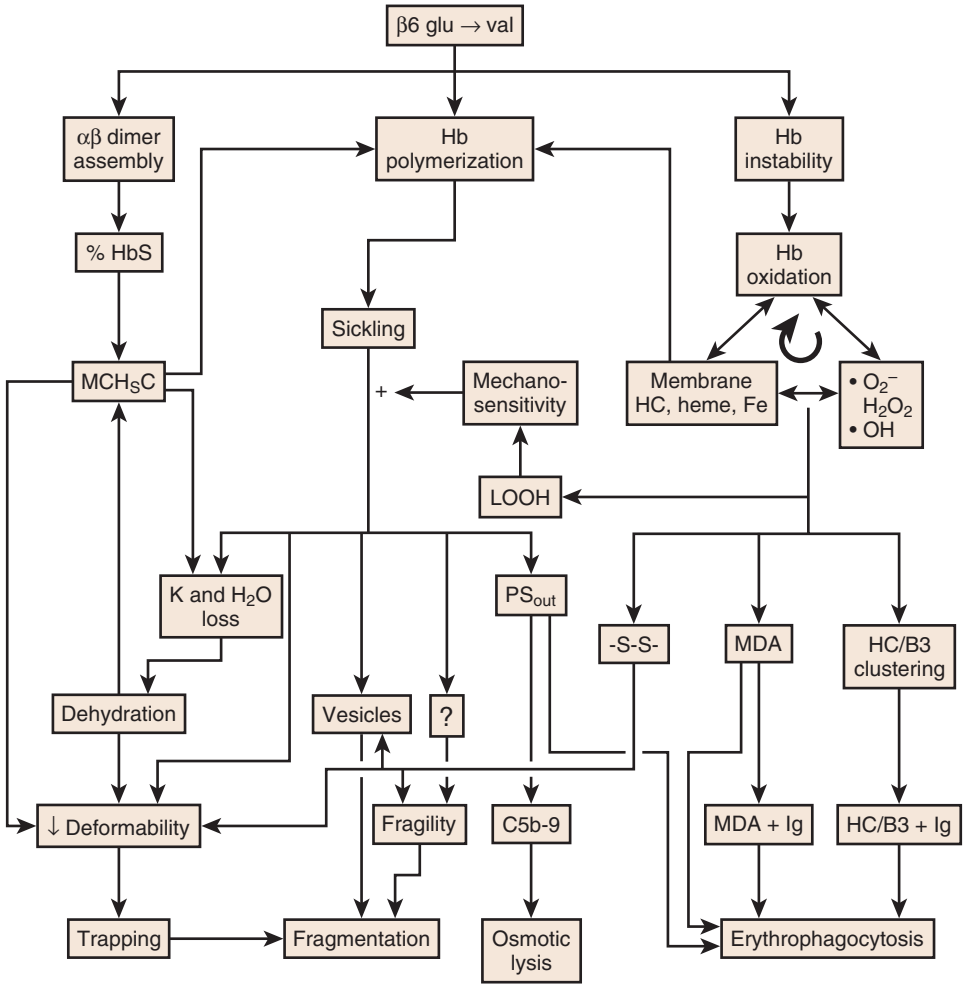

Figure 39-9 MECHANISMS LEADING TO HEMOLYSIS IN SICKLE CELL DISEASE. This integrated synthesis shows how the molecular behaviors of hemoglobin S (HbS) *(top)* cause development of multiple red blood cell (RBC) abnormalities *(middle)* that lead to the four mechanisms of accelerated RBC destruction *(bottom). (Modified with permission from* The American Journal of Hematology *from Hebbel RP: Reconstructing sickle cell disease: A data-based analysis of the "hyperhemolysis paradigm" for pulmonary hypertension from the perspective of evidence-based medicine.* Am J Hematol *86:123-154, 2011.)*

Clinically, leukocytosis in sickle cell disease is a risk factor for mortality, clinical and silent stroke, and acute chest syndrome, and it helps predict which babies will develop a severe clinical course. Sickle transgenic mice share with humans an inflammatory phenotype. The most prominent consequences of this state are endothelial activation and dysfunction and enablement of vasoocclusion (via adhesion molecule expression).

Experimental data from sickle transgenic mice, clinical data from sickle patients, and a vast relevant general medical literature suggest that this inflammatory state is best understood as a consequence of recurrent ischemia/reperfusion injury physiology (Fig. 39-10).[13,14] This well-understood, postocclusive cascade causes oxidative stress, intense inflammatory responses, and endothelial dysfunction that is systemic, not localized.

Endothelial Dysfunction

The most plausible hierarchical relationships between the multiple vascular biological abnormalities in sickle disease illustrate the probable centrality of endothelial dysfunction in their genesis (see Fig. 39-10).[13,14] In this construct, recurrent RBC sickling comprises the system input, reperfusion injury provides the incessant driving force, and systemic inflammation causing endothelial dysfunction comprises the executor of clinical disease. In a dysfunctional state, the endothelium has a proinflammatory and prothrombotic phenotype, it exhibits excessive superoxide generation (typically via endothelial NADPH [nicotinamide adenine dinucleotide phosphate-oxidase] oxidase and uncoupled endothelial nitric oxide synthase [eNOS]), and it causes diminished NO bioavailability caused by the eNOS uncoupling (itself predominantly caused by tetrahydrobiopterin oxidation). Sickle transgenic mice exhibit all of these features; the few relevant data available from humans with sickle cell anemia are consistent with this. Additional features of sickle cell anemia can help promote endothelial dysfunction: elevated asymmetric dimethylarginine, oxidized lipids, aberrant wall shear stress, microparticles, and others.[14] A state of NO deficiency is an inevitable consequence of endothelial dysfunction, but it does not cause it.[14]

Diminished Nitric Oxide Bioavailability and Vasoregulation

Sickle cell disease is such a state of diminished NO bioavailability, as evidenced in humans primarily by abnormal endothelial-dependent, flow-mediated arterial dilation.[21,22] In addition to the presumably dominant role of endothelial dysfunction with eNOS uncoupling, other contributing processes could include NO consumption by both excess superoxide and plasma oxyHb, limited NO generation from impaired L-arginine availability resulting from elevations of plasma

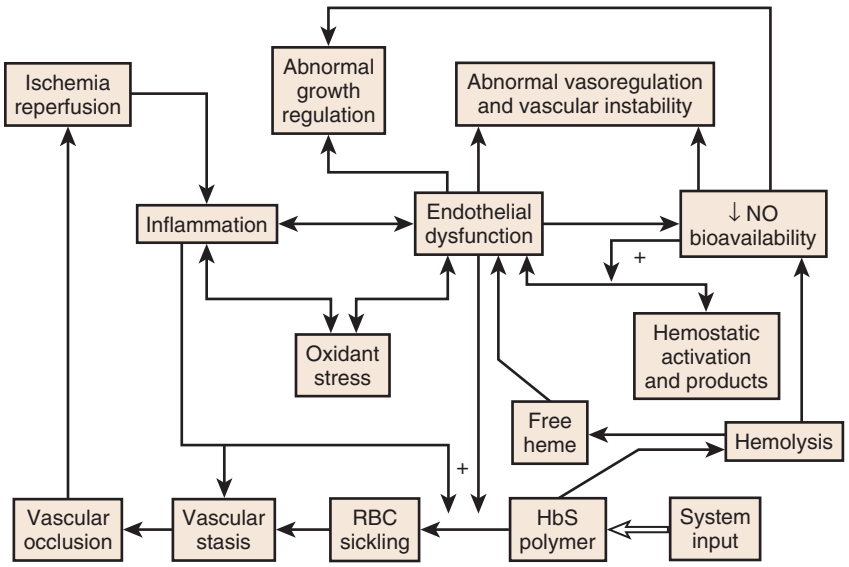

Figure 39-10 THE CENTRALITY OF ENDOTHELIAL DYSFUNCTION IN SICKLE CELL DISEASE. Sickle hemoglobin (HbS) polymerization provides the system input, ischemia–reperfusion provides the incessant driving force, and the resulting systemic inflammation is the executor of the HbS affect on vascular biology, which is realized by the disparate consequences of endothelial dysfunction. *NO,* nitric oxide; *RBC,* red blood cell. *(Modified from Hebbel RP: Reconstructing sickle cell disease: A data-based analysis of the "hyperhemolysis paradigm" for pulmonary hypertension from the perspective of evidence-based medicine.* Am J Hematol *86:123, 2011).*

and endothelial arginase (the latter being a consequence of TNF stimulation), and others.[14] The proportionate contributions of these disparate causes is unknown. NO bioavailability seems to be higher for females than males, who exhibit substantial non-NO regulation of flow.[22]

Perfusion patterns are complex in sickle disease but can generally be described as impaired microvascular flow and augmented macrovascular flow.[21] The systemic nature of the inflammation and endothelial dysfunction consequent to the ischemia–reperfusion paradigm provides a likely resolution to the enigma presented by concurrent microvascular occlusive disease (vasoocclusion) and macrovascular clinical disease (e.g., pulmonary hypertension, circle of Willis disease). In turn, this predicts dominance of different proximate determinants of the two vascular perturbations: blood cell–endothelial adhesion, deformability and polymerization for microvascular disease; and cellular and humoral endothelial stressors, and possibly aberrant wall shear stress, for macrovascular disease.

Aberrancy of both endothelial-dependent (NO-mediated) and endothelial-independent vasoregulation is apparent. Also, a state of vascular instability is emerging as a disease feature, with sickle mice exhibiting tonic upregulation of both vasoconstrictive and vasodilatory systems, as well as exaggerated α_1-adrenergic vessel wall responsiveness. Sickle humans reveal disruption of autonomic regulation (e.g., with augmented risk for hypoxia-induced perfusion decrements).[23] Notably, the underlying endothelial dysfunction in sickle disease would comprise a state of enhanced susceptibility to transient pulmonary vasoconstrictive stressors.

Systemic blood pressure in subjects with sickle cell disease is lower than in nonanemic control participants yet is higher than in comparably anemic β-thalassemic patients.

Coagulation Activation

Sickle cell anemia involves chronic activation of plasmatic coagulation, fibrinolysis, and platelets. This is accompanied by increased whole blood tissue factor (TF) and its increased expression on blood monocytes and endothelial cells, liberation of PS-positive and TF-positive microparticles, thrombin generation, consumption of antithrombotic proteins, and presence of antiphospholipid antibodies. That the abnormally externalized PS on sickle RBCs and microparticles plays a significant accelerating role for lipid-dependent coagulation reactions.[20] Notably, consequent generation of thrombin is a major endothelial cell perturbant. The biodeficiency of NO would enable TF expression and augmented platelet activation because it normally inhibits these.

Chronic Vasculopathy

The macrovascular component of sickle vascular disease appears to be a chronic inflammatory vasculopathy.[13] Most available information is obtained from the large and medium vessels at the circle of Willis, where some sickle children develop occlusive pathology characterized by intimal hyperplasia, fibrotic and proliferative changes, and damage to internal elastic lamina. Similar pathologic changes have been observed in arteries in other organs. Sickle vascular lesions do include a fatty streak and foam cells, but they do seem nonrandom in location. Clearly, this is an incompletely evaluated aspect of sickle cell anemia.

CLINICAL PHENOTYPES AND COMPLICATIONS

Some clinical complications (pulmonary hypertension, leg ulcers, priapism, stroke) are more common in patients with higher serum LDH, but others (acute chest syndrome, acute painful episodes) occur more commonly in those having lower serum LDH.[19] On this basis, it has been assumed by some that hemolytic rate per se is the etiologic factor via degree of NO consumption caused by cell-free Hb. Certainly, the basic concept that different processes underlie different clinical complications is entirely plausible. However, support for this concept of dichotomous phenotype is based solely on statistical association focusing upon outlier quartiles of serum LDH level. Corresponding differences in Hb are small, reticulocyte counts are not different, and actual correspondence with measured RBC survival has not been examined.[19] In any case, it is evident that about half of patients are in an overlap group, and the prognostic value of serum LDH has not been tested at the level of the individual patient.

Pulmonary Disease

Around 6% of adults with sickle cell anemia have pulmonary hypertension, as documented by catheter measurement of pulmonary vascular resistance or mean pulmonary artery pressure.[24] Reports of higher prevalence were based on use of a faulty diagnostic criterion.[14] The hypothesis that consumption of NO by plasma Hb causes this complication is intriguing but unproven, as the supporting data to date are amenable to alternative interpretations. For example, placental growth factor generated by erythropoietic activity also correlates with pulmonary hypertension in sickle disease, and additional features of sickle vascular pathobiology, in particular endothelial dysfunction,

are known risk contributors. It seems possible that the never-ending perfusion of the pulmonary arterial tree with sickled RBC (which induce an endothelial injury response in vitro) could play a role.

The spectrum of sickle pulmonary complications also includes chronic restrictive lung disease, pulmonary hypertension, infection, in situ and embolic thrombosis, and acute chest syndrome.[25] The latter is a life-threatening event and a predictor of subsequent chronic lung disease and stroke. Risk factors include leukocytosis, lower hemoglobin levels, and a lower level of HbF. Multiple proximate triggering events may lead to this syndrome in which inflammation, adhesion biology, NO deficiency, and endothelial permeability conspire to augment the deleterious effects of hypoxia on the lung. The predominant apparent triggers are infection in children and fat embolism (probably caused by marrow infarction) in adults. Acute chest syndrome does tend to occur after onset of acute vasoocclusive episodes.

Mortality and Sudden Death

The mortality rate is increased in sickle cell patients having higher rates of acute painful episodes,[26] perhaps revealing an association of clinically evident severity with extent of subclinical disease. Notable risk factors for mortality are a low HbF level and a high WBC count, implicating sickling and inflammation. In 1994, a large study in the United States reported a median age at death of 42 years for men and 48 years for women with sickle cell anemia; the comparable ages were 60 and 68 years, respectively, for HbSC disease.[26] This reflected a large improvement in mean life span after the introduction of prophylactic penicillin for children, revealing the earlier dominance of pneumococcal sepsis in disease natural history. Recently, further improvement has derived from chronic use of hydroxyurea for more severely affected individuals, an agent that boosts HbF level, lowers WBC count, and improves RBC hydration and survival.

The cause of death in this disease is from multiple complications, with cardiopulmonary disease being the most prominent category.[25-27] A striking incidence of sudden death is accounted for only partly by undiagnosed histopathologic pulmonary hypertension. It has been hypothesized that transient (possibly even ballistic) elevations of pulmonary artery pressure could be responsible because the state of underlying endothelial dysfunction would substantially exaggerate the vessel wall's constrictive response to potential vasoconstrictors (e.g., from nocturnal hypoxia, augmented hemolytic rate, inflammatory signaling).[14]

Stroke

Several stroke syndromes occur in sickle disease and may have differing pathogeneses. Ischemic stroke develops in about 85 of children with sickle cell anemia, with occlusive disease at the circle of Willis being the strongest risk factor; completion of the clinical stroke tends to involve thrombosis at the site of vessel wall disease. Other identified risk factors include greater anemia, a higher WBC count, systolic blood pressure at the higher end of the sickle range, acute development of hypoxia, a prior neurologic event, presence of moyamoya, low pain crisis rate, and concurrent or antecedent inflammatory conditions. Concurrent α-thalassemia or HbSC disease lower the risk; HbF level is not protective. The chronic inflammatory state may be a significant pathogenic factor.

The other sickle stroke syndromes are even less well understood; these include silent strokes during childhood associated with degradation of IQ, hemorrhagic stroke in young adults, and microvascular stroke that increases with age.

Pain

Pain signaling in sickle disease appears to be multimodal and complex, and inflammatory mediators play a major role. In adults, a higher frequency of classical acute painful episodes, assumed to be ischemic pain from vasoocclusion, is observed in those having higher hematocrit and lower HbF level at baseline and is associated with increased mortality.[11] Many of those with the disease have notable chronic, daily pain.[28] The pathogenic relationship—and any possible risk factor differences—between acute and chronic pain in this population are undefined. Individuals remote from acute painful episodes were found, in limited studies, to still exhibit fluctuations of acute phase reactants, suggesting ongoing—or at least frequent—subclinical events. Ongoing studies using sickle mice have identified substantial contributions from neuropathic and inflammatory processes.[29]

BASIS OF PHENOTYPIC DIVERSITY

The remarkable diversity of clinical phenotypes and variability of disease severity in sickle cell anemia is incompletely understood. Disease phenotype can be significantly influenced by environment, nutrition, socioeconomic status, endemic infection rates, and availability of medical care. Thus phenotypic variability is more evident in countries with lower infant mortality and childhood infection rates.

Level of Hemoglobin F

After the decline in HbF level over the first 6 months of life, most of the antisickling protection from its high level at birth is lost, but its level still varies among adults over a 20-fold range. HbF level reflects the number of F cells, the amount of HbF per F cell, and the preferential survival of F cells.[10] Known determinants account for perhaps one-half of its variance: a polymorphic *Xmn*I site 5′ to the Gγ gene in the Senegal and Arab-India β-globin haplotypes, the HBS1L-Myb intergenic region, and polymorphisms of BCL11A (a transcriptional silencer of the *HBG* gene).[30] A putative "F-cell production locus" on the X chromosome has so far escaped being identified.

α-Thalassemia

The normal genotype is αα/αα, but about 30% of African Americans have a single α deletion (–α/αα), so concordance with sickle cell disease is common; and homozygosity for the allele is seen (–α/–α). Its prevalence elsewhere varies regionally. An α-gene deletion has minimal effect on the HbF level but results in improved RBC hydration (see Fig. 39-6), a lower ISC count, improved RBC survival, and less severe anemia.[17] Yet there is no amelioration of pain severity, and some complications (osteonecrosis, retinopathy) increase, possibly because of the increased blood viscosity.

β-Globin Alleles

Compound heterozygosity for the sickle gene and another β allele can affect clinical phenotype, generally as predicted by the extent to which they admix β^A or γ chains with β^S, as presented earlier. HbSC disease presents a unique case.[31] Rather than simulating sickle trait (see Fig. 39-5A), the presence of HbC stimulates of K–Cl cotransport and causes RBC dehydration, thereby increasing the MCHC and RBC HbS concentration. Combined with a concurrent augmentation of HbS proportion (≈50% versus ≈40% in HbAS), this yields a sickling disorder only somewhat less severe than sickle cell anemia, but with an increased propensity for retinopathy and osteonecrosis. Other less common alleles can likewise interact with HbS and affect clinical phenotype via impact on polymerization.

Unexplained Phenotypic Diversity

Beyond these well-defined influences, there is still a substantial, unexplained variability in the clinical phenotype of sickle cell anemia. The

disparate biological processes that participate in vasoocclusion, macrovascular vasculopathy, hemolysis, and specific complications highlights the probability that phenotypic heterogeneity will be influenced by underlying genetic variations affecting adhesion molecules, cation homeostasis, inflammatory signaling, vasoregulation, and so on. Multiple single-nucleotide polymorphisms (SNP) associations have been detected in association with specific clinical complications, with SNPs in transforming growth factor-β–related genes emerging as a prominent feature.[30] Exaggerated endothelial cell signaling response to inflammation, apparently genetically based, has been implicated in childhood ischemic stroke. It is likely that the contribution of such additional genetic influences will begin to be identified now that modern molecular approaches are being applied to the problem of phenotypic diversity in sickle cell disease.

CHAPTER 40

SICKLE CELL DISEASE: CLINICAL FEATURES AND MANAGEMENT

Yogen Saunthararajah and Elliott P. Vichinsky

Hemoglobinopathies are the most common genetic diseases in humans. In sickle cell disease (SCD), a mutated β-globin gene produces sickle hemoglobin (Hb S). This mutation has been positively selected during human evolution because one copy of the sickle gene and one normal β-globin gene (sickle cell trait) confers a survival advantage in malaria-endemic regions. With two copies of the sickle gene (Hb SS or sickle cell anemia) or the sickle mutation and another mutated β-globin gene, for example, sickle cell–β°-thalassemia (Hb S–β thal) or Hb SC disease (Hb SC), the less soluble Hb S can polymerize in deoxygenated regions of the circulation, resulting in red blood cell (RBC) rigidity, RBC adhesion to endothelium, and hemolysis. These events activate inflammation and coagulation pathways and cause vasoocclusion.[1] These processes manifest clinically as chronic hemolytic anemia, recurrent painful episodes, and chronic organ damage from vasoocclusion. This chapter presents the diagnosis and natural history, describes overall clinical management, and as specific management by organ complications. Clinical interventions are founded on an understanding of underlying pathophysiologic processes. The exigency of living with a painful, life-threatening chronic disease in an ethnically diverse society adds complexity to the psychosocial aspects of this illness. A comprehensive management approach directed at preventing pain crises, chronic organ damage, and early mortality while effectively managing acute complications is recommended. For a full discussion of the fascinating history and molecular pathology of this disease, please see Chapter 42. Normal Hb synthesis, structure, and function are described in Chapter 33, and the thalassemias are considered in Chapter 41.

PREVALENCE

The distribution and frequency of the sickle cell gene in different areas of the world have been influenced by natural selection and transmission of the gene via trade routes and the slave trade.[2] Among African Americans,[3] the prevalence of sickle cell trait is 8% to 10% among newborns,[4] and in this population, the frequencies of the sickle cell (0.045), Hb C (0.015), and β-thalassemia (0.004) genes[4] indicate that there are 4000 to 5000 pregnancies a year at risk for SCD. The burden of this disease in the United States is dwarfed by that in the rest of the world, as evidenced by a prevalence of the sickle cell gene as high as 25% to 30% in western Africa and an estimated annual birth of 120,000 babies with SCD in Africa.[5]

DIAGNOSIS

The diagnosis of a sickle cell syndrome is suggested by characteristic findings on the complete blood count (CBC) and peripheral smear, that prompt Hb electrophoresis. If a diagnosis of SCD is confirmed, evaluation of the various organ systems at risk is required. These evaluations are discussed in the section on clinical management.

Complete Blood Count and Peripheral Blood Smear

The chronic hemolytic anemia of SCD presents with mild to moderately low hematocrit and Hb levels and a reticulocytosis of approximately 3% to 15%. Additional laboratory features of hemolysis are unconjugated hyperbilirubinemia, elevated lactate dehydrogenase (LDH), and low haptoglobin levels. The reticulocytosis accounts for high or high-normal mean corpuscular volume (MCV). If the age-adjusted MCV is not elevated, the possibility of sickle cell–β-thalassemia, coincident α-thalassemia, or iron deficiency must be considered.

In the peripheral smear (Fig. 40-1), there may be sickled forms, target cells, polychromasia indicative of reticulocytosis, and Howell-Jolly bodies demonstrating hyposplenia. The RBCs are normochromic unless there is coexistent thalassemia or iron deficiency. Sickled forms (irreversibly sickled cells [ISCs]) occur in the peripheral smear only in the SCDs and not in sickle cell trait. In Hb SS disease, ISCs predominate, and target cells may be few; in sickle cell–β-thalassemia, ISCs, target cells, and hypochromic microcytic discocytes are prominent; in Hb SC disease, target cells predominate, and ISCs are rare.

White blood cell (WBC) counts are higher than normal in Hb SS disease, particularly in patients under age 10 years. Mean WBC counts tend not to be elevated in Hb SC disease or sickle cell–β^+-thalassemia. Mean platelet counts are elevated in Hb SS disease, particularly in patients younger than age 18 years, but are usually normal in those with Hb SC disease and sickle cell–β^+-thalassemia.

Solubility Tests and Hemoglobin Electrophoresis

Solubility test results (e.g., Sickledex) are positive in both SCD and sickle cell trait. All patients require definitive diagnosis with Hb electrophoresis (which separates Hb species according to amino acid composition) (Fig. 40-2) or high performance liquid chromatography (HPLC).[6] Cellulose acetate electrophoresis at a pH of 8.4 is a standard method of separating Hb S from other variants. However, Hb S, G, and D have the same electrophoretic mobility with this method. Using citrate agar electrophoresis at pH 6.2, Hb S has a different mobility than Hb D and G, which comigrate with Hb A in this system.

Results from electrophoresis or thin-layer isoelectric focusing are similar in Hb SS disease and sickle cell–β°-thalassemia: nearly all of the Hb consists of Hb S. Although differences in the fetal Hb (Hb F) (see Variant Sickle Cell Syndromes) and Hb A_2 levels may be useful in distinguishing these syndromes, the presence of microcytosis or of one parent without sickle cell trait is a more useful indicator of sickle cell–β°-thalassemia. The diagnosis of Hb SC disease is straightforward; nearly equal amounts of Hb S and Hb C are detected. Sickle cell–β^+-thalassemia and sickle cell trait both have substantial amounts of Hb A and Hb S. This superficial electrophoretic similarity does not provide an obstacle to diagnosis: whereas sickle cell trait is associated with neither anemia nor microcytosis and has an Hb A fraction more than 50%,[7] sickle cell–β^+-thalassemia is associated with anemia, microcytosis, and an Hb A fraction that ranges from 5% to 30%.

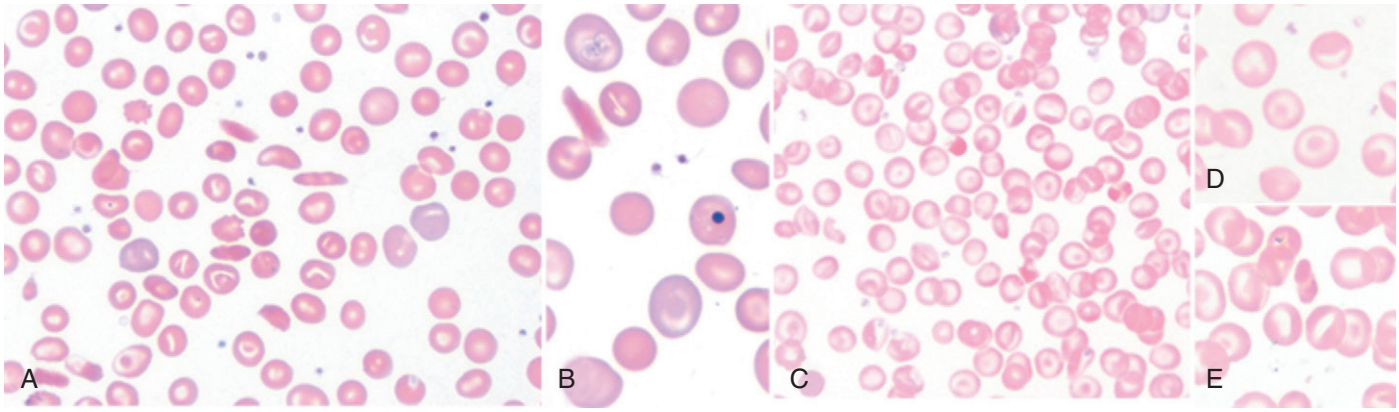

Figure 40-1 SICKLE CELL DISEASE AND HEMOGLOBIN SC PERIPHERAL BLOOD SMEARS. The peripheral smear in sickle cell disease **(A)** shows sickle cells that are mostly irreversibly sickled and sometimes referred to as "cigar forms." Higher power detail **(B)** shows a sickle cell *(upper left),* red blood cell containing a Howell-Jolly body *(middle right),* and polychromatophilic cell *(lower center).* These indicate sickle cell anemia and splenic dysfunction but marrow response with reticulocytosis, respectively. A peripheral smear of a patient with Hgb SC **(C)** shows no sickled cell, but there are target forms **(D)** and occasional cells **(E)** with hemoglobin condensed at each pole of the cell.

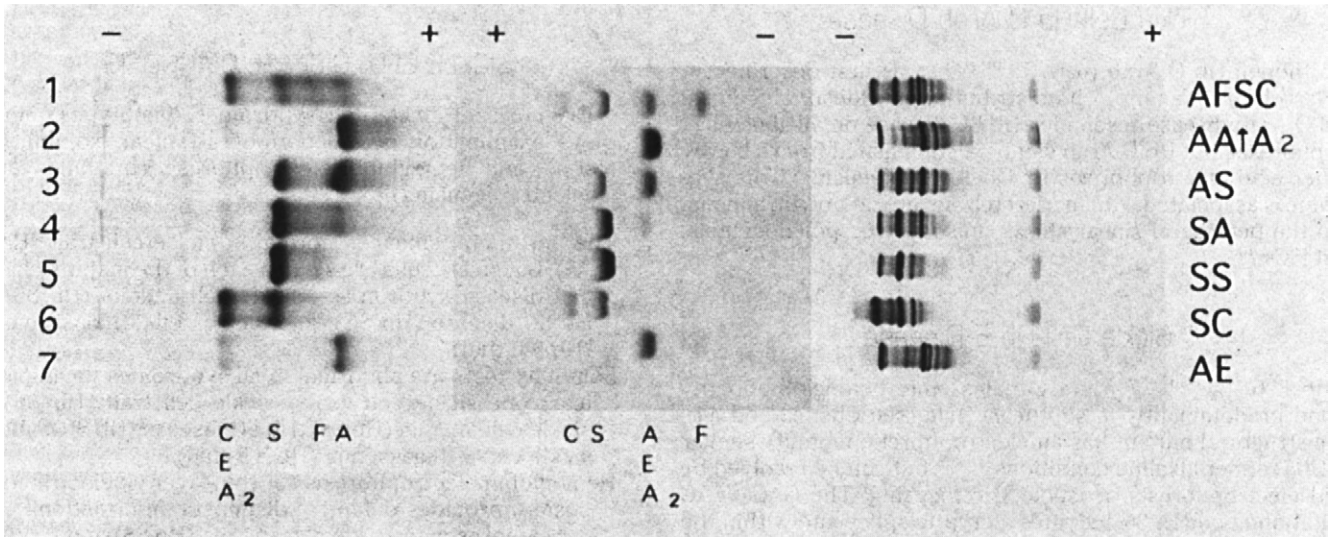

Figure 40-2 COMPARATIVE ANALYSES OF SEVERAL MUTANT HEMOGLOBINS USING ALKALINE ELECTROPHORESIS, ACID ELECTROPHORESIS, AND THIN-LAYER ISOELECTRIC FOCUSING. On the *right* are shown the components of the standard *(top)* and the phenotypes of the other six samples. Their analyses are shown by alkaline hemoglobin electrophoresis in the *left panel,* acid electrophoresis in the *center panel,* and thin-layer isoelectric focusing in the *right panel*. Locations of the various hemoglobin bands are shown *below the left and center panels*. *(Courtesy M.H. Steinberg.)*

The Hb F level is usually slightly to moderately elevated; the degree varies among patients. The amount of Hb F present is a function of the number of reticulocytes that contain Hb F, the extent of selective survival of Hb F–containing reticulocytes that become mature Hb F–containing erythrocytes (F cells), and the amount of Hb F per F cell.[8] The Arab–Indian and Senegal haplotypes are associated with higher levels of Hb F than the others.[9]

Newborn Screening

The use of prophylactic penicillin[10] and the provision of comprehensive medical care during the first 5 years of life have reduced the mortality rate from approximately 25% to less than 3%, thereby underlining the importance of early identification of infants with SCD. Based on its economy and superiority of detection, universal screening of all newborns is preferred over ethnically targeted approaches.[11,12] Blood samples for testing are obtained by heel stick and spotted onto filter paper for stable transport and subsequent HPLC. (Solubility testing is unreliable because of the large amount of Hb F present.)

As Hb S increases and Hb F declines in the first months of life (Fig. 40-3), the clinical manifestations of SCD, including anemia, emerge.[13] ISCs can be seen on the peripheral blood smear (Fig. 40-4) of children with sickle cell anemia at 3 months of age, and by 4 months of age, moderately severe hemolytic anemia is evident.

A requirement for tests used in newborn screening is the capability to distinguish among Hb F, S, A, and C. The Hb distribution pattern is described in descending order according to the quantities detected. Therefore, a newborn with sickle cell anemia who has predominantly Hb F with a small amount of Hb S and no Hb A is described as having an FS pattern. An FS pattern is obtained also in newborns who have sickle cell–β°-thalassemia, sickle cell–hereditary persistence of Hb F (HPFH), and sickle cell–Hb D or sickle cell–Hb G (i.e., Hb D and E have the same electrophoretic mobility as Hb S). A newborn with sickle cell trait will have Hb F, Hb A, and Hb S (FAS pattern).

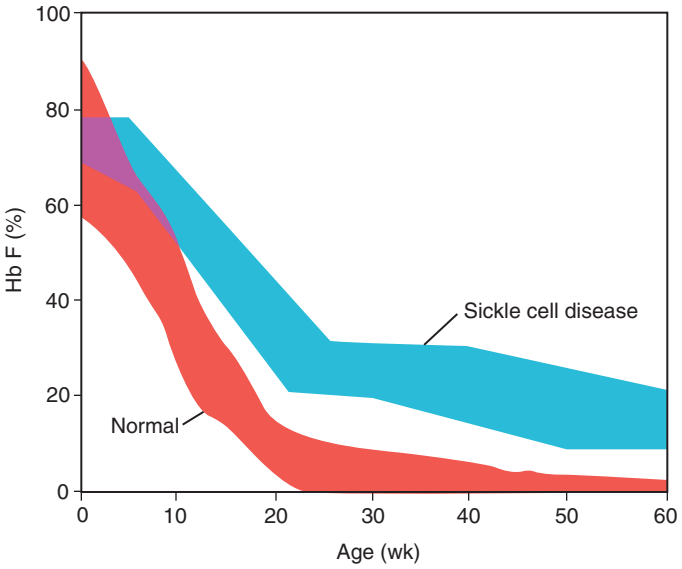

Figure 40-3 FETAL HEMOGLOBIN (HB F) DECLINE IN CHILDREN WITH HEMOGLOBINS AA AND SS. *(Data from O'Brien, Mclatosh S, Aspnes AT, et al: Prospective study of sickle cell anemia in infancy.* J Pediatr *89:205, 1976.)*

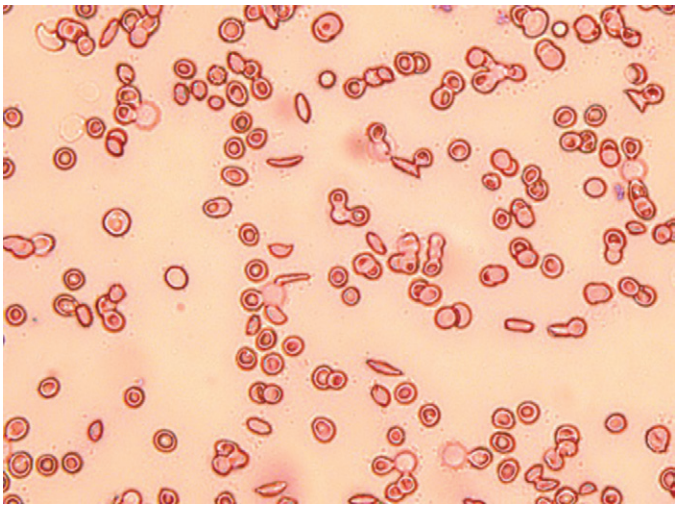

Figure 40-4 The peculiar elongated shapes of the erythrocytes is what Herrick's intern Ernest E. Irons noted, and together with a report from the German literature of *sichel formen* blood cells, inspired the name by which this condition is now known.

The quantity of Hb A is greater than that of Hb S. If the quantity of Hb S exceeds that of Hb A, the presumptive diagnosis is sickle cell–β^+-thalassemia (FSA pattern). It may not be possible to distinguish FAS and FSA patterns in newborns, so DNA-based testing or repeat Hb testing at age 3 to 6 months is recommended.

Prenatal Diagnosis

One large survey found that parents at risk for having a child with SCD were interested in prenatal diagnosis and would consider termination of pregnancy for an affected fetus.[14] Community acceptance of reproductive genetic services depends on the effectiveness of education and counseling. One major ethical issue pertains to our diagnostic skills' having outstripped our ability to predict the severity of diagnosable conditions.

Fetal DNA samples are obtained by chorionic villus sampling at 8 to 10 weeks' gestation. Polymerase chain reaction (PCR)–based

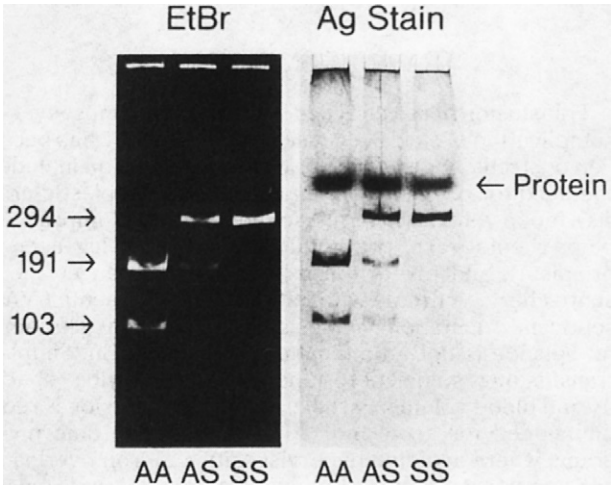

Figure 40-5 POLYMERASE CHAIN REACTION (PCR)–BASED RESTRICTION ANALYSIS FOR THE SICKLE CELL GENE. The genotypes of the DNA samples tested are shown *below*. The size in base pairs for the undigested PCR product and the products resulting from Oxa Nl are shown at the *left* in base pairs. The fragments from normal β-globin DNA (AA) shows complete Oxa Nl cleavage, from sickle cell trait DNA (AS) shows partial cleavage, and from sickle cell anemia (SS) shows no cleavage.

methods for detecting the sickle gene include restriction analysis (Fig. 40-5), allele-specific hybridization, reverse dot blotting, and allele-specific fluorescence PCR. PCR-based diagnosis for Hb SC disease is possible using specific molecular methods for detecting the Hb C gene, and the diagnosis of sickle cell–β-thalassemia can be made using reverse dot-blot methodology to screen the many African American β-thalassemia mutations, as well as the Hb S and Hb C mutations, in a single hybridization reaction.

CLINICAL PRESENTATION AND MANAGEMENT

The cardinal clinical manifestations of SCD are chronic hemolytic anemia; recurrent painful episodes; and chronic organ damage, particularly of the spleen, bones, brain, kidneys, lungs, skin, and heart. The pattern of disease manifestation varies among the major genotypes of Hb SS, Hb SC, and Hb S–β-thalassemia but also within the same genotype. Some of this variability results from additional inherited genotypes, for example, α-thalassemia or HPFH (discussed at the end of this chapter).

Typically, patients are anemic but lead a relatively normal life punctuated by painful episodes. However, it is important to realize that chronic organ damage and decreased survival occur even in patients who do not have recurrent pain. This section begins with a brief overview of natural history and survival followed by a discussion of basic management that has as its aim improving this natural history (disease modification) and then a discussion of management of organ-specific complications.

Natural History and Life Expectancy

The manifestations of disease begin after the first few months of life as Hb F levels decline and Hb S levels increase. Certain complications predominate in particular age groups. Between the ages of 1 and 3 years, affected individuals have splenomegaly and splenic sequestration (Fig. 40-6), pneumonia, and meningitis from *Streptococcus pneumoniae* and other encapsulated organisms (because of functional hyposplenism), and hand–foot syndrome; in early childhood, they have stroke, acute chest syndrome, and osteonecrosis; in midchildhood, they have pain crises, osteonecrosis, and acute chest syndrome; between ages 12 and 20 years, they have strokes, priapism, and pain

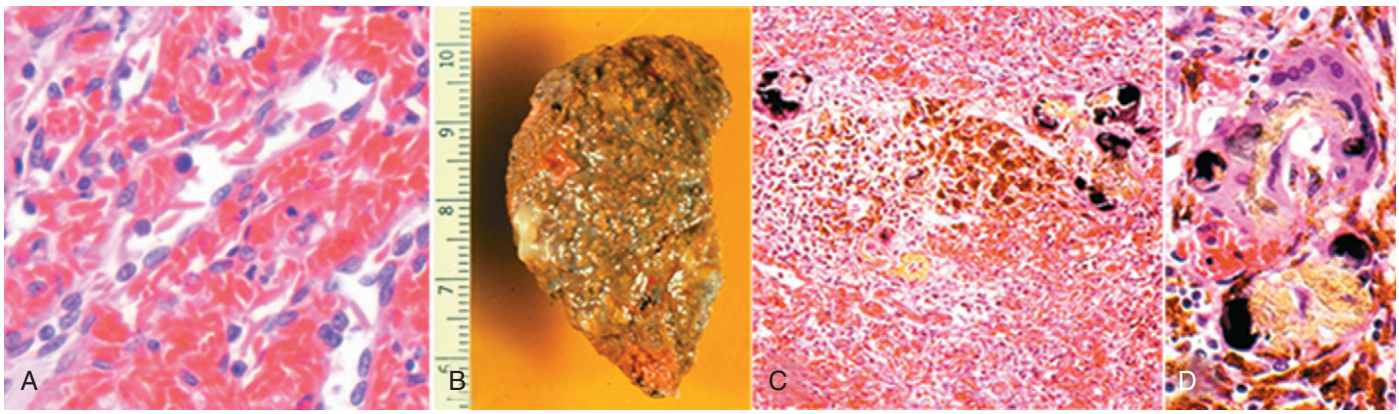

Figure 40-6 THE SPLEEN IN SICKLE CELL DISEASE. Histologic section **(A)** of the splenic red pulp shows engorgement of the splenic cords with sickled cells. In infants, excessive pooling in cords can lead to a splenic sequestration crisis. Later in life, the spleen undergoes autoinfarction. The gross pathology **(B)** shows a tiny 4.5-cm spleen with rough external surface caused by scarring from repeated infarcts. Histologic section reveals classic Gamna-Gandy bodies (**C** and **D**) also caused by repeated infarction. These are composed of hemosiderin-laden macrophages, calcium deposits, and foreign body giant cells.

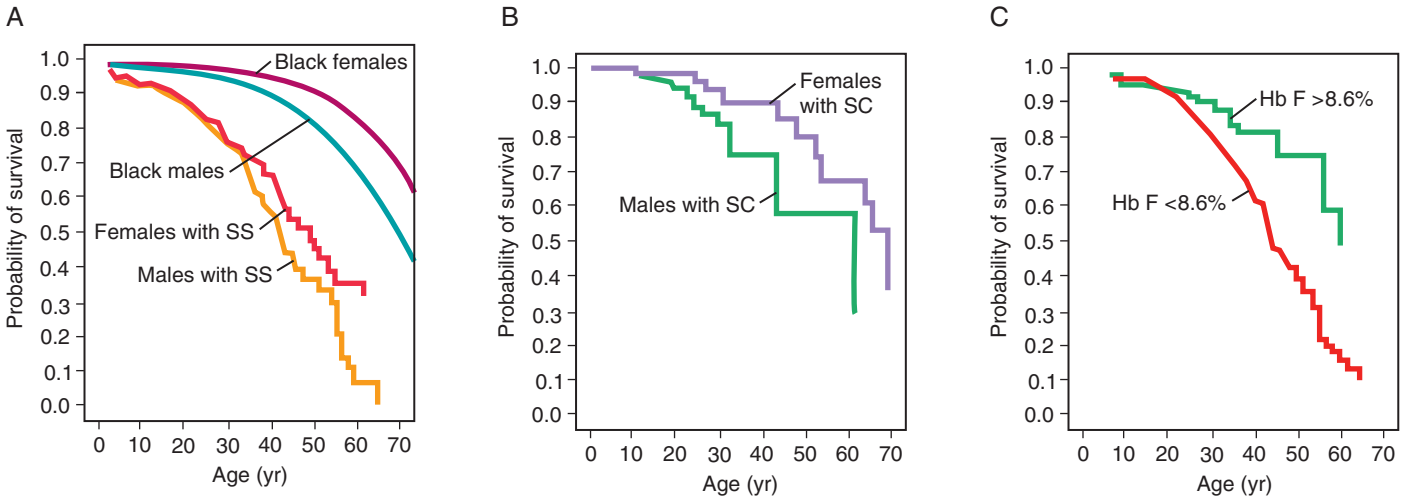

Figure 40-7 Life expectancy in patients with sickle cell disease for patients with Hb SS disease **(A)**, Hb SC disease **(B)**, and with different levels of fetal hemoglobin (Hb F) **(C)**. *(From Platt OS, Brambilla DJ, Rosse WF, et al: Mortality in sickle cell disease. Life expectancy and risk factors for early death.* N Engl J Med *330:1639, 1994.)*

crises; between ages 20 and 30 years, they have renal insufficiency, pulmonary hypertension, disabling osteonecrosis, retinopathy, leg ulcers, and pain crises; and at age older than 30 years, they have renal failure, congestive heart failure, and pain crises.

Life expectancy is decreased, although in the past 30 years, this has dramatically improved for patients in the West. In 1973, Diggs[15] reported that the mean survival was 14.3 years; in 1994, Platt et al[16] reported that life expectancy was 42 years for men and 48 years for women with sickle cell anemia (Fig. 40-7). This improvement in survival is most likely the result of improved general medical care, including prophylactic penicillin therapy and vaccination against *S. pneumoniae*.[9] These survival profiles are likely to be relevant even today, although a cohort of patients followed since 1975 show improvement in the probability of survival to age 20 years compared with patients born before 1975 (89% versus 79%).[17] The poor survival and litany of chronic organ damage in survivors emphasize the need for disease-modifying interventions to prevent vasculopathy.[17] There are indications that disease-modifying agents such as hydroxyurea (HU) can improve survival.[18,19]

Predictors of Disease Severity

The ability to predict clinical course would allow more rational tailoring of therapy to individual patients (e.g., selection of patients for high-risk but effective options such as stem cell transplant). Higher Hb F levels and the coinheritance of an α-thalassemia trait have been identified as favorable disease modifiers in multiple studies (Table 40-1).[20-22] The level of chronic anemia (which is influenced by the presence of an α-thalassemia trait and by Hb F levels) is of

considerable predictive value. Patients with more severe anemia are more likely to develop infarctive and hemorrhagic stroke,[23] to have glomerular dysfunction,[24,25] and perhaps to give birth to low-birthweight babies.[26,27] Conversely, they have fewer episodes of acute chest syndrome[28] and (after age 20 years) a lower mortality rate.[28] Progressive anemia from renal endocrine deficiency or a decrease in bone marrow function from vasoocclusion is associated with early death.[18,19]

A number of other genetic polymorphisms may be relevant to disease severity, for example, with regards to the risk of stroke. However, most of these markers are not widely used to guide decision making.[21]

Principles of Management

The twin pillars of therapy are disease modification (prevention of crises, complications, chronic organ damage, and early mortality) and compassionate, prompt, effective, and safe relief of acute crises, including pain episodes. Therefore, outpatient clinic management is mostly directed at initiating measures to prevent pain crises, prevent organ complications, and improve survival. This effort should include identification of existing organ complications and initiation of measures to prevent further deterioration. Outpatient management can thus be divided into baseline evaluations, basic treatment or disease modification, and additional treatment dictated by the organ complications that are identified. The suggested treatments are based on current understanding of SCD pathophysiology. As shown in Fig. 40-8, some treatments address only one aspect of pathophysiology, but others may have a broader impact. Inpatient management is directed at effective and safe relief of acute crises.

Baseline Evaluations

Baseline blood, urine, and other evaluations are directed at quantifying the chronic hemolytic anemia and organ-specific complications (Table 40-2). They also provide baseline parameters that can be followed to assess response to therapeutic interventions.

In pediatric patients, at least annual assessment of cerebral blood flow in the internal carotid artery and the middle or anterior cerebral artery using transcranial Doppler ultrasonography (TCD) is recommended. This evaluation is a validated predictor of stroke risk. Primary prevention with chronic transfusion is effective in such patients.[29] In adults, magnetic resonance imaging (MRI) or magnetic resonance angiography (MRA) of the brain can be used instead of TCD[30] to assess thrombotic or hemorrhagic stroke risk, especially in those with a history of stroke or seizure. The recognition of cardiopulmonary complications as a cause of early mortality in SCD warrants evaluation for this condition with either echocardiogram or brain natriuretic peptide (BNP) levels. Retinal evaluation is begun at school age and continued on an annual basis. More frequent retinal evaluations are necessary if retinopathy is noted.

Basic Management and Disease Modification

Sufficient evidence suggests that a number of treatments should be considered in all patients. These treatments have been demonstrated to decrease symptoms and complications, increase survival, or both (Table 40-3) (disease modification). There are other treatments for which there are sufficient scientific grounds or clinical data to suggest a potential impact on disease natural history. However, there is presently insufficient clinical data to make firm recommendations (see

†Best data from thalassemia patient experience.
‡Risks minimal (however, can mask vitamin B_{12} deficiency). Therefore, it is generally done.

Fig. 40-8 and Table 40-3). Although treatments such as vaccination and penicillin prophylaxis do not directly affect the sickling process or vasculopathy, they have had an impact on survival and therefore are included under the umbrella of disease-modifying therapies.

Therapeutic options are further discussed in the sections describing organ-specific complications.

Vaccination and Penicillin Prophylaxis

Children should be immunized against *S. pneumoniae, Haemophilus influenzae,* hepatitis B, and influenza.[31] Vaccination and penicillin prophylaxis can reduce the risk of serious pneumococcal infections.[9,32] Vaccination schedules recommend inoculation with heptavalent pneumococcal conjugated vaccine (PCV_7) at 2 months followed by two more doses 6 to 8 weeks apart (primary series) and a booster at 12 months. This is followed by Pneumovax at age 2 and 5 years. In adults, the Pneumovax should be readministered every 5 years (http://www.cdc.gov/vaccines/pubs/vis/default.htm).

For children younger than age 5 years, prophylactic penicillin recommendations are 125 mg penicillin V orally twice daily until age 2 to 3 years and 250 mg thereafter.[31] Penicillin prophylaxis begins at 2 months. Randomized, double-blind, placebo-controlled studies of prophylactic penicillin beginning in infancy, including the prophylactic penicillin or placebo study (PROPS), have found that this therapy reduced the incidence of *S. pneumoniae* bacteremia by 84% in children younger than 3 years.[9,32] A randomized, double-blind, placebo-controlled study, the PROPS II study concluded that it is safe to stop prophylactic penicillin therapy at age 5 years in children who have not had prior severe pneumococcal infection or splenectomy and are receiving regular follow-up care.[33] However, the power of the study was restricted by the limited number of *S. pneumoniae* systemic infection events. In an analysis of a patient population receiving penicillin prophylaxis and the Pneumovax, the rate of severe *S. pneumoniae* infections was 2.4 per 100 patient-years. This was favorable compared with the historical pre-penicillin prophylaxis rate of 3.2 to 6.9 per 100 patient-years.[34] These measures reduce risk but do not remove it. The risk of recurrent *S. pneumoniae* sepsis and death in patients who have had previous sepsis is much increased; all patients having a history of pneumococcal sepsis should remain on penicillin prophylaxis indefinitely and are not candidates for outpatient management of febrile episodes.[35] Parents must be aggressively counseled to seek medical attention for all febrile events.

Hydroxyurea and Fetal Hemoglobin Reactivation

The level of Hb F in erythrocytes plays a critical role in determining patient outcomes. Individuals who have SCD and another condition called HPFH have 70% Hb S in their RBCs but are neither anemic nor symptomatic.[36] The uniform distribution of Hb F among their RBCs interferes with Hb S polymerization, increases its solubility, and prevents RBC sickling.[37,38] Even at lower levels of Hb F seen in patients without HPFH, crisis rate and mortality are inversely proportional to Hb F level.[19-22] These findings prompted the idea that pharmacologic reactivation of Hb F production might be of benefit to patients.

Hydroxyurea is an inhibitor of ribonucleotide reductase and a cytotoxic agent that can elevate Hb F levels via an unknown pathway. A double-blind, placebo-controlled, intention-to-treat multicenter study of HU as treatment of pain crisis in SCD found that HU produced definite hematologic changes. HU was started at 0.15 mg/kg/day and escalated to 0.30 mg/kg/day as tolerated and to maintain an absolute neutrophil count no lower than $2000 \times 10^9\ L^{-1}$. There were significant increases in the levels of Hb, Hb F, F cells, F reticulocytes, packed cell volume (PCV), and MCV and declines in the mean level of leukocytes, polymorphonuclear leukocytes, reticulocytes, and dense sickle cells (Table 40-4).[39] The significant clinical changes were decreased rate of acute painful episodes, longer interval to first and second acute painful episode, fewer episodes of acute chest

Table 40-4 Hematologic Effects of Hydroxyurea Therapy

Variable	Hydroxyurea	Placebo	P
Leukocytes (103 cells/μL)	9.9	12.2	.0001
PMNs (103 cells/μL)	4.9	6.4	.0001

syndrome, and diminished number of subjects and units transfused (Table 40-5).[40] In follow-up analysis, higher pre- or posttreatment Hb F levels were associated with a reduction in mortality rate (although no significant changes were observed in the incidence of stroke, hepatic sequestration, or death in the initial study).[18] No short-term toxicity caused by HU was observed. One child born to a patient taking HU and two born to partners of patients taking HU were normal at birth. Although the follow-up analyses suggest the importance of Hb F to better outcomes, it is possible that some HU-induced changes in sickle cell erythrocytes, such as increased water content and decreased Hb S concentration,[41] may be independent of Hb F.

In the original study, only patients with two or more pain crises per year requiring hospitalization were eligible. However, other at-risk patients should be considered for HU therapy. These include patients with evidence of chronic organ damage, patients with severe anemia (unless the reticulocyte count is <250,000 μL^{-1}, in which case consider erythropoietin [EPO] deficiency from renal damage or bone marrow suppression that may require alternative treatment), and patients with indications for chronic transfusion but who have alloantibodies. After obtaining the baseline evaluations per Table 40-2, HU is usually started at 500 to 1000 mg/day with monitoring of the CBC every 4 to 8 weeks to ensure that neutropenia (absolute neutrophil count <2 × 10^9 L^{-1}) is not produced. Lower doses may be required in patients with renal insufficiency and/or relative reticulocytopenia. The dose is increased to a stable maximum HbF response or neutropenia, but most patients receive between 1000 and 2000 mg/day. Response is defined by clinical symptoms, by a persistent and significant (>0.5 g/dL) increase in total Hb or Hb F, and a decrease in LDH. These improvements in symptomatology and hematologic indices may require at least 3 to 4 months of therapy but can be seen as soon as week 6.

In studies of HU as a therapy for children with SCD, the drug was well tolerated and produced favorable hematologic changes similar to those seen in the adult population.[42] In approximately 10% of the children treated, the increase in Hb F was less than 2%. Baseline Hb F levels, baseline total Hb levels, and compliance were associated with the final Hb F level.[43] Other studies in children have documented a decrease in the number of days of hospitalization and suggest a decreased incidence of vasoocclusive crises.[44] The favorable changes in hematologic indices suggest that HU therapy might be an alternative to blood transfusions for the prevention of recurrent stroke in children with SCD.[45,46] HU therapy appears to lower transcranial Doppler velocities in children with SCD.[47] Studies in the United States and in Belgium support the potential role of HU in the prevention of cerebrovascular accidents.[46,48,49] HU was found to improve, but not correct, the abnormal cerebral oxygen saturation associated with SCD.[50]

A persistent concern pertaining to the use of HU in SCD is its putative leukemogenic effect. This concern derives from reports on HU treatment of myeloproliferative diseases, conditions associated with an inherent propensity for leukemic conversion. Although the use of HU combined with ^{32}P or alkylating agents is associated with increased leukemic conversion in patients with myeloproliferative disease,[51] reports claiming a leukemogenic effect for HU alone in polycythemia vera either lacked control subjects[52] or were not designed to assess this issue.[53] In children with the nonmalignant underlying condition of erythrocytosis secondary to inoperable cyanotic congenital heart disease, no leukemic conversion was observed.[54]

Vitamin or Nutritional Supplementation

Chronic hemolysis results in increased utilization of folic acid stores. Megaloblastic crises from folic acid deficiency have been reported.[55,56] Pediatric patients with SCD had higher homocysteine levels than age-matched control African American patients.[57] Folic acid, 1 mg/day orally, is administered as a standard of care.[58] Vitamin B_{12} deficiency can also be seen in patients with SCD. Folate replacement can mask and possibly exacerbate vitamin B_{12} deficiency.[59]

A growing body of research indicates that sickle cell patients have widespread mineral and vitamin deficiencies, including zinc, vitamin C, vitamin E, acetylcysteine, calcium, vitamin D, vitamin A, and others.[60] Fifty percent of children with SCD have evidence of osteoporosis or osteopenia that is associated with inadequate calcium and vitamin D intake.[61-63] Recently, zinc supplementation in a prospective trial documented significant improvement in linear growth and weight gain in children with SCD.[64]

Despite increased intestinal absorption of iron in SCD, the combination of nutritional deficiency and urinary iron losses results in iron deficiency in 20% of children with SCD.[65] The diagnosis of iron deficiency may be obscured by the elevated serum iron levels associated with chronic hemolysis, necessitating the detection of a low serum ferritin level or an elevated serum transferrin level for the diagnosis.

Transfusion Therapy

The two main approaches to transfusion in SCD are simple transfusion and exchange transfusion. These transfusions can be administered in an episodic fashion or in a chronic fashion. Therefore, transfusion therapy in SCD is of the following types: episodic simple, episodic partial exchange, or chronic partial exchange. In both simple

and exchange transfusion, the target Hb level is 10 to 11 g/dL (hematocrit, 30%).[66,67] Transfusing to a higher Hb or hematocrit level is avoided because a hematocrit level greater than 30% is associated with hyperviscosity if there is a substantial proportion of Hb S in the blood. In exchange transfusion, an additional objective is to achieve an Hb S percentage of less than 30% (or sometimes <50%). In partial-exchange transfusion, a proportion of the patient's diseased RBCs are removed before transfusion of normal donor RBCs; this can be done manually through phlebotomy followed by transfusion or concurrently using an automated device. In patients who need chronic transfusions, partial exchange is recommended because of the reduced iron burden of this approach. Partial exchange is also indicated if the baseline Hb level is more than 10 g/dL. Simple transfusion in this instance risks exacerbating the clinical condition through increased viscosity. For critical illness, exchange transfusion is also preferred. Although the target Hb S level should be less than 30% in exchange transfusion, decreasing Hb S levels to less than 50% may suffice depending on the severity of the complication being treated.

The volumes required for simple and exchange transfusions (Table 40-6) are particularly important for transfusing children. For normal-size adults, the general rule is that each unit of RBCs infused increases the Hb level approximately 1 g/dL.[68]

Episodic simple transfusion should be considered for blood volume replacement in aplastic crisis and splenic sequestration crises and for protection when there is a more than 20% decrease in Hb from baseline from severe illness such as septicemia or severe vasoocclusive crisis or hyperhemolysis or Hb levels of less than 5 g/dL. Episodic simple or exchange transfusion should be considered for acute chest syndrome, priapism, and preoperatively. The choice of simple versus exchange transfusion is determined by the pretransfusion total Hb level and the severity of the illness.

In the preoperative setting, simple transfusion to increase the total Hb level to 10 g/dL was effective in preventing perioperative complications and was associated with fewer transfusion-associated complications than an aggressive exchange transfusion regimen to decrease Hb S levels to less than 30%.[69] The efficacy of preoperative partial-exchange transfusion in patients with Hb SC disease undergoing abdominal surgery suggests that this type of transfusion be performed preoperatively in this group of patients.

Chronic partial-exchange transfusion is indicated in primary and secondary prevention of cerebral thrombosis as discussed in the section on neurologic complications.

Transfusion complications include alloimmunization, delayed hemolytic transfusion reactions (discussed in Exacerbations of Anemia), iron overload, and transmission of viral illness. The incidence of alloimmunization is between 19% and 30% and usually occurs with fewer than 15 transfusions.[70] Some patients seem to tolerate multiple transfusions without developing alloantibodies, but others are readily allosensitized. The high rate of alloimmunization in transfused sickle cell patients is partly attributable to minor blood group incompatibilities between the recipient and donor pool, which often differ in ethnicity.[70,71] Antibodies against the C and E antigens of the Rh group, Kell (K) and Lewis, Duffy (Fya, Fyb), and Kidd (Jk) are common.[70] In the Stroke Prevention Trial in Sickle Cell Anemia, the routine use of WBC-reduced RBCs matched for E, C, and Kell decreased the allosensitization rate compared with historical data from 3% to 0.5% per unit transfused and decreased the rate of hemolytic transfusion reactions by 90%.[72] Therefore, the recommended approach to preventing alloimmunization is to reduce leukocytes and perform limited phenotype matching for all patients (ABO, C, D, E, and Kell) and extended phenotype matching for patients with alloantibodies.[67] The management of a delayed hemolytic transfusion reaction and transfusional iron overload are discussed under Exacerbations of Anemia later.

Transmission of HIV, hepatitis B and C, and human T-cell leukemia/lymphoma virus-1 has diminished with improved screening of banked units but remains an issue. In addition to better screening programs, the use of leukocyte-depleted RBC transfusions can reduce this hazard.[73]

Table 40-6 Transfusion Formulas

Dilutional effects of transfusion on Hb S: PRBC volume (PRBCV) (mL) = $(Hct_d - Hct_i) \times TBV \times Hct_{rp}B$
Manual partial-exchange transfusion:* Hb Sf = $1 - (PRBCV \times Hct_{rp})(TBV \times Hct_i) + (PRBCV \times Hct_{rp}) \times$ Hb S_iC
Automated exchange transfusion: Exchange volume (mL) = $(Hct_d - Hct_i) \times TBVHct_{rp} - (Hct_i + Hct_d)2D$
RBC volume (mL) = $Hct_i \times TBV$

Hct_d, desired hematocrit; *Hct_i*, initial hematocrit; *Hct_{rp}*, hematocrit of replacement cells (usually 0.75); *Hb S_i*, initial Hb S; *Hb S_f*, final Hb S; *PRBC*, packed red blood cells; *TBV*, estimated total blood volume in milliliters (children, 80 mL/kg; adults, 65 mL/kg; nomograms are available).†
*In these formulas, Hct and Hb S are fractions (e.g., 40% = 0.4).

Stem Cell Transplantation

At this time, allogeneic stem cell transplantation remains the only curative option for SCD. The largest series to date has been in a pediatric population with severely symptomatic SCD failing to respond to HU. Using myeloablative conditioning and human leukocyte antigen (HLA)–matched or one-mismatch (two cases) sibling donors, with bone marrow as the source of stem cells in the majority, there was a 10% mortality rate with 90% overall survival and 82% event-free survival at a median follow-up of 54 months.[74] Similar results were obtained when related, HLA-matched umbilical cord blood was used as the source of stem cells.[75] According to these results, stem cell transplant is a therapeutic option for the severely symptomatic child with an HLA-matched sibling donor. In adults, incorporation of rapamycin (to induce immunologic tolerance) into nonmyeloablative stem cell transplant protocols has enabled stable mixed hematopoietic chimerism with associated full-donor erythroid engraftment and normalization of blood counts. The attainment of tolerance may allow extension of these potentially curative approach to alternative donor sources, an active area of research.[76,77] The issue of the cost-effectiveness of bone marrow transplantation (BMT) gains perspective from the comparative costs in the United States of $150,000 to $200,000 for an uncomplicated BMT versus up to $112,000 annually for conventional medical care of a chronically transfused, iron-overloaded patient.[78]

Education

Education regarding the nature of the disease, genetic counseling, and psychosocial assessments of patients and their families are best accomplished during routine visits. Parents of small children are instructed regarding early detection of infection and palpating enlarging spleens.

Phlebotomy

As mentioned, an Hb level of more than 10 to 11 g/dL (hematocrit 30%) in the presence of substantial amounts of Hb S (>30%) is associated with hyperviscosity. Some data indicate that phlebotomy to reduce the hematocrit and viscosity (and which may also address iron-overload) can decrease the frequency of crises in Hb SC or Hb S–β^+ disease.[79] In Hb SS disease, phlebotomy has successfully been used in combination with HU (which increases the Hb level) in secondary stroke prevention in patients previously treated with chronic transfusion.[80] Phlebotomy alone has also been used in Hb SS disease with baseline Hb levels of more than 9.5 g/dL with favorable results on the frequency and duration of pain crises. This benefit may have resulted from decreased hematocrit and viscosity and from a

decrease in intracellular Hb concentration from iron deficiency.[81] One approach to phlebotomy is to remove approximately 10 mL/kg of blood over 20 to 30 minutes followed by infusion of an equal volume of normal saline. This is repeated every 2 weeks until the target Hb level of 9 to 9.5 g/dL is achieved.

Erythropoietin or Darbepoetin

The chronic hemolytic anemia of SCD is partially compensated by vigorous reticulocytosis. A decrease in compensatory reticulocytosis will exacerbate already existent anemia and can be expected to increase clinical risk. Accordingly, chronic relative reticulocytopenia (defined as Hb <9 g/dL and absolute reticulocyte count $<250{,}000 \times 10^9$ L$^-$) was identified as a significant risk factor for early mortality in a prospective cohort study of SCD patients.[82]

In the general population, evaluation of EPO levels is usually prompted by the combination of anemia and abnormal serum creatinine level. EPO levels are then interpreted in relationship to the Hb level to assess for the possibility of EPO deficiency. In patients with SCD, this approach to diagnosis has pitfalls. Patients with SCD are already anemic; therefore, gradual anemia exacerbation is easily missed, and clinicians must weigh many possible causes in the context of complex, multisystem SCD pathology. Furthermore, patients with SCD have low serum creatinine levels at baseline. Therefore, a substantial increase in serum creatinine from baseline may nonetheless remain below the threshold defined as abnormal for the general population, potentially disguising the presence of renal damage that is sufficient to decrease renal endocrine function. Furthermore, EPO levels are not readily interpreted in the individual SCD patient: EPO levels in SCD are generally low for the level of hemoglobin.[83] One contributing factor could be increased uptake by the massive compensatory reticulocytosis. However, EPO levels are lower in SCD adults than in children,[83] and EPO levels are inappropriately lower in patients with chronic relative reticulocytopenia.[19] Hence, EPO deficiency should be considered as a possible cause of progressive anemia in patients with absolute reticulocyte counts below $250{,}000 \times 10^9$ L$^-$ even if their serum creatinine levels are in the normal range. The cumulative published experience of EPO use in SCD is limited (52 patients).[84] Although EPO by itself has been reported to increase Hb F levels, the most important role for EPO may be as replacement therapy for EPO deficiency that causes relative reticulocytopenia and progressive anemia. EPO replacement can also facilitate enhanced HU dosing and Hb F augmentation.[84] In using recombinant human EPO, caution must be exercised not to elevate the hematocrit to levels that result in hyperviscosity. Also, the reticulocyte fraction is the most adhesive, and it is possible that EPO could exacerbate or trigger sickle cell crises.[84] Patients with SCD may be relatively resistant to EPO and require doses higher than those used in other patients with chronic renal failure. The reasons for EPO resistance are unclear but may include increased inflammation-mediated suppression of erythropoiesis.[85]

Erythropoietin therapy is probably not indicated in patients receiving chronic transfusion therapy in whom encouraging endogenous Hb S containing erythropoiesis may be counterproductive.

Iron Chelation

Early death is well described in association with iron overload from β-thalassemia and hereditary hemochromatosis.[86,87] Similarly, iron overload is likely to be a problem in chronically transfused SCD patients, although the clinical significance may critically depend on the degree and duration of overload. Chelation guidelines for patients with SCD are similar to those for other chronically transfused, iron-overloaded patients; iron chelation is indicated when the total body iron level is elevated (ferritin >2000 mcg/L, quantitative liver iron of 2000 mcg/g dry weight, transfusion history >1 year of monthly transfusions).[88] Notably, the serum ferritin level may underestimate clinically significant iron overload.[89,90] Iron chelation options in the United States are deferoxamine (via continuous intravenous or subcutaneous infusion) or deferasirox (orally), both of which appear to have similar efficacy, although the oral route of administration and toxicity profile may favor deferasirox.[91,92]

Newer U.S. Food and Drug Administration (FDA)–approved methods of quantitating iron burden by Ferriscan of the liver[93] can avoid the need for liver biopsies. T2-weighted MRI of the heart indicates hemosiderosis of cardiac tissue, and when the results are abnormal, aggressive chelation is mandated.[94]

Alternatives to Hydroxyurea for Hb F Induction

Alternatives to HU for pharmacologic induction of Hb F that are being studied in clinical trials include the methyltransferase inhibitor 5-aza-2′-deoxycytidine (decitabine) and histone deacetylase inhibiters.[95] These classes of agents act on chromatin processes that regulate gene transcription.

The methyltransferase inhibitors 5-azacytidine and 5-aza-2′-deoxycytidine have produced the largest increases in Hb F of any of the pharmacologic reactivators of Hb F that have been tested.[96,97] Responding patients include those who did not respond to HU, consistent with a different mechanism of action. Although improvements in a number of surrogate clinical endpoints have been demonstrated, larger studies to confirm safety and clinical effectiveness with chronic use are required. In the United States, 5-azacytidine and decitabine have been approved by the FDA for the treatment of myelodysplastic syndrome.

The efficacy of the class of agents known as histone deacetylase inhibitors in Hb F reactivation has been reviewed.[97-99] However, the absence of large clinical trial data, practical issues with administration and stability of some agents, and the lack of FDA approval for many drugs in this class are limitations.

Preclinical studies suggest that the "imid" class of drugs (analogues of thalidomide such as pomalidomide) could have a potential role in Hb F reactivation.[100]

Preventing Red Blood Cell Dehydration With Ion Channel Inhibitors

Polymerization of Hb S is related to the Hb S concentration within the cell. Therefore, a therapeutic strategy could be to reduce the intracellular Hb S concentration by improving cellular hydration. Potential therapeutic options to maintain RBC hydration for which there are preliminary clinical data include cetiedil citrate, imidazole inhibitors of the Gardos pathway,[101] novel Gardos channel inhibitors,[102] or magnesium supplements, which inhibit potassium chloride cotransport.[103]

It also is possible to reduce the Hb concentration by reducing the Hb content with iron deficiency. It has been observed that spontaneous or induced iron deficiency (see Phlebotomy above) sufficient to reduce the serum ferritin, MCV, and mean cell Hb concentration (MCHC) resulted in variably improved Hb S polymerization, RBC survival, level of anemia, and clinical status.[104]

Anticoagulation or Antiplatelet Therapy

Although there is clear evidence of activation of the coagulation system in SCD, the role of thrombogenesis in vasoocclusive crisis remains unclear.[105] Similarly, there have been no thorough evaluations of the role of antiplatelet or antithrombotic agents for the treatment of SCD. D-dimer levels (a degradation product of cross-linked fibrin) increase during acute vasoocclusive crisis.[106]

Minidose heparin, 5000 to 7500 units every 12 hours, administered to four patients for 2 to 6 years reduced hospitalization and emergency department time by 75%, and pretreatment pain frequency recurred after heparin was discontinued.[107] Larger clinical studies will be required to better understand the risks and benefits of

heparin therapy for acute vasoocclusive crisis in SCD. Heparin has not been studied for acute arterial stroke in patients with SCD but has a role in SCD-associated dural venous sinus thrombosis.[108] The management of stroke is fully discussed under Specific Complications and Their Management.

Acenocoumarol was administered in low doses that achieved a mean international normalized ratio (INR) of 1.64 and reduced the elevated levels of prothrombin activation fragment (fragment 1+2) to 50% of pretreatment levels.[109] Clinical endpoints were not measured. In a crossover study, 29 patients were treated with acenocoumarol to target an INR of 1.6 to 2.0. No effect on crisis frequency was noted, although again, there were significant reductions in markers of coagulation system activation.[110] In 37 acutely ill sickle cell patients with elevated D-dimers, the effect of low-dose warfarin therapy (1 mg without a target INR) in 12 of them was examined. In multivariate analysis, low-dose warfarin was the only variable associated with a significant decrease in D-dimer levels, suggesting a warfarin-induced decrease in thrombin activity.[106] Therefore, oral anticoagulation, even at low doses, is associated with a decrease in laboratory markers of coagulation pathway activation in SCD; however, further clinical trials are required to understand the clinical risks and benefits.

Aspirin was compared with placebo in 49 pediatric SCD patients in a double-blind crossover study. The frequency and severity of crises were not affected by aspirin therapy.[111] Cerebral thrombosis, which accounts for 70% to 80% of all cerebrovascular accidents (CVAs) in SCD, results from large-vessel occlusion (Fig. 40-9) rather than the more typical microvascular occlusion of SCD. In the United States, there is an ongoing clinical trial testing the safety and efficacy of aspirin in diminishing the incidence and progression of cognitive defects and overt or silent stroke in pediatric patients.

The management of stroke risk and stroke is fully discussed under Specific Complications and Their Management.

Experimental Therapies

A number of therapies are in the early stages of clinical evaluation and could have a role in disease modification of SCD. These include agents that directly address sickle erythrocyte adhesion to endothelium (recombinant P-selectin glycoprotein ligand-1 [PSGL]–immunoglobulin G conjugate), agents that increase the production of nitric oxide (NO) (glutamine), and herbal extracts with unknown mechanisms of action (Niprisan).[112]

Specific Complications and Their Management

Pain Crisis

Acute Pain Episode or Crisis

Acute pain is the first symptom of disease in more than 25% of patients and is the most frequent symptom after age 2 years.[113] Pain is the complication for which patients with SCD most commonly seek medical attention.[114] An episode of acute pain was originally called a "sickle cell crisis" by Diggs, who used the expression "crisis" to refer to any new rapidly developing syndrome in the life of a patient with SCD.[115] The basic mechanism is believed to be vasoocclusion of the bone marrow vasculature causing bone infarction, which in turn causes release of inflammatory mediators that activate afferent nociceptors.[116]

Although a general correlation of vasoocclusive severity and genotype has been posited,[117] there is tremendous variability within genotypes and in the same patient over time. In one large study of patients with Hb SS disease, one-third rarely had pain, one-third were hospitalized for pain approximately two to six times per year, and one-third had more than six pain-related hospitalizations per year.[118] Over a 5-year period in the National Cooperative Study of SCD, 40% of patients had no painful episodes, and 5% of patients accounted for one-third of the emergency department visits. Pain is more frequent with the Hb SS genotype, low levels of Hb F, higher Hb levels,[28] and sleep apnea.[119] The frequency of pain peaks between ages 19 and 39 years. After the age of 19 years, more frequent pain correlates with a higher mortality rate.[28] Medical personnel who see patients only in the emergency department gain a biased view of SCD skewed by a frequently affected minority with severe disease.[120,121]

Pain may be precipitated by events such as cold, dehydration, infection, stress, menses, and alcohol consumption. Any underlying cause should be searched for and corrected, but the majority of painful episodes have no identifiable cause. Pain can affect any area of the body, most commonly the back, chest, extremities, and abdomen; may vary from trivial to excruciating; and is usually endured at home without a visit to the emergency department. There may be premonitory symptoms.[121] The duration averages a few days, with hospital admissions typically lasting between 4 and 10 days. Painful episodes are biopsychosocial events caused by vasoocclusion in an area of the body having nociceptors and nerves.[116] Pain is an effect and, as such, consists of sensory, perceptual, cognitive, and emotional components. Frequent pain generates feelings of despair, depression, and apathy that interfere with everyday life and promote an existence that revolves around pain. This scenario may lead to a chronic debilitating pain syndrome; fortunately, this is rare.

There is no specific clinical or laboratory finding pathognomonic of pain crisis. The diagnosis is established by history and physical examination. Changes in steady-state Hb values, sickled cells on blood smear, WBC counts, and so on are not reliable indicators. Numerous laboratory tests, leukocytosis, D-dimer fragments of fibrin, and markers of platelet activation have been found to lack specificity as indicators of acute vasoocclusion. Often patients can tell if they are having a typical pain crisis or something more sinister. It is thus good practice to ask the patient if it feels like usual pain crisis pain.

Initial medical assessment should focus on detection of triggers or medical complications requiring specific therapy, which include infection, dehydration, acute chest syndrome (fever, tachypnea, chest pain, hypoxia, and chest signs), severe anemia, cholecystitis, splenic enlargement, neurologic events, and priapism.[122] Pain management should be aggressive to make the pain tolerable and enable patients to attain maximum functional ability. To make the patient pain free is an unrealistic goal and risks oversedation and hypoventilation, which must be avoided. A pain chart should be started and analgesia titrated against the patient's reported pain together with medical

assessment of the patient's overall clinical status, paying particular attention to avoiding oversedation. When clinicians consistently observe a disparity between patients' verbal self-report of their pain and their ability to function, further assessment should be performed to ascertain the reason for disparity. Patients are often undertreated for pain because many physicians and other health care providers are overly concerned with the potential for addiction. Undertreatment of pain is no more desirable than overtreatment and oversedation; undertreatment can prolong the duration of a painful episode and can poison the relationship between the patient and the health care system. In assessing patient responses to conventional doses of analgesia, it must be remembered that individuals with SCD metabolize narcotics rapidly.[123]

The pain pathway should be targeted at different points with different agents, avoiding toxicity with any one class (Table 40-7). The mainstays are nonsteroidal antiinflammatory drugs (NSAIDs), acetaminophen, and opioids. NSAIDs can be used to control mild to moderate pain and may have an additive role in combination with opioids for severe pain. The most potent NSAID is ketorolac. NSAIDs should be used with caution in those with a history of peptic ulcer, renal insufficiency, asthma, or bleeding tendencies. Within limits, use the agents that the patients know work for them and avoid meperidine (Demerol), which should only be used under very exceptional circumstances. Sedatives and anxiolytics alone should not be used to manage pain because they can mask the behavioral response to pain without providing analgesia.

Treatment of persistent or moderate to severe pain should be based on increasing the opioid strength or dose.[122] One approach is to administer morphine 0.1 mg/kg intravenously or subcutaneously every 20 minutes until pain is controlled. The patient should be checked at 20-minute intervals for pain; respiratory rate, depth, and quality; and sedation until the patient is stable with adequate pain control. Subsequently, the patient should receive a maintenance dose of 0.05 to 0.15 mg/kg intravenously or subcutaneously every 2 to 4 hours. A rescue dose of 50% of the maintenance dose can be considered on an as-needed basis every 30 minutes for breakthrough pain.

During maintenance with opioids, pain control; respiratory rate, depth, and quality; and oxygen saturation should be monitored approximately every 2 hours. If respiratory depression is noted, omit the maintenance dose of morphine. For severe respiratory depression or oxygen desaturation, administer naloxone. Incentive spirometry and mandatory time out of bed are helpful in patients with chest pain to decrease the risk for hypoventilation. Adjuvant medications to consider include NSAIDs, acetaminophen, antiemetics, and antihistamines. Laxatives or stool softeners should be prescribed in keeping with close monitoring for constipation.

After 2 to 3 days, consider decreasing the dose and switching from parenteral to oral administration of opioids. For adult patients whose pain requires several or many days to resolve, a sustained-release opioid preparation is appropriate and provides a more consistent analgesia.

Hydration is a critical part of management. However, cardiac function may be significantly impaired, especially in adult patients, and standard discipline must be followed with intravenous fluid management to avoid iatrogenic fluid overload. SCD patients cannot

Table 40-7 Recommended Dose and Interval of Analgesics Necessary to Obtain Adequate Pain Control in Patients With Sickle Cell Disease

	Dose/Rate	Comments
	Severe to Moderate Pain	
Morphine	Parenteral: 0.1-0.15 mg/kg every 3-4 hr Recommended maximum single dose, 10 mg PO: 0.3-0.6 mg/kg every 4 hr	Drug of choice for pain; lower doses in elderly adults and infants and in patients with liver failure or impaired ventilation
Meperidine	Parenteral: 0.75-1.5 mg/kg every 2-4 hr Recommended maximum dose, 100 mg PO: 1.5 mg/kg every 4 hr	Increased incidence of seizures; avoid in patients with renal or neurologic disease and those who receive MAOIs
Hydromorphone	Parenteral: 0.01-0.02 mg/kg every 3-4 hr PO: 0.04-0.06 mg/kg every 4 hr	
Oxycodone	PO: 0.15 mg/kg/dose every 4 hr	
Ketorolac	IM: Adults: 30 or 60 mg initial dose followed by 15-30 mg; children: 1 mg/kg load followed by 0.5 mg/kg every 6 hr	Equal efficacy to 6 mg MS; helps narcotic-sparing effect; not to exceed 5 days; maximum, 150 mg first day, 120 mg maximum on subsequent days; may cause gastric irritation
Butorphanol	Parenteral: Adults: 2 mg every 3-4 hr	Agonist–antagonist; can precipitate withdrawal if given to patients who are being treated with agonists
	Mild Pain	
Codeine	PO: 0.5-1 mg/kg every 4 hr Maximum dose, 60 mg	Mild to moderate pain not relieved by aspirin or acetaminophen; can cause nausea and vomiting
Aspirin	PO: Adults: 0.3-6 mg every 4-6 hr; children: 10 mg/kg every 4 hr	Often given with a narcotic to enhance analgesia; can cause gastric irritation; avoid in febrile children
Acetaminophen	PO: Adults: 0.3-0.6 g every 4 hr; children: 10 mg/kg	Often given with a narcotic to enhance analgesia
Ibuprofen	PO: Adults: 300-400 mg every 4 hr; children: 5-10 mg/kg every 6-8 hr	Can cause gastric irritation
Naproxen	PO: Adults: 500 mg/dose initially and then 250 every 8-12 hr; children: 10 mg/kg/day (5 mg/kg every 12 hr)	Long duration of action; can cause gastric irritation
Indomethacin	PO: Adults: 25 mg every 8 hr; children: 1-3 mg/kg/day given 3 or 4 times	Contraindicated in psychiatric, neurologic, renal diseases; high incidence of gastric irritation; useful in gout

IM, Intramuscular; *MAOI,* monoamine oxidase inhibitor; *MS,* morphine sulphate; *PO,* oral.

concentrate their urine and are at risk for dehydration when not taking adequate fluids (60 mL/kg/24 hr in adults). Intravenous hydration is indicated when the patient is not taking oral fluids adequately. Ideally, the urine specific gravity should be kept under 1.010 by daily testing when in the hospital. Hb may decrease by 1 to 2 g/dL in an uncomplicated pain crisis; blood transfusion is not routinely indicated for an uncomplicated pain crisis.

Equianalgesic doses of oral opioids should be prescribed for home use when necessary to maintain the relief achieved in the emergency department or hospital ward. Care should be taken to appropriately taper opioids in patients who have received daily opioids over many days. In these patients, there may be physical opiate dependence, which is characterized by the onset of acute withdrawal symptoms upon cessation of opioid administration. For patients at risk for physical dependence, opiates should be titrated downward by 15% to 20% per day to zero. Physical dependence is a physiological problem, but addiction is a psychological problem characterized by craving—behavior that is overwhelmingly directed at obtaining the drug; use of the drug for purposes other than pain control; and use of the drug despite negative physical, social, legal, or psychological consequences.

If the patient is not taking a disease-modifying agent such as HU, consideration should be given to initiating such therapy either as an inpatient or during follow-up in the outpatient setting.

Chronic Pain

Chronic pain in SCD usually (but not always) has an identifiable basis such as vertebral fractures, femoral head necrosis, early degenerative changes or osteoarthritis, or chronic skin ulcers. Most patients without such identifiable complications do not require chronic pain medications similar to those used for terminal cancer because the pain from a typical vasoocclusive crisis is episodic. Inappropriately maintaining patients without chronic musculoskeletal degeneration on long-acting opiates can impair their overall psychosocial functioning. On the other hand, adequate analgesia with long-acting opiates (e.g., long-acting morphine preparations similar to those used in cancer patients) is important to maintain the psychosocial functioning of patients who do have complications that cause chronic pain. Also consider agents such as amitriptyline or antiseizure medications[124] that can address neuropathic components and help decrease the sleep impairment and depression that can occur with chronic pain. If the patient is not taking a disease-modifying agent such as HU, consideration should be given to initiating such therapy.

Chronic Anemia

Chronic hemolytic anemia is one of the hallmarks of SCD. Sickle erythrocytes are destroyed randomly, with a mean life span of 17 days.[125] The overall hemolytic rate reflects the number of ISCs.[126] The degree of anemia is most severe in sickle cell anemia, and Hb S–β^0-thalassemia, milder in Hb S–β^+-thalassemia and Hb SC disease,[127] and, among patients with sickle cell anemia, less severe in those who have coexistent α-thalassemia (Tables 40-8 and 40-1).[128]

As already noted, EPO deficiency from otherwise subclinical chronic renal damage may also contribute to a decline in Hb levels below baseline. The level of chronic anemia is a significant prognostic marker.[19]

The treatment options for the chronic anemia of SCD have already been mentioned. These strategies attempt to decrease hemolysis by increasing Hb F (HU and the experimental approaches with EPO, decitabine, and histone deacetylase inhibitors) or decreasing the intracellular Hb S concentration by preventing RBC dehydration (Gardos channel inhibitors).

Exacerbations of Anemia

The rather constant level of hemolytic anemia may be exacerbated by additional events such as aplastic crises, acute splenic

Table 40-8 Bacteria and Viruses That Most Frequently Cause Serious Infection in Patients With Sickle Cell Disease

Microorganism	Type of Infection	Comments
Streptococcus pneumoniae	Septicemia	Common despite prophylactic penicillin and pneumococcal vaccine
	Meningitis	Less frequent than in years past
	Pneumonia	Rarely documented except in infants and young children
	Septic arthritis	Uncommon
Haemophilus influenzae type b	Septicemia	
Meningitis		
Pneumonia	Much less common in recent years because of immunization with conjugate vaccine	
Salmonella species	Osteomyelitis	
Septicemia	Most common cause of bone and joint infection	
Escherichia coli and other gram-negative enteric pathogens	Septicemia	
Urinary tract infection		
Osteomyelitis	Focus sometimes inapparent	
Staphylococcus aureus	Osteomyelitis	Uncommon
Mycoplasma pneumoniae	Pneumonia	Pleural effusions; multilobe involvement
Chlamydia pneumoniae	Pneumonia	
Parvovirus B19	Bone marrow suppression (aplastic crisis)	High fever common; rash and other organ involvement infrequent
Hepatitis viruses (A, B, and C)	Hepatitis	Marked hyperbilirubinemia

Data from Buchanan GR, Glader BE: Benign course of extreme hyperbilirubinemia in sickle cell anemia: Analysis of six cases. *J Pediatr* 91:21, 1977.

sequestration, acute hepatic sequestration, chronic renal disease, or renal endocrine deficiency that may be present without overt renal failure, bone marrow necrosis, deficiency of folic acid or iron, delayed hemolytic transfusion reactions, autoimmune hemolytic anemia, or hyperhemolysis (hemolytic exacerbations) of unknown etiology. Laboratory evaluations that are very useful in the evaluation of a patient with anemia exacerbation are the reticulocyte count, LDH, alloantibody screening, the direct antiglobulin (Coombs) test, and EPO level.

Aplastic Crises

Aplastic crises are transient arrests of erythropoiesis characterized by abrupt falls in Hb levels, reticulocyte number, and RBC precursors in the bone marrow without necessarily an increase in the LDH. Although these episodes typically last only a few days, the level of anemia may be severe because the hemolysis continues unabated in the absence of RBC production. Although the mechanisms that impair erythropoiesis in inflammation are operative in infections of all types (see Chapter 24), human parvovirus B19 specifically invades proliferating erythroid progenitors, which accounts for its importance in SCD (see Chapters 19 and 24).[129] Parvovirus B19 (Fig. 40-10) accounts for 68% of aplastic crises in children with SCD,[130] but the high incidence of protective antibodies in adults makes parvovirus a less frequent cause of aplasia in this age group (see also Infections later in this chapter). Other reported causes of transient aplasia are infections by *S. pneumoniae,* salmonella, streptococci, and Epstein-Barr virus. Bone marrow necrosis, which also may be the result of parvovirus infection, characterized by fever, bone pain, reticulocytopenia, and a leukoerythroblastic response, also causes aplastic crisis.[131,132]

Inhaled oxygen therapy also causes transient RBC hypoproduction; supraphysiologic oxygen tensions curtail EPO production promptly and suppress reticulocytosis within 2 days.[133]

The mainstay of treating aplastic crises is RBC transfusion. When transfusion is necessitated by the degree of anemia or cardiorespiratory symptoms, a single transfusion usually will suffice because reticulocytosis resumes spontaneously within a few days. Transfusion may be avoided by keeping severely anemic patients on bed rest to prevent symptoms and by avoiding supraphysiologic oxygen tensions. A useful guideline for transfusion in the context of an aplastic crisis is the reticulocyte count. A patient having an aplastic crisis with a reticulocyte count that is recovering is less likely to require urgent transfusion than one with a normal or low absolute reticulocyte count.

Sequestration Crisis (Spleen or Liver)

Acute splenic sequestration of blood is characterized by acute exacerbation of anemia; persistent reticulocytosis; a tender, enlarging spleen; and sometimes hypovolemia.[134] The LDH level may remain stable or increase. Patients susceptible to this complication are those whose spleens have not undergone fibrosis—young patients with sickle cell anemia and adults with Hb SC disease or sickle cell–β^+-thalassemia. Sequestration may occur as early as a few weeks of age and may cause death before SCD is diagnosed. In one study, 30% of children had splenic sequestration over a 10-year period and 15% of the attacks were fatal.[135]

The basis of therapy is to restore blood volume and RBC mass. Because splenic sequestration recurs in 50% of cases, splenectomy is recommended after the event has abated. Alternatively, chronic transfusion therapy is used in young children to delay splenectomy until it can be tolerated safely. Because recurrence is possible during transfusion therapy, parents should be trained to detect a rapidly enlarging spleen and to seek immediate medical attention in this event. Less common sites of acute sequestration include the liver and possibly the lung.[136,137]

Delayed Hemolytic Transfusion Reaction and Autoimmune Hemolytic Anemia

Approximately 30% of patients are predisposed to develop alloantibodies, in part because of minor blood group incompatibilities in racially mismatched blood.[71,72] The corollary is that the other patients can receive multiple transfusions without demonstrating alloantibodies. After alloimmunization, there is a subsequent decrease in antibody titer that can fall below serologically detectable levels. Therefore, antigen-positive RBCs appear compatible in cross-matching and are transfused. This can result in a delayed hemolytic transfusion reaction produced by the amnestic response of the immune system (as opposed to the immediate hemolytic reaction that occurs with preformed antibody). The delayed hemolytic transfusion reaction consists of an unexplained fall in Hb, elevated LDH level, elevated bilirubin above baseline, and hemoglobinuria, all occurring between 4 and 10 days after the RBC transfusion. Delayed hemolytic reactions and hyperhemolysis have been shown to occur in 11% of pediatric patients with SCD and a history of alloantibodies.[138] In SCD, the delayed hemolytic transfusion reaction can be particularly devastating because it can be accompanied by reticulocytopenia, which together with a bystander effect of destruction of recipient blood (not just donor blood) can result in unanticipated worsening of anemia to levels below that seen before transfusion.[139] In addition to the manifestations of a delayed hemolytic transfusion reaction as listed, patients may develop acute congestive heart failure, acute renal failure, or acute chest syndrome (accompanied by vasoocclusive pain crisis). Subsequent transfusions may further exacerbate the anemia.

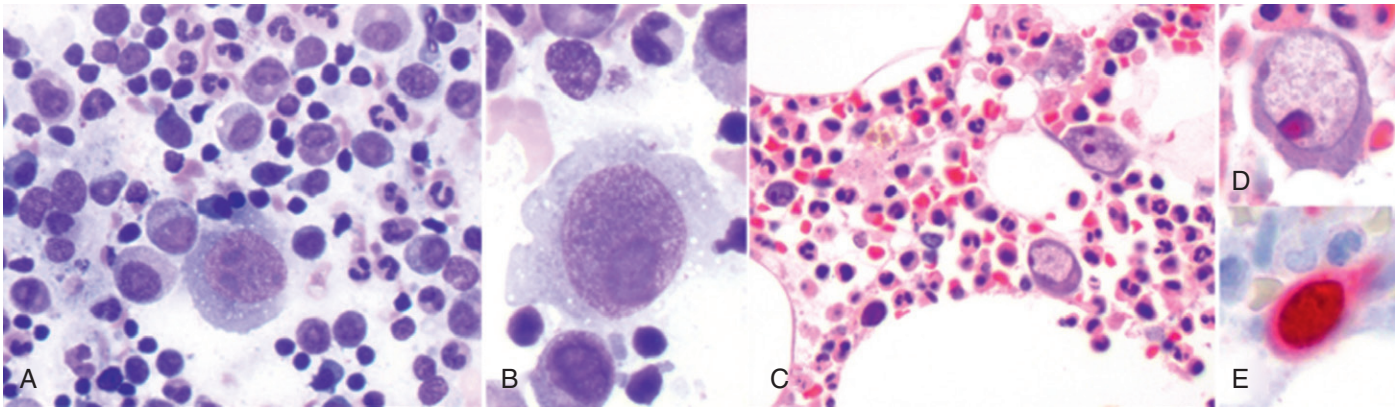

Figure 40-10 PARVOVIRUS. Bone marrow aspirate in a patient with sickle cell disease and aplastic crisis **(A)**. Note the absence of red blood cell precursors except for the single, large degenerating pronormoblast *(lower center)*. Such pronormoblasts contain large nuclear inclusions **(B)** as a result of replication of parvovirus B19. The same can be seen in the tissue sections of a bone core biopsy (**C** and **D**). The parvovirus can now be recognized immunohistochemically with an immunostain **(E)**.

Resolution of severe anemia may only occur after withholding further transfusions with subsequent reticulocyte count recovery. Corticosteroids at high doses (e.g., intravenous methylprednisolone 500 mg/day for 2 to 3 days) should be considered if the anemia is life threatening or if further transfusion is deemed necessary to save the patient's life. Intravenous immunoglobulin can also be considered, with proper attention paid to avoiding iatrogenic fluid overload. Approaches to minimizing this complication include transfusing extended-matched (see Basic Management and Disease Modification), phenotypically compatible blood.[70-72] This syndrome may or may not recur with further transfusions after a recovery period.[140]

Hyperhemolytic Crisis

Hyperhemolytic crisis is the sudden exacerbation of anemia with increased reticulocytosis and bilirubin level. If suspected, the approach to management should first be to look for an underlying etiology, which may be one of the events listed earlier: aplastic crisis (during the recovery phase when the reticulocyte count may not be decreased), sequestration crisis, delayed hemolytic transfusion reaction, or autoimmune hemolysis. Another possible cause is G6PD deficiency.[141]

Erythropoietin Deficiency

This entity is discussed under Basic Management and Disease Modification.

Nutritional Deficiencies: Folate, Iron, or Vitamin B_{12} Deficiency

This entity is discussed under Basic Management and Disease Modification.

Hypothyroidism

Iron overload in SCD can result in hypothyroidism.[142] Therefore, hypothyroidism is another etiology to consider in a SCD patient with an otherwise unexplained decrease in Hb below baseline.

Infections

Immune Deficit

The propensity of children with SCD to contract *S. pneumoniae* infection is related to impaired splenic function[143] and diminished serum opsonizing activity. Even before the anatomic autoinfarction of the spleen in patients with sickle cell anemia, defective splenic function is demonstrable by Howell-Jolly bodies on the peripheral blood smear, visible "pits" on the surface of RBCs, and abnormal results of radionuclide spleen scanning.[144] Specific syndromes exhibiting greater rates of hemolysis cause loss of splenic function at earlier ages—sickle cell anemia earlier than Hb SC disease earlier than sickle cell–β^+-thalassemia.

Infectious complications of SCD are a major cause of morbidity and mortality[145] even with current vaccination and prophylactic antibiotic regimens. The infections caused by particular organisms are shown in Table 40-8, and the specific organisms affecting different target organs are shown in Table 40-9. By 5 years of age, almost all patients are functionally asplenic, contributing to infectious susceptibility. Historically, pneumococcal sepsis has been the predominant cause of death in those younger than 20 years of age.[146]

Evaluation

The most critical aspect of infectious illness in SCD is the evaluation and treatment of febrile children. Routine evaluation includes a physical examination, a CBC, blood and urine cultures, a lumbar puncture if meningitis is suspected, and chest radiography to evaluate for pneumonia. Results of the CBC are compared with baseline values. A left shift in the differential count suggests bacterial infection.

Penicillin Prophylaxis and Pneumonia Vaccination

Data and recommendations regarding penicillin prophylaxis and pneumonia vaccination are discussed under Basic Management and Disease Modification.

Streptococcus Pneumoniae, Haemophilus Influenzae, *Atypical Mycobacteria, and Acute Febrile Illness*

Streptococcus pneumoniae bacteremia is accompanied by leukocytosis, a left shift, aplastic crisis, sometimes disseminated intravascular coagulation, and a 20% to 50% mortality rate.[145] Although concerns about *S. pneumoniae* sepsis are largely for young children, this complication also occurs in adults, often with devastating results.[147] *S. pneumoniae* is the major cause of meningitis in infants and young children with SCD, and it occurs in the setting of bacteremia.

The second most common organism responsible for bacteremia in these children, *H. influenzae* type b, accounts for 10% to 25% of episodes. *H. influenzae* bacteremia affects older children and is less fulminant than *S. pneumoniae* bacteremia, but it may be fatal.[145]

Table 40-9 Organ-Related Infection in Sickle Cell Disease

Primary Sites of Infection	Most Common Pathogen(s)	Other Pathogens	Pathophysiology	Prevention	Management
Septicemia	*Streptococcus pneumonia*	*Haemophilus influenza* type b *Escherichia coli* *Salmonella* spp.	Defective splenic function; deficiency of opsonic antibody	Vaccines* Prophylactic penicillin	Empiric intravenous antibiotics for fever
Meningitis	*S. pneumoniae*			Same as for septicemia	
Osteomyelitis and septic arthritis	*Salmonella* spp. *S. pneumonia*	*E. coli* *Proteus* spp. *Staphylococcus aureus*		—	Surgical drainage, intravenous antibiotics
Pneumonia	*Mycoplasma pneumoniae* Respiratory viruses	*Chlamydia pneumoniae* *S. pneumoniae*		Vaccines*	See pulmonary and therapy sections for management of acute chest syndrome.

Data from Buchanan GR, Glader BE: Benign course of extreme hyperbilirubinemia in sickle cell anemia: Analysis of six cases. *J Pediatr* 91:21, 1977.
*Against *Streptococcus pneumoniae* and *Haemophilus influenzae* type b.

Conjugated *H. influenzae* type b vaccines produce excellent antibody responses in children with SCD and now are administered in early infancy (http://www.cdc.gov/vaccines/recs/schedules/child-schedule.htm).

Owing to the high mortality rate of bacteremia, hospitalization, blood and cerebrospinal fluid cultures, and parenteral antibiotics have been the standard of care for children with fevers higher than 38.5° C. Prompt attention to fever can reduce the risk of severe pneumococcal sepsis. Rapid administration of antibiotics has resulted in a lower incidence of meningitis among patients with bacteremia than 20 years ago when the incidence was 50%.[148] The efficacy of ceftriaxone therapy for *S. pneumoniae* and *H. influenzae* infection[149] has led to new treatment algorithms that recommend outpatient therapy for most patients. However, resistant *S. pneumoniae* have emerged, necessitating a thorough knowledge of local resistance patterns to guide the choice of alternate antibiotics (particularly vancomycin, to which resistance has not been observed).

Please see Pulmonary Complications for further discussions regarding pneumonia and acute chest syndrome.

Meningitis

Meningitis therapy should cover *S. pneumoniae* and probably *H. influenzae* type b and should be continued for at least 2 weeks.

Salmonella and Osteomyelitis

In this patient population, osteomyelitis is commonly caused by *Salmonella* spp.[150] *Staphylococcus aureus,* the most common etiology in patients without SCD, accounts for less than 25% of SCD cases. Infection usually affects long bones, often at multiple sites.

The diagnosis is confirmed by culture of blood or infected bone. Parenteral antibiotics that cover *Salmonella* spp. and *S. aureus* are given, and antibiotic therapy is based on culture results. Parenteral antibiotics are continued for 2 to 6 weeks.[150] Surgical drainage or sequestrectomy may be required. Most patients are cured by this approach, but there may be recurrences.[150]

Articular infection is less common and is often caused by *S. pneumoniae*.[150]

Parvovirus B19

The specificity of the parvovirus B19 (see also Aplastic Crisis) for erythroid precursor cells, coupled with the accelerated erythropoiesis in hemolytic anemias, leaves sickle cell patients vulnerable to infection by this agent.[151] In SCD, parvovirus infection is a common cause of aplastic crisis, especially in children. It has been reported to cause bone marrow necrosis, acute chest syndrome, pulmonary fat embolism, hepatic sequestration, and glomerulonephritis.[129-132]

Urinary Tract Infections

Patients with SCD are at a higher risk for urinary tract infections and pyelonephritis than the general population. *Escherichia coli* is the most common uropathogen and can cause septicemia in these patients. Persistent urinary tract infections may be secondary to renal papillary necrosis. All urinary tract infections in this patient population should be considered complicated, requiring 10 to 21 days of appropriate antibiotic therapy.

Neurologic Complications

Neurologic complications occur in 25% or more of patients with SCD.[152] Neurologic complications include CVAs (consisting of transient ischemic attacks [TIAs], overt and silent cerebral infarction, cerebral hemorrhage), seizures (which can be a presenting feature of CVA), unexplained coma, spinal cord infarction or compression, central nervous system infections, vestibular dysfunction, and sensory hearing loss.[153]

Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation[154]

Histopathologic evaluation of large-vessel involvement in SCD shows a pattern of smooth muscle proliferation with overlying endothelial damage and fibrosis. Smaller arterioles and capillaries demonstrate distension, thrombosis, and vessel wall necrosis.[155,156] Aneurysmal dilation associated with hemorrhagic stroke occurs at regions of intimal hyperplasia.[157] The vessel wall changes are likely multifactorial in origin related to endothelial injury from high and turbulent flow, RBC adherence, and hypoxia. But in addition, it has been speculated that depletion of NO by the free Hb released through intravascular hemolysis may also play a role.[157] The age-specific pattern of stroke risk in SCD may be related to the higher cerebral flow rates in early childhood.[157] Cerebral thrombosis, which accounts for 70% to 80% of all CVAs in patients with SCD, results from large-vessel occlusion (see Fig. 40-9) rather than the more typical microvascular occlusion of SCD.[158] Silent infarcts are thought to result from microvascular vasoocclusion or thrombosis or chronic hypoxia in the periphery stemming from large-vessel disease.[159] In 30% of patients with SCD, major vessel stenosis results in the formation of friable collateral vessels that appear as puffs of smoke (*moyamoya* in Japanese) on angiography.[160] Moyamoya disease predisposes to thrombotic and hemorrhagic strokes, seizures, and cognitive disability.[161]

The relative risk for stroke is 200 to 400 times higher in children with SCD compared with the children without SCD. The prevalence of clinically overt stroke is 11%. Clinically silent infarction detectable by MRI affects 17% to 20% of patients by age 20 years.[162] Silent infarcts are associated with cognitive impairment. Even in patients without silent or overt cerebral infarction, cognitive functioning can be impaired.[163] Almost 50% of the children with "silent" infarcts eventually require lifelong support or custodial care because of neuropsychologic deficits.[164] Whereas infarctive strokes were common in children and those older than 30 years of age, hemorrhagic stroke was most common between ages 20 and 30 years.[23]

Sickle cell–specific risk factors for CVA include increased cerebral blood flow velocity[165] (discussed further under Primary Prevention of Cerebrovascular Accidents), a history of overt or silent cerebral infarction,[166] nocturnal hypoxemia,[167] more severe anemia, higher reticulocyte counts, lower Hb F levels, higher WBC counts, the Hb SS genotype (rather than Hb SC disease or sickle cell–β-thalassemia), nocturnal hypoxemia or sleep apnea, migraines, elevated homocysteine levels, "relative" systolic hypertension (i.e., those at the high end of the lower-than-normal range characteristic of SCD).[23,168] Genetic markers of increased risk are the Central African Republic haplotype and the absence of α-thalassemia.[157,169] Both small- and large-vessel thrombosis can occur. Specific HLA alleles separately correlate with small- versus large-vessel stroke risk, suggesting that different pathologic processes may be involved.[157]

In addition to these sickle cell–specific predictors of stroke, one must also consider the well-documented modifiable risk factors for stroke that are operational in the general population; these are hypertension, exposure to cigarette smoke (active smoking or passive exposure), diabetes, atrial fibrillation, dyslipidemia, carotid artery stenosis, postmenopausal hormone therapy, poor diet, physical inactivity, obesity, and fat distribution. Less well-documented but potentially modifiable risk factors include alcohol or drug use, oral contraceptive use, and sleep-disordered breathing.[162]

Cerebrovascular accidents are heralded by focal seizures in 10% to 33% of cases and by TIAs in 10%. CVAs are fatal in approximately 20% of initial cases, recur within 3 years in nearly 70%, and are the cause of motor and cognitive impairment in the majority. Intracranial hemorrhage results in the same signs as thrombosis, but in addition, neck stiffness, photophobia, severe headache, vomiting, and altered consciousness may occur. Coma suggests hemorrhage rather than thrombosis. A typical presentation is coma and seizures without hemiparesis. Although the mortality rate may be as high as 50%, the morbidity of survivors is low. Hemorrhage may be subarachnoid, intraparenchymal, or intraventricular, which can be differentiated by angiography. The favorable neurosurgical outcome in

subarachnoid hemorrhage caused by ruptured aneurysm justifies an aggressive approach to diagnosis, transfusion, vasodilatory therapy, and surgery.

Primary Prevention of Cerebrovascular Accidents

The overall risk of stroke in pediatric patients with SCD is 1% per year; however, in the subset of patients with transcranial Doppler evidence of a high (>200 cm/sec) cerebral blood flow velocity in the internal carotid artery or middle cerebral artery the stroke risk is in excess of 10% per year (although this is still much lower than the risk of recurrent stroke in a sickle cell patient after a first event, which is approximately 70%). In the Stroke Prevention Trial in Sickle Cell Disease (STOP), 130 children diagnosed as having clinically silent cerebral artery stenosis on the basis of high cerebral flow rates were randomized to receive chronic transfusion therapy or not. Over a period of more than 2 years, the risk of stroke was reduced to less than 1% per year in the transfused group[165] (a risk reduction of >90%). The ability of transfusion to curtail progression of large-vessel stenosis has also been proven with angiography.[170]

Because of the risks of iron overload and allosensitization with chronic transfusion, a randomized controlled trial of withdrawal of transfusion was conducted (STOP 2). This trial evaluated discontinuation of transfusion after at least 30 months in children who had not had an overt stroke and in whom the cerebral flow rates decreased to low risk (<170 cm/sec) with transfusion. This study was terminated early because of a high rate of reversion to high-risk TCD flow rates (34%) and stroke (5%) in the patients taken off transfusion compared with the group who continued transfusion.[171]

In children, MRI can also be used to assess stroke risk: 8.1% of children with an asymptomatic MRI lesion versus 0.5% of those with a normal MRI had a stroke during the ensuing 5 years.[166] A randomized trial of MRI-guided prophylactic transfusion is in progress (Silent Infarct Treatment Trial [SITT]). In adults, MRI or MRA of the brain should be used[30] to assess thrombotic or hemorrhagic stroke risk.

Chronic transfusion is associated with a significant complication rate. Therefore, there is a need for alternatives, especially because some patients and physicians believe that the 10% annual stroke risk does not warrant the risks and burdens of chronic transfusion.[154] The role of aspirin in ischemic stroke prevention in SCD is being evaluated (see Basic Management and Disease Modification). HU significantly lowered the TCD velocity values in a group of 24 children with Hb SS disease compared with an age-matched control group.[47] The role of HU is being formally evaluated in secondary stroke prevention (see Secondary Prevention). Stem cell transplantation has resulted in stabilization of cerebral vasculopathy[172] but there is a mortality risk with this procedure of between 6% and 10%.

Other modifiable risk factors for stroke (see Cerebrovascular Accidents, Pathophysiology, Incidence, Risk Factors, and Presentation) should be identified and treated. Notably, in the general population, hypertension is particularly associated with a risk for hemorrhagic stroke, and effective treatment of hypertension can produce a relative risk reduction of 26% for ischemic stroke and 49% for hemorrhagic stroke.[173] In patients with SCD followed through the Cooperative Study of Sickle Cell Disease, both diastolic and systolic blood pressures were noted to be lower than for matched control participants. Patients with systolic pressures in the higher range for the sickle cell group, even with systolic pressures less than 140 mm Hg, had an increased risk of first ischemic stroke (there were insufficient events to make firm conclusions regarding hemorrhagic stroke).[23] Therefore, at a minimum, it seems reasonable to follow population-wide recommendations for blood pressure control in patients with SCD.

Evaluation and Management of Acute Cerebrovascular Accidents

Patients with symptoms and signs of CVA should be evaluated immediately using computed tomography (CT) scanning or MRI to distinguish among TIA, cerebral thrombosis, and hemorrhage. In those with hemorrhage, angiography or MRA is indicated after partial-exchange transfusion is performed to avoid complications associated with the injected contrast material. In both thrombosis and hemorrhage, prompt partial-exchange transfusion is performed, and chronic direct transfusion to maintain the Hb S level below 30% is instituted to prevent recurrent events (see also Basic Management and Disease Modification) and promote resolution of arterial stenoses.[170]

Secondary Prevention of Cerebrovascular Accidents

The risk of recurrent stroke is approximately 70%, a risk that is reduced to around 13% with chronic transfusion.[174] Although recurrent CVAs during chronic transfusion have been reported, this therapeutic modality provides the best means of preventing recurrence (Fig. 40-11). This treatment also provides incidental protection against pain crises, bacterial infections, acute chest syndrome, and hospitalization.

Based on the data from STOP 2 (see Primary Prevention of Cerebrovascular Accidents), chronic transfusion is continued indefinitely. This may not be feasible for administrative reasons or because of allosensitization or iron overload for which the patient is unable or unwilling to undergo treatment. Therefore, clinical trials to determine if disease modifiers such as HU or decitabine can reduce stroke risk are indicated. In patients with a history of CVA transitioned from chronic transfusion to HU, the recurrent stroke rate remained stable and in the range seen with continued transfusion.[80]

Per primary prevention, all other identified modifiable risk factors for stroke should be identified and treated.

In patients with moyamoya disease, surgical approaches to therapy, such as extracranial–intracranial bypass, have been useful in improving the perfusion of affected regions of the brain.

Stem cell transplantation has resulted in stabilization of cerebral vasculopathy,[172] but the risk of a second neurologic event is higher in the peritransplant period, and the mortality rate with this procedure is between 6% and 10%.[172]

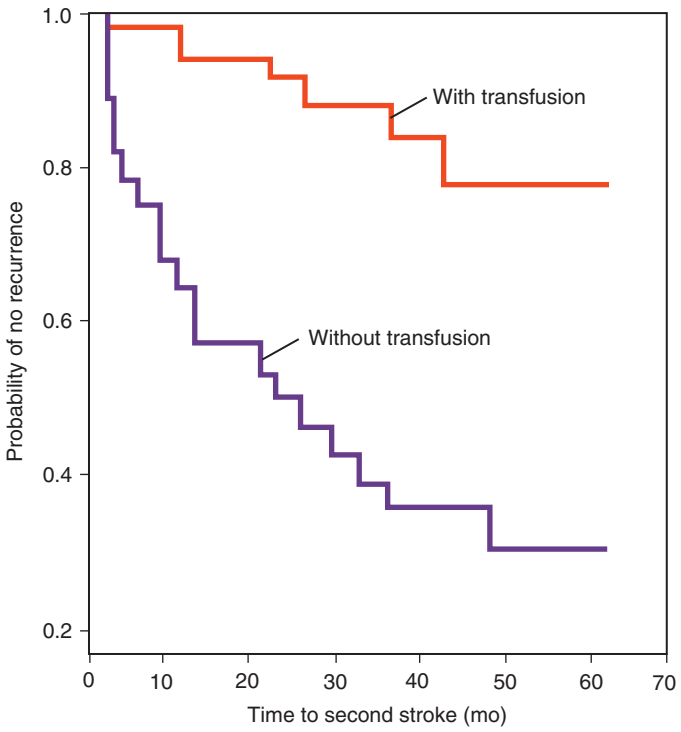

Figure 40-11 COMPARISON OF STROKE RECURRENCE OVER 62 MONTHS IN A TRANSFUSED GROUP AND IN UNTRANSFUSED HISTORICAL CONTROL GROUPS. *(Adapted with permission from Pegelow CH, Adams RJ, McKie V, et al: Risk of recurrent stroke in patients with sickle cell disease treated with erythrocyte transfusions.* J Pediatr *126:896, 1995.)*

Seizures

Seizures occur more commonly among patients with SCD. In one study, 21 of 152 patients in a pediatric clinic had seizures, four of which were related to meperidine therapy. Most had nonfocal CT and MRI studies but focal electroencephalographic changes.[175] CVAs are heralded by focal seizures in 10% to 33% of cases. Therefore, seizures in SCD ultimately may be related to the underlying vasculopathy.

Pulmonary Complications

Pulmonary disease is the leading cause of death in patients with SCD.[16] Both acute and chronic pulmonary complications are common. The common acute complications are pneumonia and acute chest syndrome, and the common chronic complication is pulmonary hypertension.

Pneumonia

Pneumonia is defined as chest infiltrates on chest radiography or chest CT scan associated with fever and an identified infectious etiology.

The risk for and increased frequency of *S. pneumoniae* infections is discussed under Infections earlier. In addition, *Mycoplasma pneumoniae, Chlamydia pneumoniae,* and *Legionella* spp. are also relatively common causes of pneumonia in patients with SCD. Antibiotic therapy for pneumonia or acute chest syndrome should cover these agents in addition to pneumococcus and *H. influenzae*.

When antibiotics are used to treat the acute chest syndrome, they should cover *S. pneumoniae, H. influenzae* type b, *M. pneumoniae,* and *C. pneumoniae*. The combination of cefuroxime and erythromycin is recommended.

Acute Chest Syndrome

Acute chest syndrome occurs in approximately 30% of patients.[176] Acute chest syndrome is defined as a new infiltrate on chest radiography or chest CT scan associated with one or more new symptoms, which include fever, chest pain, cough, sputum production, dyspnea, and hypoxia. This entity is included in discussions of SCD because processes other than infection, such as vasoocclusion, could also lead to pulmonary symptoms, signs, and chest radiographic changes. However, it should be borne in mind that the usual etiology might be both vasoocclusion and infection simultaneously, and in almost all cases of chest syndrome, antibiotics should be administered. Many episodes in which common pathogens are not cultured are caused by "atypical" agents (*Mycoplasma, Legionella,* and *Chlamydia* spp.), suggesting that antibiotic therapy include agents directed at atypical agents. Pulmonary fat embolus, evidenced by stainable fat in pulmonary macrophages obtained by bronchoalveolar lavage or sputum induction, is found in 44% to 60% of cases of acute chest syndrome.[177] Acute chest syndrome caused by pulmonary fat embolus is associated with more severe hematologic and clinical abnormalities. In adults, the mortality rate is four times higher than in children.[3,178]

Acute chest syndrome is often preceded by febrile episodes in children and by vasoocclusive pain crisis in adults (Fig. 40-12).[178] Elevation of serum phospholipase A2 (sPLA2) was detected in patients admitted with vasoocclusive pain crisis 24 to 48 hours before acute chest syndrome was clinically diagnosed.[179] Pulmonary fat embolus is often preceded by an acute painful episode. Some patients have a rapidly progressive course associated with a precipitous decrease in arterial oxygen tension; they may require intensive care treatment. If there are clinical signs of respiratory distress or when arterial oxygen tension cannot be maintained above 70 mm Hg with inhaled oxygen, partial-exchange transfusion is indicated. Artificial ventilation may be required.

In patients with pneumonia or chest syndrome, antibiotics should cover *S. pneumoniae, M. pneumoniae, Chlamydia pneumoniae, H. influenzae,* and *Legionella* spp.

Cooperative Study of Sickle Cell Disease.* Blood *89:1787, 1997.)*

Pulmonary Hypertension

Chronic complications such as pulmonary hypertension occur in as many as 60% of patients.[180-182] There does not appear to be an association with the occurrence of acute chest syndrome,[181] emphasizing that the pathophysiology of these two conditions may differ in some key features. The pathophysiology may involve thrombi in large and small arteries,[183,184] cardiac decompensation from progressive anemia, and potentially reversible increases in vascular tone from NO depletion and medial and intimal hypertrophy.[184] The recognition that pulmonary hypertension is a feature of hemolytic syndromes other than sickle cell and that markers of hemolysis correlate with the risk of pulmonary hypertension supports the idea that depletion of NO through scavenging by free Hb may have an important role in the pathophysiology of this disease.[181,185] Pulmonary hypertension usually occurs in adults and carries a poor prognosis.[186]

The association with early death and the emerging availability of candidate treatments suggest that efforts should be made to diagnose this condition in all patients with SCD.[181,185] The feasibility of an echocardiogram determined tricuspid regurgitant jet (TR-jet) velocity measurement of 2.5 m/sec to make the diagnosis was suggested by selective cardiac catheterization in a cohort of 195 patients[180]; however, the sensitivity and specificity of this test may have limitations.[185] Elevations in BNP levels correlate with an increased TR-jet and risk of early death.

In a 16-week, double-blind, placebo-controlled trial of sildenafil to treat patients with SCD with increased TR-jet velocity and a low exercise capacity, sildenafil increased hospitalization rates for pain without evidence of improvement in TR-jet velocity or BNP levels.[187] If such patients have chronic relative reticulocytopenia, measures to increase total hemoglobin could be a consideration requiring evaluation in clinical trials (see Basic Management and Disease Modification).

Other Pulmonary Complications

Other findings include restrictive and obstructive lung disease and hypoxemia.[188] High-resolution, thin-section CT scanning of the lungs may show chronic interstitial fibrosis. Airway hyperreactivity occurs in nearly two-thirds of children with SCD not diagnosed as having asthma. Thirty-six percent of 53 children with SCD were found to have sleep-related upper airway obstruction, 16% had hypoxemia, and all 15 who underwent adenotonsillectomy were symptomatically improved and had improved hypoxemia.[189] Sleep apnea may be

associated with surgically reversible exacerbations of painful episodes and strokes. Blood gas and pulmonary function measurements should be obtained as baseline data for all patients.

Hepatobiliary Complications

Hepatobiliary complications in patients with SCD include cholelithiasis, cholecystitis, acute hepatic cell crisis, acute hepatic sequestration crisis, and sickle cell intrahepatic cholestasis.[190] Chronic transfusion also places patients at risk for infection with hepatitis viruses and for transfusional hemosiderosis. Non–transfusion-related hepatic hemosiderosis can also be seen.

The serum bilirubin level is higher in sickle cell anemia (Hb SS) than in Hb SC disease or sickle cell–β^+-thalassemia as a result of a greater hemolytic rate. The level rises after the first decade, possibly as a result of chronic hepatobiliary dysfunction. The aspartate aminotransferase (AST) and alanine aminotransferase (ALT) levels are often elevated, particularly in adult patients with sickle cell anemia, but mean levels are normal. Alkaline phosphatase levels are elevated in all genotypes until puberty, which occurred later in males and in those with sickle cell anemia. Percutaneous liver biopsy is associated with a high risk of severe complications and death in SCD patients with acute hepatic syndromes.[191]

Cholelithiasis and Cholecystitis

The prevalence of pigmented gallstones in SCD is directly related to the rate of hemolysis.[192] In sickle cell anemia, gallstones occur in children as young as 3 to 4 years of age and are eventually found in approximately 70% of patients. Some have recommended the surgical removal of asymptomatic gallstones to avoid subsequent difficulty in distinguishing gallbladder pain from acute painful episodes. This approach has become more feasible with the availability of laparoscopic cholecystectomy.[193]

Acute Hepatic Cell Crisis

Acute hepatic cell crisis presents with tender hepatomegaly, worsening jaundice, and fever.[190] The likely etiology is hepatocellular cell ischemia. The AST and bilirubin are elevated, but rarely above 300 IU/L and 255 μM, respectively. This syndrome usually resolves within 3 to 14 days with supportive care alone but can progress to liver failure and fatal outcome; therefore, patients should be monitored closely and exchange transfusion initiated if they show signs of progressive liver dysfunction (e.g., increasing AST).

Acute Hepatic Sequestration Crisis

Acute hepatic sequestration crisis presents with acute hepatic enlargement and a dramatic fall in Hb concentration, the most likely mechanism being sequestration of sickled erythrocytes in the liver. Management is with supportive care and transfusions.

Intrahepatic Cholestasis

Sickle cell intrahepatic cholestasis results in severe, asymptomatic hyperbilirubinemia without fever, pain, leukocytosis, hepatic failure, or death.[194] Asymptomatic hyperbilirubinemia without signs of progressive liver dysfunction (e.g., increasing AST) does not require specific therapy. Evidence of progressive liver dysfunction should prompt consideration of acute hepatic cell crisis and exchange transfusion.

Hepatitis C Infection

Chronic hepatitis C infection in SCD occurs with a prevalence that is related to the number of transfusions received; it may be a leading cause of cirrhosis. Liver transplantation has been used successfully as therapy for this complication.[195] If indicated, interferon-ribavirin can be used to treat hepatitis C in SCD patients.[196]

Obstetric and Gynecologic Issues

Gynecologic complications (delayed menarche, dysmenorrhea, ovarian cysts, pelvic infection, and fibrocystic disease of the breast) are more common in women with SCD. Pregnancy entails increased risks to the mother and child compared with the general population.

Pregnancy

Pregnancy in patients with SCD is associated with increased risks to both the mother and fetus, although these risks are not so great as to prohibit continuation of pregnancy.[197,198] The fetal complications of pregnancy, most of which are related to compromised placental blood flow, are the increased incidence of spontaneous early abortion, intrauterine growth retardation, low birthweight, and fetal death. Maternal complications include increased rates of painful episodes, severe anemia caused by iron or folate deficiencies, exaggeration of the physiologic "anemia of pregnancy," increased infections (urinary tract infections, pneumonias, endometritis), preeclampsia, and death.[198] It is controversial whether the degree of anemia predicts the birth of babies with low birthweight. The occurrence of a perinatal death in a previous pregnancy and the presence of twins in the present pregnancy are two major risk factors for an unfavorable outcome. The course of pregnancy is more benign in Hb SC disease than in sickle cell anemia.

Better fetal and maternal outcomes in recent years are largely attributable to generally improved antenatal and obstetric care. Patients should be followed in a high-risk obstetric clinic in addition to the hematology clinic and receive the usual vitamin, mineral, and folate supplements. A high-calorie, high-protein diet can be considered. There is no specific therapeutic or preventive treatment for intrauterine growth retardation. Some experts recommend prophylactic transfusion, but a large controlled study showed no improvement in fetal outcome from this management option, although maternal symptoms are reduced. In addition to the usual indications for transfusion therapy in SCD, transfusion therapy is indicated for patients with cardiac or respiratory compromise, in preparation for cesarean section, preeclampsia, twin pregnancy, acute chest syndrome, Hb levels more than 20% below steady state or less than 5 g/dL, and previous history of perinatal mortality. If the Hb is between 8 and 10 g/dL and transfusion is indicated for any of the reasons above, partial exchange should be performed (e.g., phlebotomy of 400-500 mL and transfusion of 2 units of packed RBCs).[197] The type of delivery does not appear to represent a problem, and both spontaneous delivery and cesarean section are well tolerated.

Some experts advise that hypertonic saline injections are contraindicated for elective termination of pregnancy because of the risk of sickling-induced vasoocclusion. However, most methods of abortion are well tolerated. There are anecdotal reports of a higher incidence of acute painful episodes after therapeutic abortion; inpatient intravenous hydration before and for the 24 hours after the procedure is recommended.

Birth Control

Modern non–estrogen-containing intrauterine devices should be considered. Although depot injections of medroxyprogesterone (Depo-Provera) given every 3 months may be safe with regards to stroke risk,[199] there is a risk of bone loss, a consideration in patients with SCD and their propensity to skeletal complications. Oral contraceptives containing low doses of estrogen can be considered with no clear evidence of increased stroke demonstrated to date, although the patients' overall stroke risk should probably still be taken into consideration until there is more phase IV follow-up on the clinical experience. Another caution with low-dose estrogen oral contraception is the risk of contraceptive failure with less than excellent compliance. There may be risks to contraception, but against this must be weighed the risks of unintended pregnancy. Sexually active women should have routine pelvic examinations and birth control instructions.

Renal Complications

Hypertension, proteinuria, hematuria, increasing anemia, and nephrotic syndrome reliably predict progression to renal failure, which are clinical indices to pay attention to because the serum creatinine may be misleading. Patients with sickle cell anemia exhibit an increased proximal tubular secretion of creatinine. Thus, patients may have a significant decline in renal function before it is detectable by measuring creatinine clearance.[200] The mean age at presentation with end-stage renal disease is 41 years.[201] Serum creatinine levels are low in all genotypes until age 18 years, when young men experience a rise, apparently related to increasing muscle mass. Creatinine levels increase with age in all genotypes, presumably because of declining renal function (see also organ-specific complications, kidney in Clinical Presentation and Management, later).

Other risk factors for the development of chronic renal failure include use of NSAIDs[202] and a genetic predisposition associated with the Central African Republic (CAR) β-globin haplotype; the latter has been suggested as an indication for BMT to prevent this outcome.[203] Acute renal failure from infarction may result from hypovolemia, sepsis, hepatorenal syndrome, cardiac failure, renal vein thrombosis, and rhabdomyolysis. These patients typically survive and recover their renal function with no increased risk of developing chronic renal failure.

There are seven well-described nephropathies that affect patients with either sickle cell trait or disease. These are gross hematuria, papillary necrosis, nephrotic syndrome, renal infarction, inability to concentrate urine, pyelonephritis, and renal medullary carcinoma.[200]

Renal transplantation is recommended for patients with sickle cell and end-stage renal diseases.

Renal Endocrine (Erythropoietin) Deficiency

This is discussed under Basic Management and Disease Modification.

Gross Hematuria

Hematuria may result from microthrombi formation in the peritubular capillaries of the renal medulla or from frank papillary necrosis. Significant hematuria may resolve with high urinary flow through oral hydration and bed rest. Hematuria that lasts longer than 1 to 2 weeks or the need for transfusion may require maintenance of a high urinary flow using a combination of hypotonic fluids and loop diuretics and urinary alkalinization using sodium bicarbonate and acetazolamide. These therapies are aimed at changing the acidic, hypertonic environment of the renal medulla that favors erythrocyte dehydration, increased Hb S concentrations, and Hb S polymerization. If bleeding persists for 72 hours despite these measures, then alternative treatment should be considered. These may include oral urea,[204] ε-aminocaproic acid, and vasopressin. Embolization or nephrectomy should be reserved for prolonged, life-threatening cases of hematuria that require multiple transfusions.

Increased hematuria can also be seen as a consequence of delayed hemolytic transfusion reactions (discussed in Exacerbations of Anemia).

Papillary Necrosis

Papillary necrosis is most often detected incidentally by imaging or microscopic examination of urine in asymptomatic patients. Sloughed papilla may cause ureteral obstruction and urinary tract infection. In addition to broad-spectrum antibiotics, this occurrence requires emergent relief of the obstruction with a retrograde ureteral stent or placement of a percutaneous nephrostomy tube. NSAIDs should be avoided in patients with papillary necrosis. Otherwise treatment is as for hematuria.

Proteinuria

Proteinuria has been found in 20% to 30% of patients with SCD. Increasing age and low Hb levels correlate with proteinuria. Proteinuria can progress to nephrotic syndrome characterized by proteinuria, hypoalbuminemia, edema, and hyperlipidemia. Angiotensin-converting enzyme (ACE) inhibitors produce a significant reduction in sickle proteinuria, although it is unclear if ACE inhibitors might slow or halt the progression of proteinuria to nephrotic syndrome and renal failure.[205,206] Angiotensin II inhibitors are being studied for a potential role in decreasing sickle cell–related proteinuria and renal function deterioration.

Hyposthenuria and Other Abnormalities of Tubular Function

The inability to maximally concentrate urine (hyposthenuria) in response to water deprivation is an early finding of sickle cell nephropathy. Both sickle cell trait and SCD patients may be affected. Hyposthenuria is the cumulative result of recurrent microinfarcts in the vasa recta caused by sickling (Fig. 40-13). When water deprived, these patients cannot maximally concentrate their urine and develop hypovolemia and dehydration.

Other abnormalities of renal tubular dysfunction found in sickle cell anemia include an incomplete form of distal renal tubular acidosis with hyperchloremic metabolic acidosis and hyperkalemia.[207] The hyperkalemia may respond to oral sodium bicarbonate.

Urinary Tract Infections

Urinary tract infections and pyelonephritis are discussed under infectious complications.

Renal Medullary Carcinoma

Sickle cell trait has been reported to be associated with renal medullary carcinoma.[208] Presentation is with gross hematuria, abdominal or flank pain, or significant weight loss. The disease may be metastatic at diagnosis, and the prognosis is poor. There is a weak association of renal medullary carcinoma with Hb SC disease but no identified association with sickle cell anemia. The reason for these patterns of disease is unknown.

Priapism

Priapism is a condition that is characterized by a sustained erection that does not result from sexual desire and is not relieved by sexual activity. Stuttering priapism is a separate entity that is characterized by multiple, brief episodes of sustained unwanted erection. It has been reported to affect 6.4% to 42% of boys and men with SCD[209] and can also occur in sickle cell trait. Its peak frequencies are between ages 5 and 13 years and 21 and 29 years. Priapism is most likely to develop in patients with lower Hb F levels and reticulocyte counts, increased platelet counts, and the Hb SS genotype. Priapism caused by SCD is usually ischemic, or low-flow, priapism. (High-flow priapism is caused by unregulated arterial flow and can be distinguished from low-flow priapism by a blood gas obtained from the corpora.) Most likely, priapism begins with a physiologic erection. The relative stasis of blood within the corpora leads to a decrease in oxygen tension and development of acidosis, predisposing to Hb S polymerization in the corporal sinusoids, venous occlusion, and low-flow priapism. Pain develops as the corpora become increasingly ischemic after approximately 4 hours of erection. In a minority of patients, usually postpubertal, the engorgement also affects the corpus spongiosum and glans. The mild acidosis that accompanies hypoventilation during sleep may also contribute to the pathophysiology. Impotence is the primary complication of priapism, although patients with a history of multiple episodes of priapism and significant corporeal fibrosis may report fair erections and maintain active sex lives. Corporeal ischemia during priapism may induce local inflammation, causing the fibrosis responsible for impotence.

The goal of treatment is to relieve priapism and maintain potency. Patients should be educated to seek medical attention for unrelenting

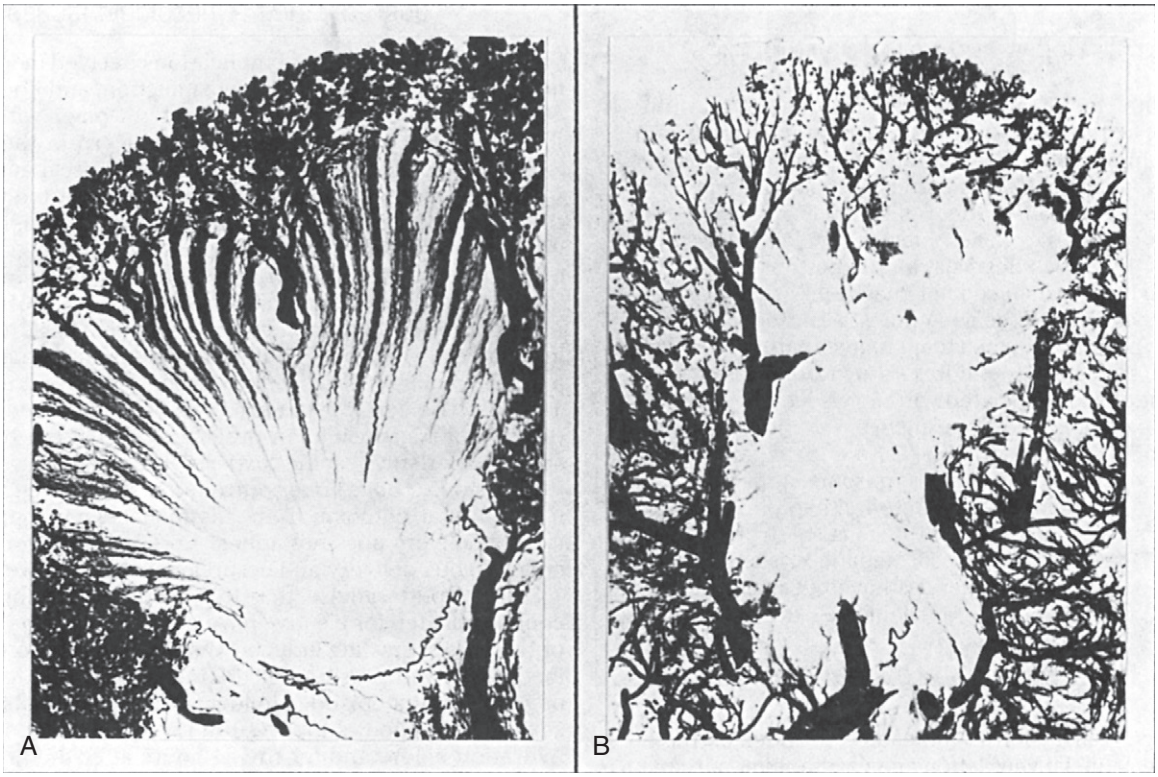

Figure 40-13 Postmortem microangiographic studies of the vasa recta in a normal individual **(A)** and a patient with sickle cell anemia **(B)**. *(With permission from Bertles JF, Döbler J: Reversible and irreversible sickling: A distinction by electron microscopy.* Blood *33:884, 1969.)*

erection of more than 2 hours' duration. Detumescence within 12 hours is optimal to retain potency. After 72 hours, impotence is more likely. The strategy is prompt initiation of supportive medical therapy with intravenous hydration and analgesia and involvement by a urology consultant if the priapism persists for more than 4 hours; aspiration of blood from the corpora with or without irrigation and injection of an α-adrenergic agonist should be considered (Guidelines of the American Urological Association, guidelines.gov/content.aspx?id=3741). If priapism persists 12 hours, options include partial-exchange transfusion to reduce the Hb S level to less than 30% with a total Hb of less than 10 g/dL or irrigation as outlined above. The latter procedure is less effective after 36 hours of priapism. Irrigation should be performed using penile anesthesia (dorsal nerve block; circumferential penile block; or subcutaneous, local, penile shaft block). All irrigation in boys should be performed under conscious sedation. There is anecdotal evidence for the use of hydralazine to treat acute priapism.[210]

Preventing recurrent priapism is an important component of management. Strategies include HU administration; chronic transfusion; the antiandrogen bicalutamide;[211] self-administration of the α-adrenergic agent etilefrine orally and for episodes lasting over 1 hour, by intracavernous injection; and monthly administration of intramuscular gonadotropin-releasing hormone analogue.[212,213] Prophylactic pseudoepinephrine (Sudafed) appears beneficial in preventing recurrent mild episodes.

Surgical creation of shunts is reserved for severe cases resistant to the above interventions. As many as 45% of patients who have priapism develop some degree of impotence.[214] When impotence persists for 12 months, a semirigid penile prosthesis may be implanted.

Ocular Complications[215]

The retina is particularly vulnerable to vasoocclusion, and annual retinal examination is part of routine health care maintenance for patients with SCD. Superficial retinal hemorrhages have a pink "salmon patch" appearance. Deeper retinal hemorrhages have a "black sunburst" appearance. Other manifestations of sickle cell retinopathy include iridescent spots, retinal neovascularization, and retinal detachment. More subtle signs of sickle cell retinopathy are optic nerve head vascular changes, vascular tortuosity, macular changes (e.g., microaneurysms and vascular loops), and peripheral arteriovenous anastomoses. Other ophthalmologic complications are anterior chamber ischemia, tortuosity of conjunctival vessels, retinal artery occlusion, and angioid streaks. Sickle cell retinopathy is best seen by fluorescein angiography (Fig. 40-14). The earlier onset and greater frequency of proliferative retinopathy in Hb SC disease and sickle cell–β^+-thalassemia compared with sickle cell anemia and sickle cell–β^0-thalassemia suggest that retinal vessels are more susceptible to occlusion by more viscous blood than by more rigid individual cells. Peripheral sickle retinopathy may require vision-saving therapy with laser photocoagulation. Orbital compression syndrome caused by vasoocclusion of the periorbital marrow space and subperiosteal hemorrhage has been observed to result in headache, fever, and palpebral edema. In this situation, culture, CT scan, and MRI should be used to rule out infectious, neoplastic, and other hemorrhagic etiologies. Conservative therapy, including local measures, analgesia, fluids, transfusion, and careful ophthalmologic surveillance, is recommended unless compression of the optic nerve ensues, in which case surgical decompression should be considered.

Bone Complications

Chronic tower skull, bossing of the forehead, and fish-mouth deformity of the vertebrae are the result of extended hematopoietic bone marrow, causing widening of the medullary space, thinning of the trabeculae and cortices, and osteoporosis. Osteonecrosis may cause a steplike depression of the vertebrae, selected shortening of the cuboidal bones of the hands and feet, and acute aseptic or avascular

necrosis. The excruciating pain of bone infarction in the "hand–foot syndrome" that occurs around age 2 years of age is often the first symptom of SCD (Fig. 40-15).[216] This dactylitis resolves spontaneously and is treated with hydration and analgesia. Bone infarcts are demonstrable using nuclear medicine scintigraphy or MRI. Serial scans specific for bone osteoclasts, bone marrow macrophages, and inflammatory cells may be useful adjuncts for distinguishing bone marrow infarction from osteomyelitis, but it is essential to obtain cultures directly from the affected tissue before starting antibiotics. Treatment of osteomyelitis is addressed in the Infection sections.

Bone necrosis occurs with equal frequency in the femoral and humeral heads, but the femoral heads more commonly undergo progressive joint destruction as a result of chronic weight bearing. The process is associated with increased intraosseous pressure and is most sensitively detected by MRI. Aggressive physical therapy appears to prevent progression in mild cases and should be considered in the therapy of avascular necrosis. Core decompression surgery to relieve increased intraosseous pressure can be used in early-stage osteonecrosis (i.e., no radiographic evidence of bone collapse) to prevent disease progression. In more advanced disease, joint replacement can be considered. There is a 30% likelihood that a second hip revision will be required within 4 to 5 years of prosthetic hip placement in patients with SCD.[217]

Arthritic pain, swelling, and effusion may be related to periarticular infarction or gouty arthritis.

Bone marrow infarction causes reticulocytopenia, exacerbation of anemia, a leukoerythroblastic picture, and sometimes pancytopenia.[131,132] Pulmonary fat embolism is a rare complication of bone marrow infarction.[218] It is associated with fat globules in the sputum and refractile bodies visible in the optic fundi. It is a life-threatening event that may require prompt exchange transfusion and perhaps the use of heparin and corticosteroids.[218]

Dermatologic Complications

Leg ulcers are major causes of morbidity in SCD as a result of their frequency, chronicity, and resistance to therapy. Most occur near the medial or lateral malleolus (Fig. 40-16), may be associated with

venous hypertension[219] and hemolytic rate,[220] and are frequently bilateral.[221] They may begin spontaneously or as a result of trauma and may become infected, most commonly by *S. aureus, Pseudomonas* spp., streptococci, or *Bacteroides* spp. Systemic infection, osteomyelitis, and tetanus are rare complications. Ulcers are resistant to healing and tend to be recurrent in well over half of cases. Their incidence has been reported to vary from 25% to 75%.[222] Ulcers rarely occur in patients younger than age 10 years and are most common in sickle cell anemia, less common in sickle cell–β°-thalassemia, and nonexistent in Hb SC disease and sickle cell–β⁺-thalassemia.[221] The incidence in sickle cell anemia patients declines substantially in those who have coexistent α-thalassemia.[221] Low steady-state Hb levels and low Hb F levels are associated with an increased risk of leg ulceration.[223] Males have a threefold greater risk for developing leg ulcers than females. Treatment of leg ulcers requires persistence and patience; healing usually takes weeks. Therapy[224] begins with gentle debridement to remove nonviable, superficial tissue from more vital areas. Wet-to-dry dressings and DuoDerm hydrocolloid dressings facilitate devitalization. When debridement is complete, zinc oxide–impregnated Unna boots are used to promote healing. Bed rest speeds healing,[225] and topical antibiotics may be required. It may be necessary to use elastic wraps or leg elevation to control edema. Rapid healing of leg ulcers has been reported in patients treated with intravenous arginine butyrate.[226] Oral zinc, local hyperbaric oxygen, chronic transfusion, recombinant EPO, propionyl-L-carnitine, skin grafts, pentoxifylline, and becaplermin (platelet-derived growth factor) may have therapeutic roles and should be considered in individual cases but have not been formally tested for their effectiveness in accelerating resolution of sickle cell–associated leg ulcers.

Myofascial syndromes consist of soft tissue swelling in subcutaneous edema that may have a *peau d'orange* appearance. These may be large or discrete lesions a few centimeters in diameter. These lesions are probably the result of dermal or subdermal vasoocclusion. Treatment is symptomatic.

Cardiac Complications

The chronic anemia of SCD is compensated by high cardiac output, which results in chronic chamber enlargement and cardiomegaly, and mild to moderate mitral and tricuspid regurgitation even in young children. The electrocardiogram shows evidence of left ventricular hypertrophy and less often first-degree block and nonspecific ST-T wave changes. Left ventricular dilation correlates with age and inversely correlates with total Hb.[227] An age-dependent loss of cardiac reserve may predispose to heart failure in adult patients stressed by fluid overload, transfusion, exacerbation of anemia, hypoxia, or hypertension. Cardiac function can be improved by transfusion.[228] Acute myocardial infarction in the absence of coronary disease has been reported, and in one autopsy series, 9.7% of 72 consecutive patients with SCD had myocardial infarction.[229] It appears that myocardial infarction may occur with normal coronary arteries as a result of increased oxygen demand exceeding limited oxygen-carrying capacity or as a result of microcirculatory impairment. As mentioned earlier, pulmonary hypertension (>30 mm Hg) is a relatively common finding in patients with SCD and can be associated with right ventricular hypertrophy. It has been suggested that the increased rate of sudden death observed in SCD may be related to cardiac autonomic dysfunction, as detected by abnormal heart rate variability in response to selected postural maneuvers.[230]

Multiorgan Failure

This disastrous acute event involves multiple organ systems, including the lungs, brain, kidneys, liver, hematologic system, and heart, and usually leads to death.[231] It may be precipitated by infection, vasoocclusion, or fat embolus and consists of a constellation of life-threatening processes, including hypoxemia, acidosis, inflammation, vascular permeability, severe anemia, disseminated intravascular coagulation, renal failure, and hepatic failure. In addition to therapy specific for these processes, exchange transfusion, plasma infusion or exchange, and corticosteroids should be considered.

Psychosocial Issues

Modern insights into the psychosocial adjustment of patients with SCD have provided a level of understanding that allows interventional therapy. Although most patients with SCD are generally well adjusted,[232] there are risks of depression, low self-esteem, social isolation, poor family relationships, and withdrawal from normal daily living.[232] Particular stressors are recurrent and unpredictable pain and the response to it, curtailed activity because of pain, misinterpretation of the meaning of pain, and depression leading to learned helplessness. Although some patients with SCD become addicted to narcotics, this is uncommon and usually is the result of social influences rather than pain therapy. Well-adjusted patients have active coping strategies, family support, and support from the extended family unit common in African American society. Interventional approaches should emphasize recognizing and reinforcing individual strengths; confronting pathologic behavior; and establishing coping skills through reinterpreting pain, diverting attention from pain, and using support systems.[233] Attention to psychosocial concerns is vital to the psychosocial well-being and integration into society of patients with SCD (see Chapter 93).

Growth and Development

By age 2 years, children with SCD have detectable growth retardation that affects weight more than height and has no clear gender difference.[234] By adulthood, normal height is achieved, but weight remains lower than that of control participants. More severe growth delay is noted in children with sickle cell anemia and sickle cell–β°-thalassemia; Hb SC disease is associated with a less severe growth delay. Girls with SCD have retarded sexual maturation that is greater in those with sickle cell anemia and sickle cell–β°-thalassemia than those with Hb SC disease and sickle cell–β⁺-thalassemia[234]; it is associated with elevated gonadotropin levels for the stage of sexual development and delayed menarche. Boys also have delayed sexual maturation, which is more severe in those with sickle cell anemia than those with Hb SC disease.[234] Retarded sexual maturation in boys can be attributable to primary hypogonadism, hypopituitarism, or hypothalamic insufficiency. The etiology of these multiple endocrine deficiencies may relate to underlying sickle cell pathophysiology or iron overload and emphasizes the importance of a comprehensive basic management and disease modification approach as outlined earlier in this chapter. Improved growth has been reported with HU,[235] transfusion,[235] folic acid supplementation, zinc supplementation,[236] and nutritional supplementation.[237] When children have both SCD and hypersplenism, splenectomy may result in improved protein turnover, metabolic rate, and growth parameters.[238]

VARIANT SICKLE CELL SYNDROMES

The sickle cell syndromes that result from inheritance of the sickle cell gene in simple heterozygosity or in compound heterozygosity with other mutant β-globin genes are sickle cell trait, Hb SC disease, and sickle cell–β-thalassemia. These and other less common compound heterozygosity syndromes are reviewed.

Sickle Cell Trait

The prevalence of sickle cell trait is approximately 8% to 10% in African Americans and as high as 25% to 30% in certain areas of western Africa.[4] Approximately 2.5 million people in the United States and 30 million in the world are heterozygous for the sickle cell gene.

Sickle cell trait is largely a benign carrier condition with no obvious laboratory hematologic manifestations under basal conditions: RBC morphology, RBC indices, and the reticulocyte count are normal, and sickle forms (ISCs) are not seen on the peripheral blood smear. The usual partition of Hb A and Hb S in sickle cell trait is 60:40 owing to a greater posttranslational affinity of α chains for β^A than for β^S chains.[6] When α-thalassemia is coinherited with sickle cell trait, the preferential affinity results in a decreased percentage of Hb S relative to the number of α-globin genes deleted (i.e., αα/αα 40% Hb S; −α/αα 35% Hb S; −α/−α 29% Hb S; −−/−α 21% Hb S).[127]

There are a few clinical complications of sickle cell trait; splenic infarction occurs at high altitude.[239] It is a cause of hematuria and hyposthenuria.[240] The frequency of urinary tract infection may be increased. There is an association with renal medullary carcinoma.[208] There is an increased risk for venous thrombosis with an approximately twofold increase in risk and sickle trait explaining 7% of thrombotic episodes in African Americans.[241] Armed forces recruits in basic training with the sickle-cell trait have a substantially increased, age-dependent risk of exercise-related sudden death.[242]

Despite the known complications, past experiences with discrimination in the employment market and health insurance industry provide reminders that the rare clinical events in sickle cell trait provide no real justification for regarding it as anything but a benign carrier condition.[243] Newborn screening programs detect a large number of infants with sickle cell trait; for these parents, genetic counseling is essential. Parents should understand that their child has a benign hereditary condition with some risks as above but that there is a risk for a subsequent child to be born with SCD.

In individuals who appear to have sickle cell trait but are symptomatic, the laboratory diagnosis must be verified. Hemoglobins other than S that polymerize may account for reports of "sickle cell trait" associated with clinical problems. Examples are heterozygous Hb S Antilles and Hb Quebec-CHORI. In the latter case, the Hb variant was distinguished from Hb A using mass spectroscopy.

Hb SC Disease

The gene for Hb C ($\alpha_2\beta_2^6$Glu→Lys) is approximately one-fourth as frequent among African Americans as the sickle cell gene.[8] Although oxygenated Hb C forms crystals, Hb C does not participate in polymerization with deoxy-Hb S. However, HbC sustains potassium chloride cotransport and RBC dehydration, raising the intraerythrocytic concentration of Hb S to levels that support polymerization, sickling, and clinical symptoms. As a result of a longer circulatory survival of Hb SC RBCs compared with Hb SS cells (i.e., 27 versus 17 days),[124] the degree of anemia and reticulocytosis is frequently mild: 75% of the patients have a milder level of anemia (hematocrit level >28%) than is usually seen in sickle cell anemia. The predominant RBC abnormality on the peripheral smear is an abundance of target cells; folded ("pita bread") cells, ISCs, "billiard ball" cells, and crystal-containing cells may also be seen.

Splenomegaly may be the only physical finding, and the frequency of acute painful episodes is approximately half that in Hb SS disease, with a life expectancy two decades longer.[16] Nonetheless, significant morbidity can occur. The incidence of fatal bacterial infection is less than in sickle cell anemia, but there is still an increased risk of *S. pneumoniae* and *H. influenzae* infection. Osteonecrosis occurs in approximately 15% of patients.[244] There is a higher incidence of peripheral retinopathy in Hb SC disease than in sickle cell anemia. Coexistent α-thalassemia reduces risk of chronic organ complications.[244] There is an association between renal medullary carcinoma and Hb SC disease.

Sickle Cell–β-Thalassemia

The gene frequency of β-thalassemia among African Americans is 0.004, one-tenth that of the sickle cell gene,[8] and hence there is one-tenth the prevalence of compound heterozygous sickle cell–β-thalassemia in this population. Sickle cell–β-thalassemia is divided into sickle cell–β^+-thalassemia and sickle cell–β^0-thalassemia, which have, respectively, reduced or no amounts of Hb A present. Most β-thalassemia mutations among African Americans result in β^+-thalassemia. Sickle cell–β^+-thalassemia is subclassified according to the percentage of Hb A present: type I has 3% to 5%, type II has 8% to 14%, and type III has 18% to 25%. Eighty percent of African American α-thalassemia mutations are attributable to the promoter region mutations [−88 (C to T) and −29 (A–G)] that result in a type III phenotype. Compound heterozygous sickle cell–β^0-thalassemia occurs infrequently.

In sickle cell–β-thalassemia, the RBCs are hypochromic and microcytic. The ISCs present on the peripheral blood smear are more numerous in sickle cell–β^0-thalassemia than in sickle cell–β^+-thalassemia. The hematologic and clinical severity is a function of the amount of Hb A inherited (Table 40-10).

Additional mitigating influences in sickle cell–β-thalassemia are elevated levels of Hb A_2 and, in sickle cell–β^+-thalassemia, levels of Hb A up to 30%. These affect both the solubility and polymerization of Hb S. Hb F is a more active inhibitor of polymerization than Hb A, as shown by Hb S solutions with 15% to 30% Hb A (resembling sickle cell–β^+-thalassemia) having delay times 10 to 100 times longer than pure Hb S solutions, and Hb S solutions with 20% to 30% Hb F (resembling Hb S–HPFH) having delay times 1000 to 1,000,000 times longer. A further influence mitigating the polymerization, sickling, and clinical aspects of sickle cell–β-thalassemia is the reduced MCHC, which retards Hb S polymerization. Hematologic values for sickle cell anemia, the sickle cell–β-thalassemias, and Hb S–HPFH are found in Table 40-10.

Sickle Cell–Hb Lepore Disease

The Hb Lepore gene is a crossover fusion product of the δ- and β-globin genes, the product of which, in the case of Hb Lepore Boston, has the same alkaline electrophoretic mobility as Hb S. Therefore, patients with the Hb Lepore trait can appear to have sickle cell trait but with only 12% Hb S from thalassemic expression of the abnormal fusion gene. Again, because of the electrophoretic similarity with Hb S, compound heterozygous Hb S–Hb Lepore Boston resembles sickle cell anemia or sickle cell–β^0-thalassemia electrophoretically but clinically have less severe anemia, resembling that of sickle cell–β^+-thalassemia. The diagnosis is also suggested by the low to low-normal Hb A_2 levels that result from the incapacitation of one δ-globin gene by the crossover. Hb F levels vary. The peripheral smear shows microcytosis, hypochromia, and ISCs. Vasoocclusive complications occur, and splenomegaly is common.

Sickle Cell–Hb D Disease[245]

Because Hb D Punjab or Hb D Los Angeles ($\alpha_2\beta_2^{121}$Glu→Gln) has a similar electrophoretic mobility to Hb S under alkali conditions, Hb SD disease was first reported as an unusual case of sickle cell anemia. Hb D can be distinguished from Hb S by acid electrophoresis or isoelectric focusing. There is moderately severe hemolytic anemia, and the peripheral smear shows marked anisocytosis and poikilocytosis, target cells, and ISCs. The clinical manifestations of this syndrome are similar to those of sickle cell anemia.

Sickle Cell–Hb O Arab Disease[246]

Although Hb O Arab ($\alpha_2\beta_2^{121}$Glu→Lys) was first described in an Israeli Arab family, its distribution is widespread. Sickle cell–O Arab disease resembles Hb SC disease on alkaline electrophoresis, but Hb O Arab can be distinguished from Hb C by acid electrophoresis or isoelectric focusing. This syndrome is associated with moderately severe hemolytic anemia, and the peripheral smear shows anisocytosis, poikilocytosis, and ISCs.

Table 40-10 Hematologic Variables Associated With Sickle Cell Anemia and the Different Sickle Cell–β-Thalassemia Syndromes

Genotype	Hb*	%Hb A†	%Hb F†	%Hb A_2*	MCV*	Reticulocytes*	*n*
Hb SS‡	7.83	0	4.56	2.87	85.9	10.18	≈123
Hb S–β°-thalassemia‡	8.85	0	5.86	5.02	69.3	7.2	≈41
Hb S–β⁺-thalassemia, type I§	8.37	3-5	6.8	4.90	63.7	9.7	3
Hb S–β⁺-thalassemia, type II§	10.28	8-14	5.2	4.68	70.0	6.6	14
Hb S–β⁺-thalassemia, type III¶	11.55	18-25	5.1	4.66	73.3	1.27	76
Hb S-HPFH¶	14.6	0	25.8	1.95	81.7	2.4	4

*The mean data for each variable are shown. Units of measure are grams per deciliter for Hb, percentage of total hemoglobin for Hb F and A2, fl for MCV, and percentage of total red blood cells for reticulocytes.
†Percentage Hb A that defines the Hb S-β⁺-thalassemia type.[245]

Hb, Hemoglobin; *HPFH,* persistence of fetal hemoglobin; *MCV,* mean corpuscular volume.

Sickle Cell–Hb E Disease[247]

Hb E ($\alpha_2\beta_2^{26}$Glu → Lys) is a β-thalassemic hemoglobinopathy found predominantly in southeast Asia (see Chapter 41). The structural mutant has an electrophoretic mobility similar to Hb C under alkaline conditions but can be resolved by acid electrophoresis or isoelectric focusing. The GAG→AAG mutation in codon 26 activates a cryptic splice site within the first intron of the β^E gene, causing alternate splicing and decreased expression of the structural mutant. As a result, Hb E makes up only 30% of the total Hb in compound heterozygosity for the sickle cell and Hb E genes. Hb SE disease is essentially benign in at least 50% and possibly most patients, with only mild hemolysis, no vasoocclusive complications, and no remarkable abnormality of RBC morphology. However, vasoocclusive complications and manifestations of chronic hemolytic anemia such as pain crisis, splenic infarction, recurrent pneumonia, and frontal bossing have been reported.

Coinherited Hemoglobin Abnormalities That Interact With Sickle Cell Disease: Hereditary Persistence of Fetal Hemoglobin and α-Thalassemia Trait

Sickle Cell–Hereditary Persistence of Fetal Hemoglobin

Adult Hb (or in the case of sickle cell anemia Hb S) replaces Hb F as a result of the switch from γ- to β-globin synthesis that occurs in fetuses. Because of the inhibitory effect of Hb F on Hb S polymerization and cellular sickling (see Chapter 42), the high fraction of Hb F at birth masks the expression of SCD until Hb S levels increase to 75% at approximately 6 months of age (see Fig. 40-3). Conditions that preserve elevated levels of Hb F into adulthood similarly modulate the course of SCD. The compound heterozygous conditions sickle–HPFH (Hb SS–HPFH) and sickle cell–β°-thalassemia–HPFH both have higher Hb F levels and milder clinical courses than are characteristic of sickle cell anemia.[117]

Hereditary persistence of Hb F results from one of several large deletions of the δ- and β-globin genes that retard the switch from the production of Hb F to adult Hb. A more recently discovered variety of HPFH is not caused by a deletion but by one of many point mutations that upregulate the expression of the γ-globin gene. The clinical expression of deletional and nondeletional HPFH differs in that the 15% to 35% Hb F in the former is distributed in a pancellular fashion, the 1% to 5% Hb F in the latter is distributed in a heterocellular fashion, and certain mild types of nondeletional HPFH express high Hb F levels not in simple heterozygosity but only in conditions of erythropoietic stress, such as compound heterozygosity with the sickle cell gene. It is likely that many cases of apparent sickle cell anemia with unexplained elevations of Hb F are the result of a nondeletion HPFH mutation.

The gene frequency of the deletional HPFH locus is 0.0005 among African Americans, resulting in a calculated incidence for compound heterozygous sickle cell–deletional HPFH of 1/100 that of sickle cell anemia. Sickle cell–deletional HPFH provided the first evidence that Hb F was a potent inhibitor of Hb S polymerization: individuals with pancellular distribution of 25% Hb F were generally neither anemic nor affected with vasoocclusive manifestations (see Table 40-10).[248] Hb electrophoresis revealed only Hb S, F, and A_2, which resembles sickle cell anemia, sickle cell–β°-thalassemia, and sickle cell–δβ°-thalassemia. Notable differences, however, are the pancellular distribution of 15% to 35% Hb F, Hb A_2 levels less than 2.5%, and the absence of anemia.[249] The generally benign course of sickle cell–deletional HPFH is uncommonly associated with vasoocclusive complication.

Sickle Cell Anemia With Coexistent α-Thalassemia

Prevalences of the silent carrier of α-thalassemia syndrome (genotype -α/αα) and α-thalassemia trait (genotype –α/–α) among African Americans are approximately 30% and 2%, respectively.[250] The peripheral blood smear contains less polychromasia and fewer sickle forms and more hypochromia and microcytosis, commensurate with the numbers of α-globin genes deleted. Increased Hb A_2 levels are associated with increasing α-globin gene deletions; the Hb F levels are not consistently affected.

Clinically, the impact of α-globin gene deletions on sickle cell is not as consistent as that of high Hb F.[21] Because of the powerful effect of Hb S concentration on the kinetics and extent of Hb S polymerization (see Chapter 42), the lower MCHC from α-globin gene deletions decreases the hemolytic rate, and anemia is milder in subjects with both α-thalassemia syndrome (genotype -α/αα) and trait (genotype –α/–α) (see Table 40-1). There is a decreased incidence of leg ulcers but an increased incidence of osteonecrosis. The frequency of retinal vessel closure is higher but not the incidence of retinopathy. Complications related to hemolysis (e.g., leg ulcers, chronic renal damage) may be decreased, but the heterogeneity of the patients in previous studies and mixed results make conclusions difficult. Similarly, the influence of α-gene deletions on survival in patients with SCD is not well understood.[21]

CHAPTER 41

HEMOGLOBIN VARIANTS ASSOCIATED WITH HEMOLYTIC ANEMIA, ALTERED OXYGEN AFFINITY, AND METHEMOGLOBINEMIAS

Edward J. Benz, Jr., and Benjamin L. Ebert

Hemoglobinopathies are inherited diseases caused primarily by mutations affecting the globin genes. Nearly 1000 mutations that alter the structure, expression, or developmental regulation of individual globin genes, and the hemoglobins they encode, have been described; most do not produce clinical disease. Many are highly instructive for students of gene structure, function, and regulation, but further consideration of most is not warranted in a clinically oriented textbook. The gene mutations that cause sickle cell anemia and the thalassemia syndromes are by far the most important mutations that cause clinical morbidity, in terms of both the complexity of the clinical syndromes they cause and the number of patients affected. These conditions are considered in detail in other chapters (see Chapters 38, 39, and 40). This chapter reviews other abnormalities of the hemoglobin molecule that produce clinical syndromes. Each variant is uncommon. In the aggregate, however, hemoglobinopathies represent important problems for hematologists because they must be considered as possible causes for conditions about which hematologists are often consulted: hemolytic anemia, cyanosis, polycythemia, jaundice, rubor, splenomegaly, and reticulocytosis.

The major hemoglobinopathies producing clinical symptoms, other than sickle cell anemia and thalassemias, can be classified as those hemoglobins exhibiting altered solubility (unstable hemoglobins), hemoglobins with increased oxygen affinity, hemoglobins with decreased oxygen affinity, and methemoglobins (Table 41-1). A few acquired conditions in which toxic modifications of the hemoglobin molecule are important (e.g., carbon monoxide poisoning) are also considered briefly.

The sections that follow emphasize hemoglobinopathies that produce the most severe or dramatic alterations in clinical phenotype and those in which a single clinical abnormality (e.g., hemoglobin precipitation) predominates. It is important to emphasize at the outset, however, that although more than 100 mutations affect solubility or affinity, only a few are clinically important. The abnormal functional properties of most mutant hemoglobins can be detected readily in sophisticated research laboratories, but only a few mutant hemoglobins produce laboratory or clinical abnormalities relevant to clinical practice. Moreover, many mutations are pleiotropic, affecting several functional properties of the hemoglobin molecule. Thus a single mutation can increase oxygen affinity and reduce solubility, or produce methemoglobinemia and reduce solubility.

Table 41-2 summarizes the major forms of structurally abnormal hemoglobin, with examples. This table serves as a point of reference for the remaining sections of the chapter.

UNSTABLE HEMOGLOBINS

Unstable hemoglobins are hemoglobins exhibiting reduced solubility or higher susceptibility to oxidation of amino acid residues within the individual globin chains. More than 100 unique unstable hemoglobin mutants have been documented. Most exhibit only mild instability in in vitro laboratory tests and are associated with minimal clinical manifestations. Both α- and β-globin variants can cause this condition. Approximately 75% of the mutations described, however, are β-globin variants. This probably reflects the potential for α-globin variants to exert pathologic effects in utero. Clinical symptoms of unstable hemoglobins also depend in part on the quantitative proportion of the abnormal hemoglobin. Because the α-globin genes are duplicated, mutations in an individual locus generally produce only 25% to 35% abnormal globin. By contrast, a simple heterozygote at the single β-globin locus usually produces approximately 50% of the abnormal variant.

The mutations that impair hemoglobin solubility usually disrupt hydrogen bonding or the hydrophobic interactions that either retain the heme moiety within the heme-binding pockets or hold the tetramer together (Fig. 41-1). Some alter the helical segments (e.g., hemoglobin [Hb] Geneva [$\beta^{28Leu\rightarrow Pro}$]), others weaken contact points between the α and β subunits (e.g., Hb Philadelphia [$\beta^{35Tyr\rightarrow Phe}$]), and still others derange interactions of the hydrophobic pockets of the globin subunits with heme (e.g., Hb Köln [$\beta^{98Val\rightarrow Met}$]). The common pathway to reduced solubility invariably involves weakening of the binding of heme to globin. Actual loss of heme groups can occur, for example, in Hb Gun Hill, in which five amino acids, including the F8 histidine, are deleted. In other cases, mutations that introduce prolines into helical segments disrupt the helices and interfere with normal folding of the polypeptide around the heme group. Another feature of these mutations is disruption of the integrity of the tetrameric structure of globin chains. Only the intact hemoglobin tetramer can remain dissolved at the high concentrations that must be achieved within the circulating red blood cell (see Chapters 31 and 43).

Pathophysiology of Unstable Hemoglobin Disorders

The mechanisms by which unstable hemoglobin mutations produce hemoglobin precipitation remain incompletely understood. However, the major outlines of the process have been described (Fig. 41-2). The fundamental step in pathogenesis appears to be derangement of the normal linkages between heme and globin. Loss of appropriate globin chain folding and interaction may ultimately destabilize the heme-globin linkage or lead to partial proteolysis of the chain, thereby releasing heme from that linkage. Once freed from its cleft, heme probably binds nonspecifically to other regions of the globin molecule, forming precipitated hemichromes, which lead to further denaturation and aggregation of the globin subunits. These form a precipitate containing α- and β-globin chains, globin fragments, and heme, called the *Heinz body*.

Heinz bodies interact with delicate red blood cell membrane components (see Chapters 31 and 43), thereby reducing red blood cell deformability. These rigid cells tend to be detained in the splenic microcirculation and "pitted," reflecting attempts by the splenic macrophages to remove the Heinz bodies. Red blood cell damage can be aggravated by the release of free heme into the red blood cell. Several biochemical perturbations correlate with the presence of free heme, such as generation of reactive oxidants (i.e., hydrogen peroxide, superoxide, and hydroxyl radicals). The end result of this process is premature destruction of the red blood cell, producing hemolytic anemia.

Individual unstable hemoglobins vary in their propensity to generate Heinz bodies and hemolysis. For example, Hb Zurich exhibits relatively mild insolubility. Hemolysis is minimal in nonstressed patients with this variant and becomes clinically apparent only in the

Table 41-1 Classification of Hemoglobinopathies

Structural hemoglobinopathies—hemoglobins with altered amino acid sequences that result in deranged function or altered physical or chemical properties

ABNORMAL HEMOGLOBIN POLYMERIZATION—HBS

ALTERED OXYGEN AFFINITY

High affinity—polycythemia
Low affinity—cyanosis, pseudoanemia

HEMOGLOBINS THAT OXIDIZE READILY

Unstable hemoglobins, hemolytic anemia, jaundice
M hemoglobins—methemoglobinemia, cyanosis

THALASSEMIAS—DEFECTIVE PRODUCTION OF GLOBIN CHAINS

α-Thalassemias
β-Thalassemias
δβ-, γδβ-, αβ-Thalassemias
Structural hemoglobinopathies—structurally abnormal Hb associated with coinherited thalassemia phenotype
HbE
Hb Constant Spring
Hb Lepore

HEREDITARY PERSISTENCE OF FETAL HEMOGLOBIN—PERSISTENCE OF HIGH LEVELS OF HBF INTO ADULT LIFE

Pancellular—all red blood cells contain elevated HbF levels
Nondeletion forms
Deletion forms
Hb Kenya
Heterocellular—only specific subpopulation of red blood cells contain elevated levels of HbF

"ACQUIRED HEMOGLOBINOPATHIES"

Methemoglobin due to toxic exposures
Sulfhemoglobin due to toxic exposures
Carboxyhemoglobin
HbH in erythroleukemia
Elevated HbF in states of erythroid stress and bone marrow dysplasia, usually heterocellular

Hb, Hemoglobin.

Table 41-2 Mutations Producing Abnormal Hemoglobin Molecules*

Residue	Mutation	Common Name(s)	Molecular Pathology
ABNORMAL SOLUBILITY			
β6	Glu→Val	S	Polymerization
β6	Glu→Lys	C	Crystallization
β121	Glu→Gln	D-Los Angeles, D-Punjab	Increases polymer in S/D heterozygote
β121	Glu→Lys	O-Arab	Increases polymer in S/O heterozygote
INCREASED OXYGEN AFFINITY			
α92	Arg→Gln	J-Capetown	Stabilizes R state
α141	Arg→His	Suresnes	Eliminates bond to Asn 126 in T state
β89	Ser→Asn	Creteil	Weakens bonds in T state
β99	Asp→Asn	Kempsey	Breaks T state intersubunit bonds
DECREASED OXYGEN AFFINITY			
α94	Asp→Asn	Titusville	Alters R state intersubunit bonds
β102	Asn→Thr	Kansas	Breaks R state intersubunit bonds
β102	Asn→Ser	Beth Israel	Breaks R state intersubunit bonds
METHEMOGLOBIN			
α58	His→Tyr	M-Boston, M-Osaka	Heme liganded to Tyr not His
α87	His→Tyr	M-Iwate	Heme liganded to both His and Tyr
β28	Leu→Gln	St Louis	Opens heme pocket
β63	His→Tyr	M-Saskatoon	Tyr ligand stabilizes ferriheme
β67	Val→Glu	M-Milwaukee-I	Negative charge stabilizes ferriheme
β92	His→Tyr	M-Hyde Park	Bond of His to heme disrupted
UNSTABLE			
α43	Phe→Val	Torino	Loss of heme contact
v94	Asp→Tyr	Setif	Alters subunit contacts
β28	Leu→Gln	St Louis	Polar group in heme pocket
β35	Tyr→Phe	Philadelphia	Loss of dimer bond favors precipitation
β42	Phe→Ser	Hammersmith	Loss of heme
β63	His→Arg	Zurich	Opens heme pocket
β88	Leu→Pro	Santa Ana	Disrupts helix
β91	Leu→Pro	Sabine	Disrupts helix
β91-95	Deletion	Gun Hill	Shortens F helix
β98	Val→Met	Köln	Alters heme contact

*Partial list includes some of the most widely studied hemoglobin structural mutations.

presence of additional oxidant stresses, such as infection, fever, or the ingestion of oxidant agents. Because of the propensity of unstable hemoglobins to be hypersensitive to oxidation, some patients with unstable hemoglobins can exhibit episodic hemolysis in response to many of the same oxidative stressors as those exacerbating the clinical phenotype of glucose-6-phosphate dehydrogenase (G6PD)–deficient patients (see Chapter 42).

Patterns of Inheritance and Clinical Manifestations

Unstable hemoglobins are usually inherited as autosomal dominant disorders. However, the rate of spontaneous mutation appears to be high, so the absence of affected parents or siblings does not rule out the presence of an unstable hemoglobin in an individual family. Nonetheless, the presence of a positive family history can be a useful adjunct to diagnosis and should provoke consideration of an unstable hemoglobin as the cause of the familial hemolytic diathesis.

The clinical syndrome associated with unstable hemoglobin disorders is often called *congenital Heinz body hemolytic anemia*. This term derives from the fact that only the most severe cases were detected before the widespread availability of sophisticated methods for detecting and characterizing abnormal hemoglobins. Clinical manifestations are highly variable, ranging from a virtually asymptomatic state in the absence of environmental stressors to severe

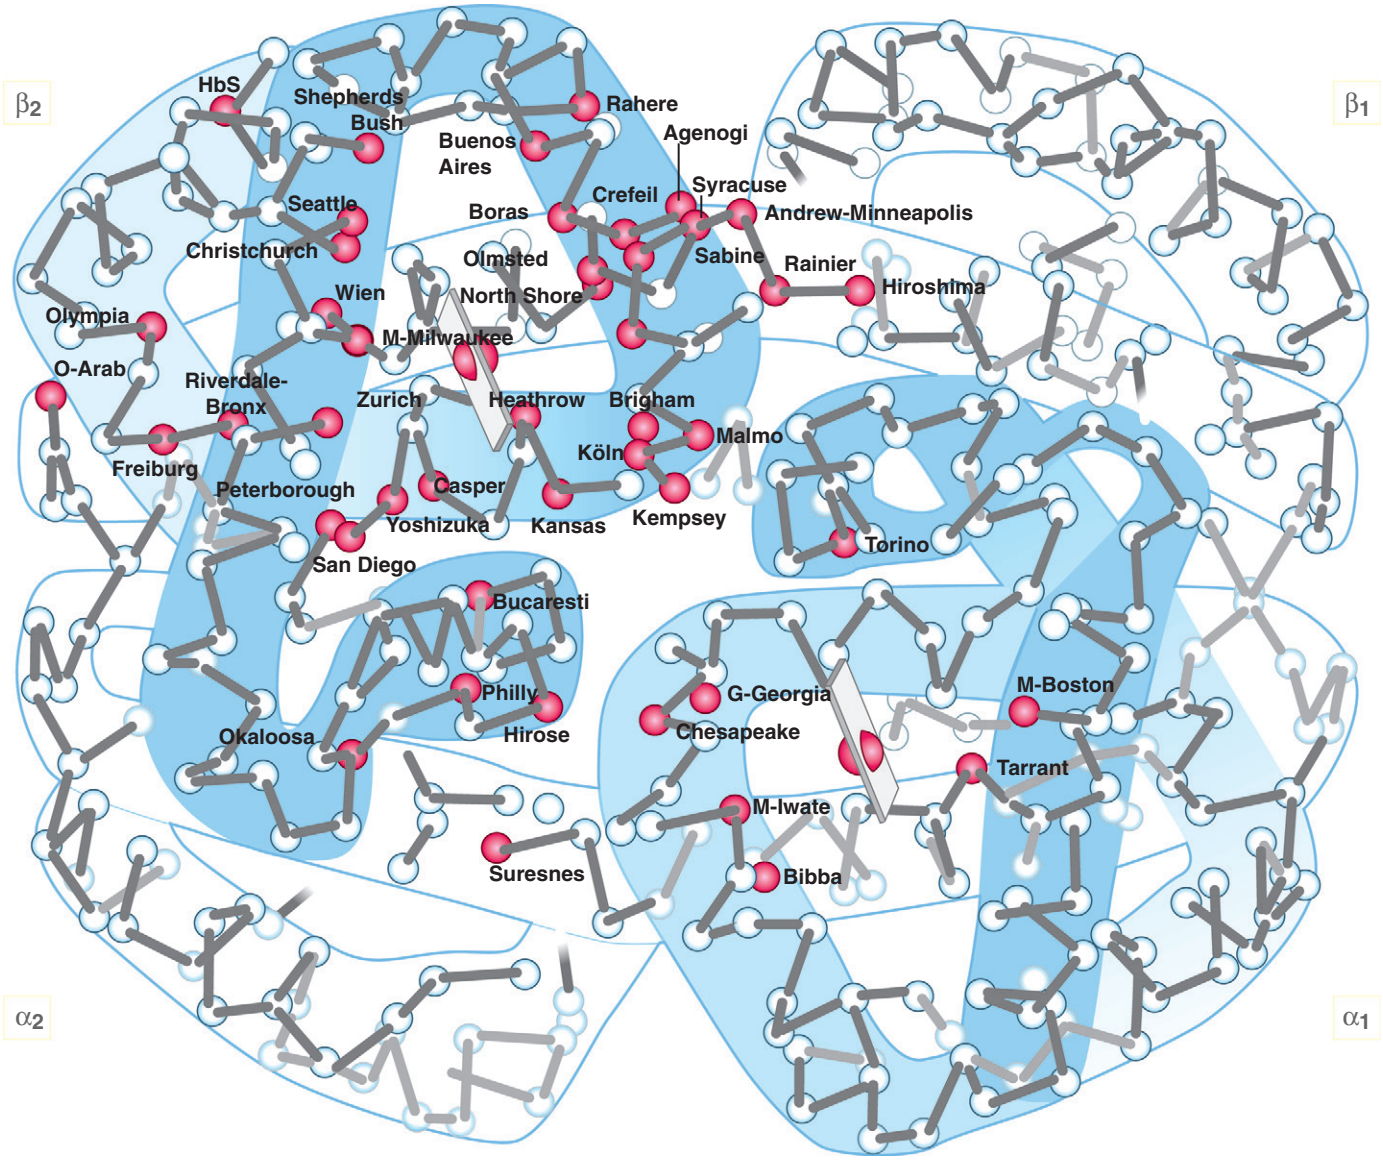

Figure 41-1 HEMOGLOBIN TETRAMER SHOWING THE POSITION OF THE MORE COMMON, CLINICALLY SIGNIFICANT HEMOGLOBIN MUTANTS. Most of those that have been described occur on the β-chain at invariant residue sites, near critical intermolecular contacts, or in proximity to the prosthetic heme-binding site. *(Modified from Dickerson RE, Geis I:* Hemoglobin: Structure, function, evolution, and pathology, *Menlo Park, Calif, 1983, Benjamin-Cummings. Copyright Irving Geis.)*

hemolytic anemia manifesting at birth. Patients with chronic hemolysis present with variable degrees of typical symptoms, including anemia, reticulocytosis, hepatosplenomegaly, jaundice, leg ulcers, and a propensity toward premature biliary tract disease.

For hemoglobin variants with a given degree of reduced solubility, the degree of anemia may fluctuate because some of these variants also exhibit altered oxygen affinity. Thus Hb Köln has increased oxygen affinity, resulting in relatively higher levels of tissue hypoxia and erythropoietin stimulation at any given level of hematocrit (see Diagnosis); therefore patients with Hb Köln tend to have higher hematocrit levels than expected on the basis of hemolytic severity because of increased erythropoietin stimulation. By contrast, Hb Hammersmith exhibits decreased oxygen affinity, improving oxygen delivery and allowing patients to function at a lower hematocrit level. Hb Zurich possesses, for complex molecular reasons, a higher-than-normal affinity for carbon monoxide. A high hemoglobin carbon monoxide level develops in patients with Hb Zurich who also smoke. Binding of carbon monoxide protects Hb Zurich from denaturation, thus reducing hemolysis, so these people tend to exhibit lesser degrees of hemolytic anemia than do nonsmoking relatives.

Diagnosis

The presence of an unstable hemoglobin should be suspected in patients with one or more stigmata of accelerated red blood cell destruction: chronic or intermittent hemolytic anemia or jaundice, premature development of bilirubin gallstones or biliary tract disease (as a result of accelerated red blood cell turnover), unexplained reticulocytosis, or bouts of intermittent symptoms that can be related to exposure to oxidant drugs or infections. Other suggestive symptoms include dark urine, transient jaundice, and leg ulcers.

Laboratory diagnosis depends on identification of a mutant hemoglobin that precipitates more easily than normal hemoglobin. The peripheral blood smear may or may not show evidence of hemolysis (i.e., poikilocytosis, polychromasia, or shift cells; Fig. 41-3, *A*). The morphologic evidence for precipitated hemoglobin is the Heinz body, the intraerythrocytic inclusion body detected by staining the peripheral blood smear with a supravital dye, such as brilliant cresyl blue or new methylene blue (see Fig. 41-3, *B, C*). The spleen removes Heinz bodies efficiently, especially if hemolysis is not particularly acute or brisk. Thus Heinz bodies may not be demonstrable at all times. Two

provocative laboratory maneuvers are used to aid detection, both of which unmask the tendency of unstable hemoglobins to precipitate: the heat instability test (heating of a hemoglobin solution to 50° C) or the isopropanol instability test (insolubility in 17% isopropanol).

Hemoglobin electrophoresis or hemoglobin analysis by mass spectrometry should be performed but *should not be relied on as the major diagnostic criterion for ruling in or ruling out a hemoglobinopathy.* Many amino acid substitutions that have a profound effect on solubility do not change the overall charge on the hemoglobin molecule. For example, Hb Köln, the most common of the unstable hemoglobin mutations, arises from a mutation changing the valine at position 98 to a methionine. This mutation is electrically neutral; it does not alter electrophoretic mobility. Therefore these variants do not form an abnormal band on an electrophoresis gel. Demonstration of an abnormal band would clearly add strong evidence in support of the diagnosis. A normal electrophoretogram, however, should never be regarded as strong evidence against the presence of a mutant hemoglobin, especially if the clinical picture or family history otherwise supports the diagnosis. Mass spectrometry analysis of hemoglobin and direct globin gene sequencing are supplanting electrophoresis as diagnostic strategies. They usually provide unambiguous identification of the sequence abnormality. However, electrophoresis is still in use in many clinical settings. Thus the aforementioned precautions in interpretation are still worth noting.

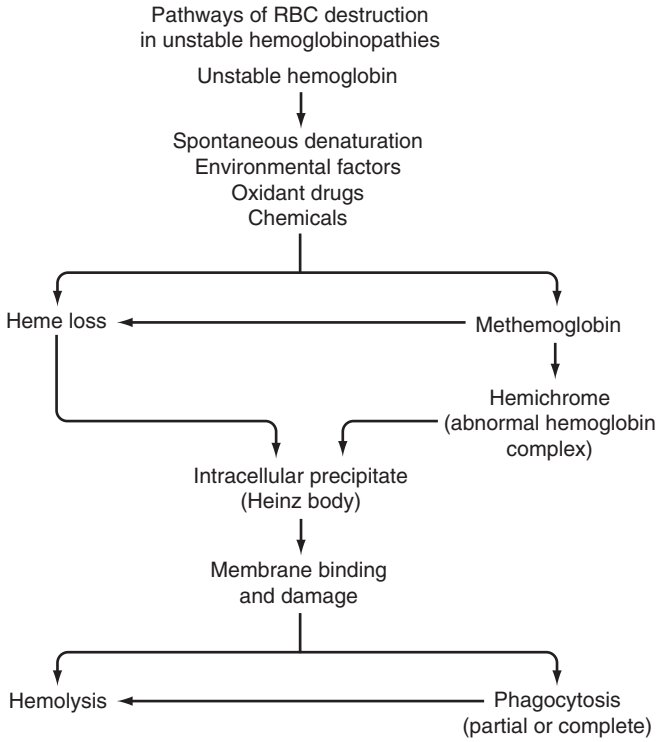

Figure 41-2 PRESUMED MECHANISMS BY WHICH DENATURATION OF HEMOGLOBIN LEADS TO ERYTHROCYTE DESTRUCTION. The rate of travel through the various pathways probably differs for the different hemoglobin variants and for a variety of stresses to which the protein is subjected. *RBC,* Red blood cell. *(From Wynngaarden JB, Smith LH Jr, Bennett JC, editors:* Cecil textbook of medicine, *Philadelphia, 1992, WB Saunders.)*

Additional sophisticated analyses of hemoglobin can be obtained from reference laboratories if detailed characterization seems warranted. For example, abnormal hemoglobin or globin bands migrating to novel positions on an isoelectric focusing gel can result from hemoglobin or globin moieties lacking heme in groups. When heme is added to the sample and the proteins are reanalyzed, these bands disappear. This behavior is nearly diagnostic of an unstable variant.

Detection of unstable hemoglobins is occasionally compromised by the selective precipitation of the unstable variant into Heinz bodies. Because most patients are heterozygotes, this phenomenon greatly reduces the apparent percentage of the variant in soluble form. Thus even a variant possessing altered electrophoretic mobility may be very difficult to detect. Indeed, some unstable hemoglobins, such as Hb Geneva or Hb Terre Haute, are so unstable that no mutant gene product can be detected in the steady state. These abnormal hemoglobins actually produce a thalassemic phenotype. They are detectable only by isotope labeling studies or direct analysis of the globin genes.

The amino acid sequence predicted from genetic sequencing may rarely be inaccurate because of posttranslational conversion into an unstable hemoglobin. For example, in the first reported case of congenital Heinz body hemolytic anemia due to Hb Bristol, the DNA sequence predicts a valine-to-methionine substitution at β67. Through posttranslational modification, the methionine is altered to aspartate, a hydrophilic residue that disrupts the heme pocket.

The differential diagnosis of unstable hemoglobin variants is usually straightforward if the general category of hemolytic disorders is suspected. The most common form of G6PD deficiency can also manifest with bouts of intermittent or chronic hemolysis exacerbated by oxidant drugs or infection (see Chapter 42). This diagnosis should be considered, as should other causes of chronic or intermittent hemolytic anemia, such as red blood cell membrane disorders (e.g., hereditary spherocytosis) or immune hemolytic anemias. Spherocytes are relatively rare in patients with unstable hemoglobin disorders; this is sometimes a useful discriminant.

Management

The severity of the clinical complications of unstable hemoglobins varies enormously. Many patients can be managed adequately by observation and education to avoid agents that provoke hemolysis. Some patients require transfusions during bouts of severe acute hemolytic anemia. Patients who have significant morbidity because of chronic anemia or repeated episodes of severe hemolysis should be considered candidates for splenectomy, especially if hypersplenism has developed. Children with severe hemolysis may require transfusion support until they are old enough (at least 3 or 4 years of age) to undergo splenectomy without unacceptable immunologic compromise. Splenectomy is usually effective for abolition or reduction

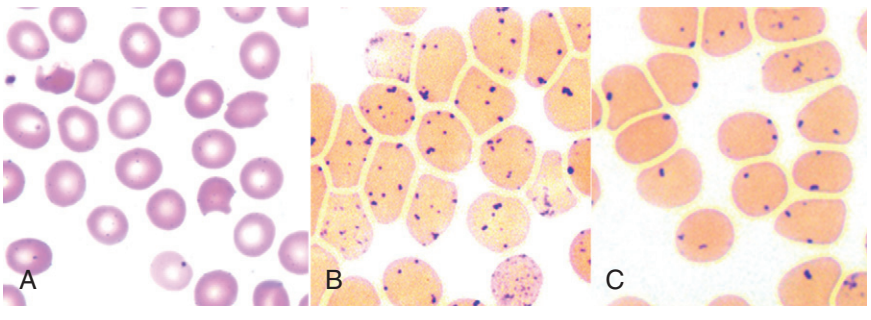

Figure 41-3 UNSTABLE HEMOGLOBINS; PERIPHERAL BLOOD SMEAR AND HEINZ BODY PREPARATION. The peripheral smear **(A)** shows "bite" cells with pitted-out semicircular areas of the red blood cell membrane as a result of removal of Heinz bodies by macrophages in the spleen. The Heinz body preparation **(B)** shows increased Heinz bodies in the same specimen, when compared to a control **(C)**.

of anemia. However, splenectomy should be used only as a last resort because of the long-term risks of overwhelming sepsis and thrombosis. Infection often exacerbates hemolysis. Fever should therefore prompt close monitoring of patients for evidence of hemolysis or infection.

HEMOGLOBINS WITH INCREASED OXYGEN AFFINITY

Efficient oxygen delivery by hemoglobin depends on the sigmoid shape of the hemoglobin-oxygen affinity curve. During the transition from the fully deoxygenated to the fully oxygenated state, the initial oxygenation steps occur with difficulty. In fact, the act of binding the first oxygen molecule increases the affinity of the molecule for subsequent oxygen-binding events, thus creating the sigmoid shape of the curve. The necessary intramolecular reorganization occurs only when the precise arrangement of hydrogen bonds, hydrophobic interactions, and salt bridges is broken and formed in the proper sequence.

Mutant hemoglobins exhibiting altered oxygen affinity arise from amino acid substitutions at the interface between α- and β-chains or in regions affecting the hydrogen bonds, hydrophobic interactions, or salt bridges that influence the interaction of heme with oxygen. A second major class of mutations alters binding to 2,3-diphosphoglycerate (2,3-DPG), which in turn alters oxygen affinity when bound to hemoglobin.

Pathogenesis and Pathophysiology

High-affinity hemoglobins exhibit higher avidity for oxygen, causing the oxygen dissociation curve to shift to the left; an example is Hb Kempsey ($\beta^{99Asp\rightarrow Asn}$) (Fig. 41-4). These hemoglobins bind oxygen more readily than normal and retain more oxygen at lower partial pressure of oxygen (Po_2) levels. They thus deliver less oxygen to tissues at normal capillary oxygen pressures. The PO_2 in the normal lung (90 to 100 mm Hg) is well above that needed to saturate hemoglobin fully with oxygen (60 mm Hg). These variant hemoglobins cannot acquire any additional oxygen in the lung despite their higher affinity. At capillary PO_2 (35 to 45 mm Hg), however, high-affinity hemoglobins deliver *less* oxygen. At normal hematocrit levels, a mild tissue hypoxia results, triggering increased production of erythropoietin and red blood cells, thus resulting in polycythemia. In extreme cases, hematocrit levels of 60% to 65% can be encountered.

Many types of mutations can increase oxygen affinity. Some alter interactions within the heme pocket, others disrupt the Bohr effect or the salt-bond site, and still others impair the binding of HbA to 2,3-DPG. Loss of 2,3-DPG binding results in increases in oxygen affinity. These and numerous other examples that have been analyzed at the molecular level have greatly aided our understanding of the molecular basis for reversible oxygen binding.

Diagnosis

High-affinity hemoglobins are a cause of familial unexplained erythrocytosis (see Chapters 24 and 67). Functional testing of the hemoglobin is the key to diagnosis. Oxygen affinity is usually measured as P_{50}, the Po_2 at which hemoglobin is 50% saturated with oxygen (see Fig. 41-4). The hemoglobin preparation is exposed to increasing oxygen pressures, and the relative percentages of oxyhemoglobin and deoxyhemoglobin are determined. The values are plotted on a curve, and the 50% saturation point is determined. A shift to the left means that the hemoglobin reaches 50% saturation at a lower Po_2. High-affinity variants are thus associated with a lower-than-normal P_{50} value. Hemoglobin electrophoresis can, but may not, reveal an abnormal band.

The most common cause of a low P_{50} value is carbon monoxide. Carbon monoxide stabilizes hemoglobin in the R "oxy" state without the need for oxygen binding. The oxygen affinity curve is therefore extremely left shifted and is hyperbolic, rather than sigmoidal, in shape. The clinical consequences of mild chronic carbon monoxide poisoning are the same as those seen with high-affinity hemoglobin variants. The most common cause of carbon monoxide toxicity is cigarette smoking, although chronic carbon monoxide exposure can elevate the hematocrit level in people such as caisson workers or tunnel toll collectors. Severe acute carbon monoxide poisoning can cause rapid death as a result of tissue hypoxia.

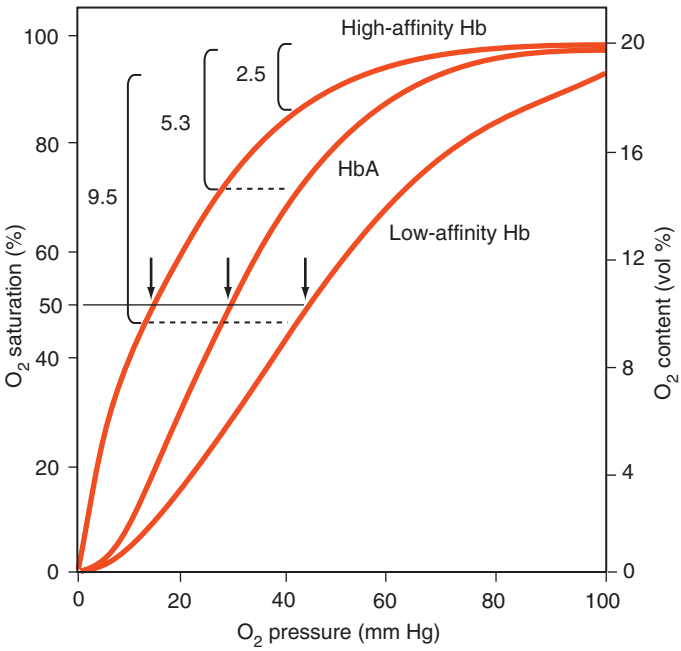

Figure 41-4 HEMOGLOBIN-OXYGEN DISSOCIATION CURVES ARE ILLUSTRATED FOR NORMAL HEMOGLOBIN (HBA) AND FOR MODEL ABNORMAL HEMOGLOBINS WITH HIGH AND LOW OXYGEN AFFINITIES. On the abscissa, the partial pressure of oxygen (Po_2) is indicated in millimeters of mercury. On the left ordinate, the saturation of hemoglobin with oxygen is indicated as a percentage; on the right ordinate, the oxygen content of the hemoglobin is expressed as volume percent. The three inverted arrows show the Po_2 at which the hemoglobin is 50% saturated (P_{50}) for the three hemoglobins. This value is lowest for the high-affinity hemoglobin. As the Po_2 drops from 100 (arterial) to 40 (tissues) mm Hg, hemoglobin desaturates, giving up a portion of its bound oxygen; the numbers on the brackets indicate the amount of oxygen unloaded by the three hemoglobin types expressed as volume percent. Note that the high-affinity hemoglobin delivers less than one-half the oxygen that HbA gives to the tissues, resulting in tissue anoxia, increased erythropoietin secretion, and erythrocytosis. Conversely, the low-affinity hemoglobin is even more efficient than HbA in supplying tissues with oxygen, resulting in diminished erythropoietin production and anemia. *(From Wynngaarden JB, Smith LH Jr, Bennett JC, editors:* Cecil textbook of medicine, *Philadelphia, 1992, WB Saunders.)*

Management

Most patients with high-affinity hemoglobins have mild erythrocytosis; they do not require intervention. Very rarely, the hematocrit level is very high (>55% to 60%). The blood viscosity is then sufficiently elevated to require therapeutic phlebotomy. Carbon monoxide poisoning is treated with supplemental oxygen. When a patient breathes room air, the half-life of carboxyhemoglobin is 4 to 6 hours, but the half-life is 40 to 80 minutes with the use of normobaric oxygen and 15 to 30 minutes with the use of hyperbaric oxygen. Carbon monoxide detectors, designed to detect occult carbon monoxide poisoning, are now required in many municipalities and are predicted to prevent numerous fatalities from occult carbon monoxide poisoning.

HEMOGLOBINS WITH DECREASED OXYGEN AFFINITY

Pathogenesis

Low-affinity hemoglobin variants, such as Hb Kansas ($\beta^{102Asn\rightarrow Thr}$), arise from mutations that impair hemoglobin-oxygen binding or reduce cooperativity. In cases of Hb Kansas, the threonine position, β^{102}, cannot form a hydrogen bond with aspartic acid at position α^{94}. Because this aspartate residue stabilizes the R (oxy) state, Hb Kansas binds oxygen less well and exhibits a right-shifted P_{50} value (see Fig. 41-4).

Most low-affinity variants possess enough oxygen affinity to become fully saturated in the normal lung. At the low capillary P_{O_2} in other tissues, these hemoglobins deliver *higher* than normal amounts of oxygen. They become more desaturated than normal hemoglobins. Two abnormalities result from this high level of oxygen delivery. First, because tissue oxygen delivery is so efficient, normal oxygen requirements can be met by lower-than-normal hematocrit levels. This situation produces a state of "pseudoanemia," in which the low hematocrit level is deceiving because both oxygen delivery and the patients are completely normal. Second, the amount of desaturated hemoglobin circulating in capillaries and veins can be greater than 5 g/dL. Cyanosis may thus be associated with these variants. This usually ominous finding is entirely misleading in these individuals, because it reflects no morbidity.

Diagnosis

Patients with unexplained anemia or cyanosis who appear to be entirely well in all other respects should be evaluated, especially if there is a positive family history. Testing for the abnormal variant follows the same reasoning as that just described for high-affinity variants. The oxygen dissociation curve will be shifted to the right, and the numeric value of the P_{50} will be higher than normal.

Management

Patients with low-affinity hemoglobins are usually asymptomatic. No treatment is required. It is important to document that a low-affinity hemoglobin is the cause of an apparent anemia or cyanosis to preempt inappropriate workups and provide reassurance to the patient. Cyanosis in some patients can pose a cosmetic problem, but correction with transfusions is rarely justified.

METHEMOGLOBINEMIAS

Methemoglobin results from oxidation of the iron moieties in hemoglobin from the ferrous (Fe^{2+}) to the ferric (Fe^{3+}) state. Normal oxygenation of hemoglobin causes a partial transfer of an electron from the iron to the bound oxygen. Iron in this state thus resembles ferric iron and the oxygen resembles superoxide (O_2^-). Deoxygenation returns the electron to the iron, with release of oxygen. Methemoglobin forms if the electron is not returned. Methemoglobin constitutes 3% or less of the total hemoglobin in normal humans. Under normal circumstances, these levels in humans are maintained at 1% or less by the methemoglobin reductase enzyme system (the reduced form of nicotinamide adenine dinucleotide [NADH]–dehydratase, [NADH]-diaphorase, erythrocyte cytochrome b_5).

Pathogenesis and Clinical Manifestations

Methemoglobinemias of clinical interest arise by one of three distinct mechanisms: (1) globin chain mutations that result in increased formation of methemoglobin, (2) deficiencies of methemoglobin reductase, and (3) "toxic" methemoglobinemia, in which normal red blood cells are exposed to substances that oxidize hemoglobin iron to such a degree that normal reducing mechanisms are subverted or overwhelmed (see Chapter 42; Table 41-3).

DRUGS

NADH, Reduced form of nicotinamide adenine dinucleotide.

Abnormal hemoglobins producing methemoglobinemia (M hemoglobins) arise from mutations that stabilize the heme iron in the ferric state. Classically a histidine in the vicinity of the heme pocket is replaced by a tyrosine; the hydroxyl group of the tyrosine forms a complex that stabilizes the iron in the ferric state (Fig. 41-5). The oxidized heme iron is relatively resistant to reduction by the methemoglobin reductase system.

Methemoglobin has a brownish to blue color that does not revert to red on exposure to oxygen. Patients with methemoglobinemia thus appear to be cyanotic. In contrast to truly cyanotic people, however, aterial partial pressure of oxygen (Pa_{O_2}) values are usually normal. Patients with these hemoglobins are otherwise asymptomatic because methemoglobin is rarely greater than 30% to 50%, the levels at which symptoms becomes apparent.

Hereditary methemoglobinemia resulting from methemoglobin reductase deficiency (cytochrome-b_5 reductase deficiency) is very rare. Mutations in the b_5 reductase gene cause two distinct phenotypes. In cases of type I methemoglobin reductase deficiency, patients suffer solely from cyanosis; in cases of type II disease, patients manifest both cyanosis and severe mental retardation. One isoform of the b_5 reductase gene is expressed in diverse tissues for participation in a variety of cellular processes. A second isoform, produced by alternative splicing, is expressed in erythrocytes, producing a soluble protein that reduces methemoglobin. Mutations causing type I methemoglobin reductase deficiency occur throughout the gene and result in an unstable protein. Such mutations are primarily significant in erythrocytes that, without nuclei, cannot replace the degraded protein. Mutations causing type II disease occur in the critical NADH or flavin adenine dinucleotide (FAD)–binding domains, causing inactivation of the protein in all tissues and the more severe clinical phenotype.

Like patients with M hemoglobins, patients with methemoglobin reductase deficiency exhibit slate-gray "pseudocyanosis." Even homozygotes, however, rarely accumulate more than 25% methemoglobin, a level compatible with minimal symptoms. Heterozygotes can have normal methemoglobin levels but are especially sensitive to agents causing methemoglobinemia.

A third toxic form of methemoglobinemia is caused by exposure to certain chemical agents and drugs that accelerate the oxidation of methemoglobin (Table 41-4). Some compounds directly oxidize hemoglobin, whereas other compounds produce reactive oxygen intermediates that oxidize hemoglobin. Nitrite compounds are especially notorious and common. Some of these compounds also have a propensity to exacerbate G6PD deficiency and the precipitation of unstable hemoglobins.

Nitrates are a frequent environmental cause of toxic methemoglobinemia. Nitrates do not directly interact with either hemoglobin or the reductase pathway but are converted to nitrites in the gut. Well

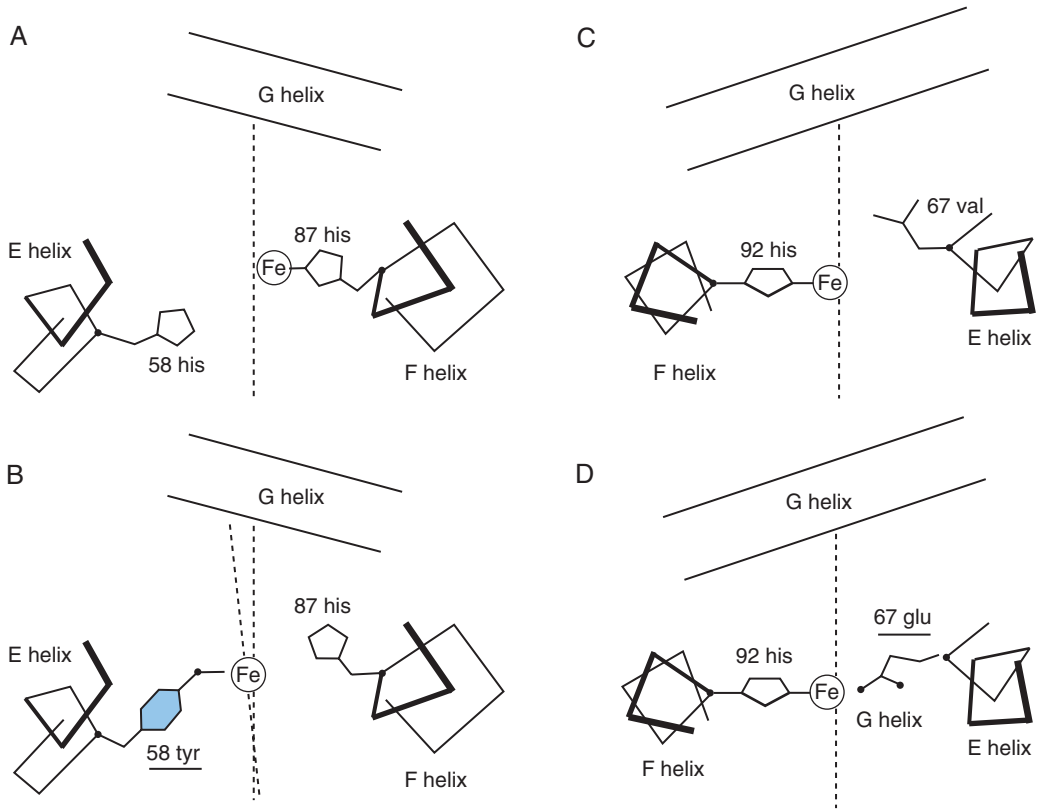

Figure 41-5 MODIFICATIONS OF THE HEME AND ITS ENVIRONMENT THAT ACCOUNT FOR TWO COMMON M HEMOGLOBINS. **A,** Hemoglobin A has a His residue at the α58(E7) position. **B,** In hemoglobin M-Boston, the histidine is replaced by a tyrosine, the phenolic side chain of which is capable of covalently binding to the heme iron, resulting in stabilization in the oxidized form. **C,** HbA has a Val residue at position β67(E11). **D,** Hb M-Milwaukee has a glutamic acid substitution for the β67 valine. The carboxylic side chain of the Glu forms a bond with iron, shifting the equilibrium toward the ferric state. *(Modified from Dickerson RE, Geis I:* Hemoglobin: Structure, function, evolution, and pathology, *Menlo Park, Calif, 1983, Benjamin-Cummings. water is a frequently encountered source of excessive nitrates. In general, substantial intake of these agents is required before significant amounts of methemoglobin are generated. Very young infants have lower levels of methemoglobin reductase in erythrocytes and are therefore more susceptible to these agents than are adults. However, all age-groups are at risk, given sufficient exposure. Systemic acidosis, particularly in young infants suffering from diarrhea and dehydration, can also cause clinically significant methemoglobinemia.

Acquired methemoglobinemia is virtually the only situation in which life-threatening amounts of methemoglobin accumulate. In general the only symptom produced when methemoglobin constitutes less than 30% of total hemoglobin is the cosmetic effect of cyanosis. As levels of methemoglobin rise to greater than 30%, however, patients begin to exhibit symptoms of oxygen deprivation, such as malaise, giddiness, and other alterations of mental status. The symptoms reflect a true lack of oxygen availability at the tissue level. Methemoglobin is a markedly left-shifted hemoglobin that delivers little oxygen to the tissues. When methemoglobin accounts for more than 50% of total hemoglobin, loss of consciousness, coma, and death can rapidly ensue. At this level the blood is chocolate brown.

Diagnosis

Methemoglobinemia should be suspected in patients with unexplained cyanosis. It is obviously a medical emergency when any patient has cyanosis and altered mental status; a normal PaO_2 should trigger a consideration of methemoglobinemia. The ingestion of nitrites as a suicidal gesture, especially in people knowledgeable with respect to chemistry, medicine, or pharmacology, should be

considered. Methemoglobinemia can be suspected from the brownish color of blood when it is drawn. Laboratory detection is simple; methemoglobin exhibits characteristic peaks of absorption at 630 and 502 nm, rendering it easily distinguishable from normal hemoglobin. Pulse oximetry, using a ratio of absorption at 660 nm and 940 nm, gives an inaccurate reading of 85% oxygen saturation for blood with 100% methemoglobin. The inherited M hemoglobin mutants are frequently detectable by altered electrophoretic mobility, especially if ferricyanide treatment in vitro is used to convert all the hemoglobin solution to methemoglobin.

In the case of toxic methemoglobinemia, recognition of exposure to an appropriate agent provides the most important historical clue. Acute poisoning can represent a life-threatening emergency; therefore laboratory evaluation for methemoglobin should be requested for any person displaying atypical cyanosis or cyanosis occurring along with more normal than anticipated blood gas values. Methemoglobin due to deficiencies of the reductase system can be further evaluated in reference laboratories by direct analysis of these enzymes.

Management

Patients with M hemoglobins are usually asymptomatic and require no management. The secondary cyanosis can present a cosmetic problem. The cyanosis is not reversible because ascorbic acid and methylene blue are usually ineffective.

Patients with deficiency of the reductase system usually do not require treatment. Cyanosis in these cases can be improved by treatment with oral methylene blue, 100 to 300 mg/day, or 500 mg/day of oral ascorbic acid. Riboflavin (20 mg/day) has also been reported to be effective and may be the preferred agent, because methylene blue produces discolored (blue) urine, and ascorbic acid can cause sodium oxalate stones.

Emergency treatment of high levels of toxic methemoglobinemia begins with 1 to 2 mg/kg of intravenous methylene blue as a 1% solution in saline. It is usually infused rapidly (over 3 to 5 minutes); the dose can be repeated at 1 mg/kg after 30 minutes if necessary. This treatment is usually effective. Methylene blue acts through the reduced form of nicotinamide adenine dinucleotide (NADPH) reductase system, which in turn requires G6PD activity. The method is therefore ineffective in patients who also have G6PD deficiency. These patients, or patients who are severely affected, may require exchange transfusion. Oral ascorbic acid is not useful for emergency situations because it acts too slowly. Follow-up maintenance management, however, can be accomplished with either ascorbic acid or oral methylene blue.

Mild cases of methemoglobin intoxication do not require treatment. The patient can be monitored for 1 to 3 days, during which time methemoglobin levels gradually return to normal if the offending agent is eliminated. The most important follow-up therapy for patients with toxic methemoglobinemia involves a thorough search for the offending agent and its removal from the environment.

CHAPTER 42

RED BLOOD CELL ENZYMOPATHIES

Elizabeth A. Price, Stavroula Otis, and Stanley L. Schrier

When evaluating the patient with hemolytic anemia, it is good practice to determine whether the hemolysis is due to an intracorpuscular or extracorpuscular defect. With the exception of paroxysmal nocturnal hemoglobinuria, intracorpuscular causes of hemolysis are all hereditary and involve the three major compartments of the red blood cell (RBC): hemoglobin, the plasma membrane, and the RBC's metabolic machinery. Abnormalities of hemoglobin and the plasma membrane are covered elsewhere. This section is devoted to an analysis of the abnormalities of the RBC's enzymatic-metabolic machinery. The study of human RBCs has afforded numerous insights into cellular enzymatic pathways. Defects in the enzymes of these pathways can be categorized according to which essential functions of RBC metabolism are crippled by their deficiency. The following functions, when impaired, are deleterious to RBC survival:

1. **Maintenance of RBC reducing power:** The RBC's reducing power is of paramount importance to its survival. Red cells are loaded with the oxygen they carry to the tissues and are constantly bombarded with reactive oxygen species. The erythrocyte has a remarkable ability to absorb extreme oxidative stress by virtue of the enzymes involved in glutathione metabolism and generation of the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). These enzymes provide the red cell with tremendous reducing power by serving as a large reservoir of electrons that can be donated to hemoglobin, lipoproteins, and other intracellular proteins damaged by oxidative stress.
2. **Generation of adenosine triphosphate (ATP):** The RBC uses energy in the form of ATP to energize the pumps and membrane transport mechanisms that allow the red cell to maintain its stable internal environment. The mature red cell is incapable of oxidative phosphorylation because it has lost its mitochondria and mitochondrial enzymes. As such, the red cell must rely on the less efficient, classic Embden-Meyerhof pathway of glycolysis for ATP generation. The glycolytic enzymes catalyzing this evolutionarily conserved pathway are critical for the production of the ATP requisite for the pumps and transport mechanisms, as well as the production of the reduced form of nicotinamide adenine dinucleotide (NADH) needed for cytochrome-b_5 reductase (Cb5R), the major methemoglobin reductase.
3. **Maintenance of hemoglobin in a functional state:** The enzymes that catalyze the formation of NADH and NADPH play a critical role in maintaining hemoglobin in its reduced state by supplying Cb5R (the major methemoglobin reductase) and the alternative methemoglobin reductase with its cofactors. The enzymes that catalyze the formation of 2,3-bisphosphoglycerate (2,3-BPG) via the Rapoport-Luebering shunt also play an important role in hemoglobin function because 2,3-BGP binds to the end of the β-globin chain and facilitates the off-loading of oxygen from hemoglobin to the tissues.
4. **Degradation of ribosomal proteins:** The RBC is unique in that it transitions from a typical nucleated cell capable of protein synthesis and oxidative and anaerobic metabolism to a cell devoid of organelles, incapable of protein synthesis, and dependent on glycolysis for energy production. The RBC must modify its membrane and volume accordingly and expel ribosomal proteins, which could otherwise prove deleterious. Pyrimidine 5′-nucleotidase is effective in degrading the ribosomal contents into smaller components that can pass through the RBC membrane.

For the most part, these enzyme deficiencies are exceedingly rare, with a few notable exceptions. The more prevalent enzyme deficiencies presumably offer an evolutionary advantage, whereas the rare deficiencies likely represent spontaneous mutations that offer no selective advantage.

ENZYMOPATHIES OF GLUTATHIONE METABOLISM

Glutathione Metabolism

Glutathione is a key player in numerous cellular functions, including free radical scavenging, redox reactions, and biosynthesis of deoxyribonucleic acid (DNA), proteins, and leukotrienes. GSH also plays a role in neurotransmission and neuromodulation. In the RBC, glutathione is present in extremely high concentrations, higher than any other cell in the body, and plays a critical role in protecting the RBC from oxidant injury. The ratio of reduced glutathione (GSH) to oxidized glutathione (GSSG) is maintained at high levels in the red cell by two mechanisms: (1) GSSG is converted to GSH by glutathione reductase, and (2) GSSG is actively transported out of the erythrocyte.

GSH is a tripeptide composed of glutamate, cysteine, and glycine. γ-glutamylcysteine synthetase catalyzes the first and rate-limiting step in the synthesis of GSH (Fig. 42-1). The product of this reaction, γ-glutamylcysteine, is then converted to GSH in the presence of glycine via glutathione synthetase, the enzyme that catalyzes the second and final step in GSH synthesis (see Fig. 42-1). Oxidation of GSH by glutathione peroxidase or other free radicals leads to the formation of glutathione disulfide (GSSG) and other mixed disulfides of proteins that contain free –SH groups (like hemoglobin). GSSG is rapidly restored to reduced glutathione via glutathione reductase and its cofactor NADPH. NADPH is maintained at high levels by glucose-6-phosphate dehydrogenase (G6PD). Defects in each of these enzymes have been described and are extremely rare, with the notable exception of G6PD deficiency.

G6PD Deficiency

History

G6PD deficiency was first recognized in the early 1950s during the Korean War when approximately 10% of African American soldiers given the antimalarial drug primaquine developed a self-limited hemolytic anemia. This phenomenon led to further investigations on healthy volunteers who were given 30 mg of primaquine daily. Most subjects tolerated the drug well, but a minority developed a self-limited hemolytic anemia. Pursuant studies showed that ^{51}Cr-labeled RBCs from primaquine-sensitive subjects transfused into nonsensitive subjects were rapidly destroyed, whereas RBCs from nonsensitive subjects transfused into primaquine-sensitive subjects

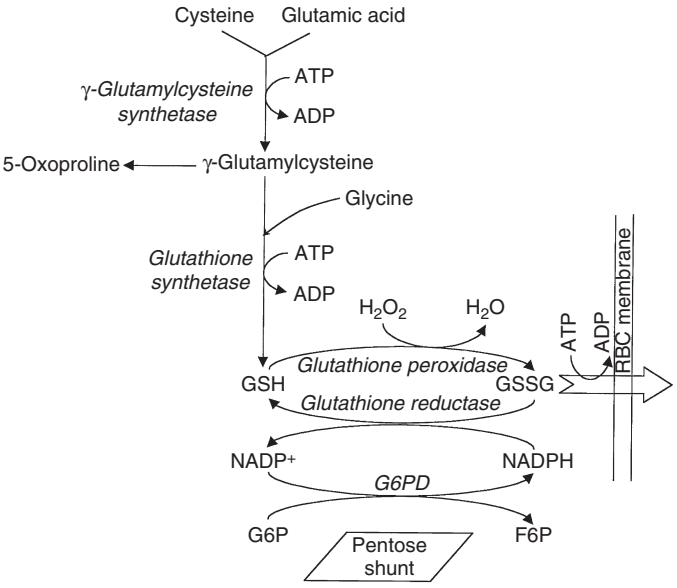

Figure 42-1 GLUTATHIONE PATHWAY. *ADP,* Adenosine diphosphate; *ATP,* adenosine triphosphate; *F6P,* fructose 6-phosphate; *G6P,* glucose 6-phosphate; *G6PD,* glucose-6-phosphate dehydrogenase; *GSH,* reduced glutathione; *GSSG,* oxidized glutathione; *NADP+,* oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH,* reduced form of nicotinamide adenine dinucleotide phosphate; *RBC,* red blood cell.

survived normally even when the host's RBCs were rapidly destroyed.[1,2] These findings established clearly that primaquine sensitivity was due to an intrinsic defect of the erythrocyte. Subsequent studies showed that younger, more metabolically active RBCs were resistant to destruction, whereas older RBCs were being destroyed, suggestive of an underlying metabolic defect.[3] By 1956, researchers had systematically deduced that the primary defect was in the G6PD enzyme.[4-8] In 1961 the G6PD gene was discovered to be X-linked, due to its linkage to red-green color blindness.

Epidemiology

G6PD deficiency is the most prevalent human enzyme deficiency in the world, affecting an estimated 350 to 400 million people. The geographic distribution of G6PD deficiency coincides with the geographic distribution of endemic malaria, implicating a survival benefit. The highest prevalence of G6PD deficiency is in sub-Saharan Africa, followed by the Middle East, Mediterranean Europe, and Southeast Asia.[9,10]

The most common allelic variants of G6PD are G6PD A- and G6PD Mediterranean. In fact, these two variants coexist at polymorphic frequencies in several populations, most notably in countries surrounding the Persian Gulf.[11] G6PD A- accounts for approximately 90% of G6PD in Africa but is also prevalent in North and South America, the West Indies, Italy, the Canary Islands, Spain, Portugal, and the Middle East.[12-16] G6PD Mediterranean is prevalent in all countries surrounding the Mediterranean Sea, as well as the Middle East, India, and Indonesia.[14,17]

In addition to geographic overlap, numerous studies support the premise that polymorphic variants of G6PD confer a survival benefit in malaria-endemic regions. Ruwende et al[18] showed that the G6PD A- allele is associated with a substantial reduction in the risk for severe *Plasmodium falciparum* malaria for female heterozygotes (46% risk reduction) and male hemizygotes (58% risk reduction). In addition, several in vitro studies comparing the growth of malarial parasites in G6PD-B (wild type) erythrocytes to growth in G6PDA- and G6PD Mediterranean erythrocytes have shown protracted growth in the G6PD-deficient cells.[19-24] Growth is also blunted in G6PD-deficient RBCs taken from female heterozygotes, whose cells have undergone random X-chromosome inactivation, when compared to parasite growth in RBCs with normal G6PD activity from the same individuals.[25]

Oxidant injury to the parasite itself appears to be one mechanism by which G6PD deficiency confers its protective effects. Due to the host cell's impaired ability to restore intracellular NADPH and GSH, malarial parasites in G6PD-deficient RBCs may be more vulnerable to the reactive intermediates they generate (particularly oxidized iron) when they break down hemoglobin.[26,27] Other studies have shown that malaria-infected, G6PD-deficient RBCs undergo phagocytosis by macrophages at an earlier stage of parasite maturation than do normal malaria-infected RBCs, which could be another means by which G6PD-deficient cells offer a selective advantage.[20]

The prevalence of G6PD deficiency in the United States ranges from 0.5% to 7% and is most common among African American males, affecting approximately 10%.[10,28] Screening for G6PD deficiency is generally reserved for individuals at increased risk, such as human immunodeficiency virus (HIV)–infected individuals from susceptible racial and ethnic groups. The overall prevalence rate of G6PD deficiency among HIV-infected patients is estimated to be approximately 6.8%.[29] Because HIV patients are more likely to be exposed to oxidant drugs like dapsone, primaquine, and sulfonamides, primary care guidelines for management of HIV recommend screening patients from higher prevalence ethnic or racial groups (e.g., African and Mediterranean descent) for G6PD deficiency either at baseline or before initiating therapy with an oxidant drug.[30]

Pathobiology

G6PD is a cellular housekeeping enzyme that catalyzes the first step in the hexose monophosphate shunt, wherein glucose 6-phosphate (G6P) is converted to ribose 5-phosphate (Fig. 42-2), a precursor of many important molecules like ribonucleic acid (RNA), DNA, ATP, coenzyme A, nicotinamide adenine dinucleotide (NAD), flavin adenine dinucleotide (FAD). Another major role of the hexose monophosphate shunt is to maintain high levels of NADPH, which acts as a cofactor for GSH. Most cells have alternate enzymatic pathways that can generate NADPH, but RBCs lack a nucleus, mitochondria, and other organelles necessary to produce these enzymes and are therefore particularly dependent on G6PD and the hexose monophosphate shunt for maintaining high levels of NADPH and GSH to protect against oxidative stress.

G6PD is encoded by a gene located on the telomeric region of the long arm of the X chromosome (Xq28) that spans 18 kb, and consists of 13 exons and 12 introns. The G6PD gene product comprises 515 amino acids with a molecular weight of 59 kDa.[31] The enzyme is active as a tetramer or dimer. Stability of the active quaternary structure is crucial for normal G6PD activity.

Within the RBC, oxidant injury leads to the oxidation of sulfhydryl groups on the hemoglobin molecule, resulting in the formation of disulfide bridges, which in turn leads to decreased hemoglobin solubility and ultimately the irreversible precipitation of oxidized hemoglobin.[32,33] Under normal conditions oxidized hemoglobin is reduced by GSH, which itself is oxidized in the process but restored to its reduced form by intracellular NADPH, whose levels are maintained by G6PD. In the G6PD-deficient RBC, GSH is not restored to adequate levels under oxidative stress, leading to a buildup of free radicals and insoluble hemoglobin within the cell, which can be visualized under the microscope as Heinz bodies. Precipitated hemoglobin is disruptive to the structure and function of the RBC membrane and leads to increased membrane permeability, osmotic fragility, and cell rigidity. The compromised integrity of the cell membrane results in both intravascular hemolysis and rapid removal of these cells within the splenic pulp.[34]

Over 400 variants of the G6PD enzyme have been identified by biochemical methods, 100 of which reach polymorphic levels. Most variants are due to point mutations and, to a lesser extent, small in-frame deletions that result in missense mutations. Gross deletions, nonsense mutations, frame-shift mutations, and splicing defects are

not reported for this gene, because mutants showing 100% deficiency of the G6PD enzyme would presumably be incompatible with life.[35-37]

The World Health Organization classifies the G6PD variants based on their enzymatic activity and the degree of associated hemolysis (Table 42-1).[38,39]

Wild-type G6PD is referred to as G6PD B (Western). It is the most common worldwide normal isoenzyme and is the ancestral human sequence, as demonstrated by showing that G6PD B matches the sequence of G6PD in the chimpanzee, our nearest relative, and by analysis of linkage disequilibrium.[12,40] The numerous G6PD variants differ in molecular stability and enzymatic activity. The degree of hemolysis associated with each isoenzyme is dependent on the type of defect and severity of oxidant injury. Class I variants are severe, occur sporadically, and lead to chronic hemolytic anemia. Class II and III variants are found at much higher frequencies than class I variants, and are implicated in providing protection against malaria. Class IV and V variants are of no clinical significance.

In normal erythrocytes the G6PD enzyme operates at 1% to 2% of its maximum potential, leaving a large reserve of reductive potential for times of severe oxidative stress.[41] This potential is variably decreased in G6PD-deficient erythrocytes. Under normal conditions a mild to moderate deficiency in the activity of G6PD is not deleterious, and there are no clinical or laboratory signs of hemolysis in these individuals. Under conditions of oxidative stress, however, the reductive potential of G6PD-deficient erythrocytes is overwhelmed, resulting in acute hemolysis. Oxidative stress may be due to exogenous

Table 42-1 World Health Organization Classification of G6PD Variants

Class	Enzymatic Activity	Degree of Associated Hemolysis
I	Severely deficient	Chronic hemolysis
II	Severely deficient (<10% residual activity)	Acute, episodic
III	Moderately to mildly deficient (10%-60% residual activity)	Acute, episodic
IV	Mildly deficient to normal (60%-150%)	Absent
V	Increased (>150%)	Absent

G6PD, Glucose-6-phosphate dehydrogenase.

agents like drugs, fava beans, chemicals (e.g., naphthalene, antifungal sprays), and herbs (e.g., *Coptis sinensis,* calculus bovis), or the result of a systemic process like infection, liver injury, and diabetic ketoacidosis.[35]

Clinical Manifestations

Most people with G6PD deficiency have no clinical symptoms and are not anemic. In fact, the majority of affected individuals live out their lives unaware of their status. Diagnosis typically occurs when an episode of acute hemolysis is triggered by exposure to oxidant drugs, infection, or ingestion of fava beans. Unusual presentations include hemolysis precipitated by complications of diabetes, myocardial infarction, and strenuous physical exercise.[42-44]

The symptoms are characteristic of acute hemolysis and include fatigue, jaundice, pallor, dark urine, and abdominal and low back pain. In the case of drug-induced hemolysis, symptoms occur 2 to 4 days after drug ingestion and are associated with a 3 to 4 g/dL drop in hemoglobin level. The bone marrow responds appropriately by generating a reticulocytosis that peaks approximately 7 to 10 days after the onset of hemolysis.[1]

Depending on the G6PD variant, hemolysis can be self-limited despite continuation of the offending drug, or it can be protracted despite discontinuation of the offending drug. Class III G6PD variants have a moderately shortened half-life (e.g., the half-life of G6PD A- is approximately 13 days) when compared to the half-life of wild-type G6PD (approximately 62 days).[45,46] Consequently, hemolysis is restricted to older RBCs that are more deficient in G6PD. As the older RBCs are eradicated, they are replaced by reticulocytes with higher concentrations of G6PD. The concentration of G6PD in these younger cells is sufficient to overcome the oxidative stress induced by the offending agent, and the hemolytic process is thereby self-limited, even when the offending agent is continued. In contrast, individuals with a Class II variant of G6PD (such as G6PD Mediterranean) experience a more severe drug-induced hemolysis because the half-life of these variants is on the order of hours,[45] making all erythrocytes, young and old, more vulnerable to oxidant injury. In these individuals, hemolysis continues well after discontinuation of the culprit drug.[47,48]

Favism

For centuries fava beans have been associated with the clinical sequelae of acute hemolysis.[49] The beans are a staple food in the Mediterranean, Middle East, and Far East, and their ingestion results in acute hemolysis in susceptible individuals. Only a minority of G6PD-deficient individuals develop hemolytic anemia after ingestion of the bean, suggesting other genetic factors at play.[50-52] Two components of

the fava bean, divicine and isouramil, may play a role in driving hemolysis by further impairing the reductive capacity of the G6PD-deficient RBC.[53] Favism develops within 5 to 24 hours of bean ingestion and is characterized by the typical symptoms of acute intravascular hemolysis: headache, nausea, back pain, chills, fever, hemoglobinuria, and jaundice. Favism has also been reported in breastfed babies whose mothers consumed fava beans.[54]

Neonatal Jaundice

Among the clinical manifestations associated with G6PD deficiency, neonatal jaundice now carries the highest risk for potentially devastating clinical consequences, namely, kernicterus.[55] Contrary to what is commonly believed, jaundice in neonates with G6PD deficiency is not the result of hemolysis. In fact, most neonates have normal hemoglobin and reticulocyte levels, and the RBC life span is only modestly shortened, if at all.[56] Rather, the hyperbilirubinemia is secondary to the newborn liver's inability to adequately conjugate bilirubin.[57] This problem is compounded when the newborn also inherits a mutation of the uridine diphosphate-glucuronosyltransferase 1 (UGT1A1) gene promoter that is associated with Gilbert syndrome, increasing the risk for neonatal jaundice.[58] Over 30% of kernicterus cases are associated with G6PD deficiency,[59] raising the question of whether G6PD deficiency should be included in routine newborn screening programs.

Congenital Nonspherocytic Hemolytic Anemia

As mentioned earlier, class I G6PD variants have very low enzymatic activity and/or marked instability, resulting in lifelong hemolysis due to the everyday oxidative stresses encountered by the circulating erythrocyte. These variants are sporadic, and almost all arise from independent mutations clustering in exons 10 and 11, which are close to the substrate binding domain in the folded protein.[60] The disorder is first suspected when affected infants develop severe neonatal jaundice, or it is discovered later when the typically mild anemia is exacerbated by oxidant drug exposure, infection, or parvovirus-induced aplastic crisis.

Laboratory Manifestations

Under normal conditions, most G6PD-deficient individuals (class II and III variants) are not anemic and have no laboratory evidence of hemolysis. In the setting of oxidative stress, the laboratory findings are those of any acute hemolytic process and include anemia, reticulocytosis, hyperbilirubinemia, increased lactate dehydrogenase (LDH), decreased haptoglobin, and hemoglobinuria. The peripheral blood smear is notable for Heinz bodies (precipitated sulfhemoglobin), and on occasion for "bite cells" (also known as *hemiblister cells, eccentrocytes,* and *cross-bonded cells*), which occur when denatured hemoglobin binds to the cell membrane, creating a puddling of hemoglobin to one side of the cell with an adjacent membrane-bound clear zone.[61,62]

Diagnosis

The enzymatic activity of G6PD can be quantitated by measuring the rate of NADPH production in red cell hemolysates that contain G6P and NADP+ (the enzyme's substrates); this is done using a spectrophotometer, which can measure the rate of NADPH formation at wavelength 340 nm. This method is used to make a biochemical definitive diagnosis. For more rapid screening of at-risk populations, there are several semiquantitative methods available. The most simple, sensitive, and inexpensive screening test is the fluorescent spot test.[63] In this procedure, NADPH production is detected by virtue of its fluorescence under ultraviolet light. As with the quantitative test, G6P and NADP+ are added to a hemolysate of the patient's red cells, and fluorescence under ultraviolet light indicates enzyme activity, whereas absence of fluorescence indicates enzyme deficiency. Other semiquantitative tests have been used but require definitive testing to confirm an abnormal result.[64,65] False negatives are a concern when diagnostic tests are performed during or right after an acute hemolytic episode in the midst of a reticulocytosis. Younger RBCs have higher levels of G6PD than older RBCs, so when the patient's red cell population is weighted toward younger cells, the deficiency may go undetected. Females heterozygous for G6PD are particularly difficult to diagnose due to the natural mosaicism for X-chromosome enzymes. Heterozygotes with extremely skewed X-inactivation can have enzymatic activity ranging anywhere from hemizygote to normal. Molecular diagnostic methods are more reliable for making the diagnosis of females suspected of being heterozygous for G6PD deficiency.

Therapy

Treatment of the clinical sequelae of G6PD deficiency is straightforward. In the case of acute hemolysis, removal of the inciting agent (e.g., drug, fava beans) is recommended. This maneuver is of particular importance in patients with Class I and II variants, in whom even the young RBCs lack adequate G6PD activity to resist ongoing exposure to oxidative agents. Class III variants, on the other hand, usually undergo a self-limited hemolysis that resolves despite ongoing exposure to the inciting agent. In cases of severe, symptomatic anemia, blood transfusion may be necessary, especially in patients with a blunted erythropoietic response (e.g., HIV, infection, drug-related myelosuppression). Very rarely, congenital nonspherocytic hemolytic anemia is severe enough to mandate ongoing transfusions, which may lead to iron overload in the absence of appropriate iron chelation. Folic acid supplementation is also recommended for patients with congenital nonspherocytic hemolysis. Antioxidants like vitamin E and selenium may also be beneficial in these patients, but there are no consistent data to support their use.[66]

In the event of neonatal jaundice, the treatment is the same as that recommended for neonatal jaundice arising from other causes. Mild cases do not require treatment, intermediate cases require phototherapy, and severe cases require exchange transfusion (total bilirubin >20 mg/dL). The true key to management of G6PD is prevention of its clinical sequelae, which requires awareness of the disorder on the part of both the physician and the patient. The disease should always be suspected in patients with a nonimmune hemolytic anemia and patients with an otherwise unexplained personal or family history of recurrent jaundice, splenomegaly, or cholelithiasis. G6PD deficiency should be considered in any neonate with hyperbilirubinemia, especially those of high-risk ethnic descent. There has been considerable debate in recent years as to whether testing for G6PD deficiency should be a routine part of neonatal screening tests. Interestingly, in a study done in Cleveland, Ohio, investigators found that the routine cord blood screening protocol for isoimmune hemolytic disease had a lower yield and higher cost than their pilot protocol for cord blood G6PD deficiency screening,[67] both of which are considered major risk factors for neonatal jaundice. One caveat to routine screening of all newborns is that heterozygous females and hemizygous males with residual enzyme activity greater than 20% are likely to be erroneously classified as "normal" due to the limitations of the fluorescent spot test,[68,69] instilling a false sense of security and subverting the prevention of complications.

Once the diagnosis of G6PD deficiency is established, patients must be counseled to avoid drugs, chemicals, and foods known to precipitate hemolysis. Although there are some medications classically connected to hemolysis in G6PD patients, there are a number of medications for which there is considerable confusion as to whether they are safe in G6PD-deficient patients. In an attempt to better clarify which are truly high-risk drugs, investigators in Israel performed a comprehensive literature search and categorized drugs according to how much evidence there is in the literature to contraindicate their use.[70] They found only seven medications for which there is solid evidence to prohibit their use in G6PD-deficient

patients: dapsone, methylthionine chloride (methylene blue), nitrofurantoin, phenazopyridine, primaquine, rasburicase, and tolonium chloride (toluidine blue). Their review found no substantial evidence to absolutely contravene the use of other medications in normal therapeutic doses.

Prognosis

Except for rare cases of severe congenital nonimmune hemolytic anemia and severe neonatal jaundice, the prognosis of patients with G6PD deficiency is excellent with no apparent impact on life expectancy.

Future Directions

Current screening tests for G6PD deficiency do not reliably identify female heterozygotes or male hemizygotes with greater than 20% residual enzyme activity. This is problematic because these groups remain at risk for hemolytic complications. It would be useful to devise a rapid and inexpensive screening test that could detect patients with moderately reduced enzymatic activity (20% to 60%), so they too may be counseled on avoiding exogenous agents that could precipitate a hemolytic crisis. It would also be useful to devise a simple in vitro method to determine whether new drugs will cause hemolysis. Simply incubating RBCs with the drug in question is unreliable, most likely because drug metabolites are often the culprits, rather than the original drug. And finally, the value of G6PD screening of all newborns must be flushed out, because this is a major cause of neonatal kernicterus, even in first world countries.[71-73]

γ-Glutamylcysteine Synthetase Deficiency

As described earlier, γ-glutamylcysteine synthetase catalyzes the first step in glutathione synthesis. Deficiency of this enzyme is exceedingly rare. Only nine patients in seven families have been reported worldwide.[74] All nine patients developed a relatively mild hemolytic anemia, and four of the nine manifested neurologic problems, including spinocerebellar degeneration, peripheral neuropathy, and mental retardation.[75-78]

Glutathione Synthetase Deficiency

Glutathione synthetase deficiency is the most common of the inborn errors of GSH metabolism, with more than 70 patients in over 50 families reported worldwide.[74] Patients are homozygous or compound heterozygous for mutations in the glutathione synthetase gene. The clinical presentation is variable, and patients are categorized as mildly, moderately, or severely affected.[79] Mildly affected patients have an isolated hemolytic anemia, whereas moderately affected patients develop a metabolic acidosis within the first few days of life due to the buildup of 5-oxoproline, a metabolite of γ-glutamylcysteine (the substrate of glutathione synthetase). Under normal circumstances GSH negatively feeds back on γ-glutamylcysteine synthetase, but in patients with moderate to severe glutathione synthetase deficiency there is loss of negative feedback, leading to the accumulation of 5-oxoproline in body fluids, resulting in metabolic acidosis and massive 5-oxoprolinuria. Severely affected patients may also develop recurrent bacterial infections and progressive dysfunction of the central nervous system (CNS). The mechanism behind CNS involvement remains unclear. Autopsy of the first patient described with glutathione synthetase deficiency revealed selective atrophy of the granule cell layer of the cerebellum, focal lesions in the frontoparietal cortex, and bilateral focal lesions in the thalamus and visual cortex.

The diagnosis of glutathione synthetase deficiency is suspected in patients with a nonimmune hemolytic anemia, elevated levels of 5-oxoproline in the urine, and markedly reduced RBC glutathione content. The diagnosis is confirmed by demonstrating low levels of glutathione synthetase in cultured skin fibroblasts and/or RBCs or by demonstrating mutations in the glutathione synthetase gene.[74] Treatment involves correcting the metabolic acidosis with bicarbonate and protecting the cells against further oxidant injury by administering antioxidants like vitamin C and vitamin E. N-acetylcysteine was used in the past to protect against oxidant damage but is no longer recommended because studies have shown that cysteine, which is known to be neurotoxic at high concentrations, accumulates in the tissues of patients with glutathione synthetase deficiency.[80,81] Patients with glutathione synthetase deficiency should avoid the same agents known to precipitate acute hemolysis in patients with G6PD deficiency.

Glutathione Reductase Deficiency

Glutathione reductase restores intracellular GSH by reducing GSSG in the presence of NADPH and FAD, a derivative of the water-soluble vitamin riboflavin. Consequently, malnourished patients, or patients who are otherwise deficient in riboflavin, develop an acquired partial deficiency of glutathione reductase. Riboflavin deficiency can be demonstrated by testing the in vitro activity of glutathione reductase with and without exogenously added FAD. Acquired glutathione reductase deficiency has no documented hematologic phenotype and is easily corrected by administration of physiologic quantities of riboflavin.

Congenital deficiency of glutathione reductase has been reported in two Dutch families. In the first family, the eldest of three siblings from a consanguineous marriage developed a hemolytic crisis after ingesting fava beans.[82] All three siblings (one male, two female) were found to be homozygous for a large deletion in the glutathione reductase gene encoding almost the entire dimerization domain of the enzyme.[83] In the second family, an infant was born with severe neonatal jaundice and found to be a compound heterozygote for a nonsense and missense mutation in the glutathione reductase gene.[83] There was no evidence of enhanced hemolysis in this infant, which is consistent with the neonatal jaundice associated with G6PD deficiency.

Glutathione Peroxidase Deficiency

Glutathione peroxidase is a selenium-containing enzyme that catalyzes the oxidation of GSH by hydrogen peroxide, producing GSSG and water. Although rare cases of glutathione peroxidase deficiency have been described in association with hemolysis,[84-86] a causative relationship between the two has not been clearly established. There are several reported cases of normal individuals with reduced glutathione peroxidase activity and no evidence of hemolysis.[87,88]

ENZYMOPATHIES OF THE GLYCOLYTIC PATHWAY

Pyruvate Kinase Deficiency

Epidemiology

Pyruvate kinase (PK) deficiency is the most common red cell enzymopathy leading to congenital nonspherocytic hemolytic anemia. The prevalence has been estimated by gene frequency studies to be 51 cases per million in the general white population.[89] However, recognized clinical cases in the Northern United Kingdom based on a registry study initiated in 1974 had a much lower prevalence,[90] suggesting premature disease-related death, clinically mild disease, or diagnostic error.[91] Conversely, the prevalence of homozygous PK deficiency was found to be quite high (1 in 830) in a small, remote town in the Western United States,[92] likely due to consanguinity within the community. Common mutations have well-defined geographic

associations. Mutation 1529A is frequently seen in the United States[93] and central Europe,[94] 1456T is commonly found in Southern Europe,[95-97] and 1468T is the most common mutation found in Asia.[89,98] PK deficiency is an autosomal recessive disease, and affected patients are typically double heterozygotes, or, less commonly, homozygous for the same mutation. Homozygous mutations are usually seen in groups with marked consanguinity, and homozygous PK deficiency has been well described in the Amish populations of Pennsylvania and Ohio.[99,100]

Pathobiology

PK catalyzes the irreversible transfer of phosphate from phosphoenolpyruvate to adenosine diphosphate (ADP), forming ATP and pyruvate in the second ATP-generating step of the glycolytic pathway. There are four distinct PK isoforms, M_1, M_2, L, and R types, encoded by two separate genes (PKM and PKLR).[101] PKM_1 and PKM_2 are produced from the PKM gene by alternative RNA splicing.[102] The M_2 isoform is expressed in early fetal and proliferating tissues and remains the dominant form in adults in leukocytes and platelets. PKM_1 is found in skeletal muscle, heart, and brain.[103] PKL, found in the liver, and PKR, in red cells, are both encoded by the PKLR gene on chromosome 1q21 through the use of alternate promoters.[104] PKM_2 is expressed in normal erythroid precursors[105] and is gradually replaced during maturation by the PK-R isoform. The functional enzyme is a tetramer, and each isoform has characteristic kinetic properties,[103] although all isoforms except M_1 are allosterically activated by fructose 1,6-diphosphate (FDP).[106,107] More than 190 mutations in the PKLR gene encoding the red cell PK have been identified, most of which are missense mutations (www.pklrmutatinodatabase.com). Mutations may alter the stability of the enzyme or the enzyme's affinity for its substrate, phosphoenolpyruvate (PEP), or its allosteric activator, FDP.[106,108] There appears to be some correlation with the location of the mutation and the severity of the hemolytic anemia, with more severe disease being associated with disruptive mutations and with missense mutations directly involving the active site or protein stability.[92,101]

The mechanism of hemolysis in PK deficiency is not fully understood. Reticulocytes are preferentially destroyed in the spleen and the liver,[109] and following splenectomy a striking reticulocytosis may be seen.[110,111] It has been suggested that the higher metabolic requirement of reticulocytes renders them more vulnerable to PK deficiency than mature erythrocytes, leading to increased destruction.[109] The defect in ATP generation may contribute to the anemia, although it is likely not the sole cause, because other disorders with more severe ATP deficiency do not have significant hemolytic anemia.[112] The metabolic derangements found in PK deficiency may also lead to increased apoptosis and ineffective erythropoiesis, as seen in the spleen of a patient with PK deficiency[113] and in a mouse model.[114] The metabolic defect is distal to the Rapoport-Leubering shunt, and thus the concentration of 2,3-BPG is increased. Although accumulation of 2,3-BPG may lead to further impairment in glycolysis through inhibition of hexokinase,[101] the resultant shift in the oxyhemoglobin dissociation curve to the right[115] leads to improved tolerance of the anemia.[116]

Clinical and Laboratory Manifestations

Clinical severity in patients with PK deficiency is widely variable, ranging from fully compensated hemolysis to a transfusion-dependent anemia. Newborns may present with severe hemolytic anemia and pronounced jaundice, requiring exchange transfusion.[117] In the worst cases, hydrops fetalis[118] with intrauterine or neonatal death may rarely occur.[119] Severe liver dysfunction has also been reported as an unusual cause of death in infants with PK deficiency.[120] Early onset of symptoms is typically associated with a more severe clinical course.[121] Heterozygotes for PK deficiency who are heterozygotes or homozygotes for the Gilbert syndrome polymorphism may have neonatal jaundice that persists in childhood.[92] The anemia is relatively stable in adults,[121] although transient worsening may occur with infection,[122] pregnancy, or the use of certain medications, including oral contraceptives.[123] Gallstones may be present. Extramedullary hematopoiesis can occur even in patients who are transfusion independent[124] and may lead to characteristic bone deformities.[125] Extradural extramedullary hematopoiesis leading to spinal cord compression and neurologic deficits has been reported,[126] with good response to surgical excision and radiation therapy.[126] Leg ulcers are seen rarely.[127] Recurrent venous thromboembolic disease was reported in one adult patient who underwent splenectomy as a young child,[110] and idiopathic pulmonary arterial hypertension was reported in another patient who had undergone splenectomy at age 5.[128]

Iron overload has been reported in nontransfused[129,130] and transfusion-dependent patients and may be severe, leading to cirrhosis and cardiac and endocrine dysfunction.[131] Splenectomy and the presence of hemochromatosis-related genes may increase the risk for iron overload.[132] Serum levels of the iron regulatory protein hepcidin were lower in PK-deficient patients compared to controls, and growth differentiation factor 15 (GDF15) levels were higher, suggesting suppression of hepcidin as a contributing mechanism of iron overload in some PK-deficient patients.[133]

Although PK deficiency does not localize to geographic areas of malarial endemicity, PK deficiency may be protective against malaria.[134] In a mouse model of infection with *Plasmodium chabaudi,* mice carrying a loss-of-function mutation in the PKLR gene had reduced blood-stage parasite replication and improved survival compared to control mice.[135] In vitro, erythrocytes from homozygous PK-deficient patients have decreased invasion by *P. falciparum* compared to normal or heterozygous PK-deficient control erythrocytes.[136] In addition, phagocytosis of ring-stage infected erythrocytes from patients with homozygous and heterozygous mutations was increased compared to control subjects.

Laboratory findings are those typical for hemolytic anemia, including low hemoglobin, increased reticulocyte count, high LDH, low haptoglobin, and elevated indirect bilirubin. Reticulocytosis may be suppressed in the context of the normal hypoplastic phase of erythropoiesis following birth, making the diagnosis more challenging.[137] The bilirubin is usually less than 6 mg/dL: if higher, the patient may have coexisting Gilbert syndrome.[101,138] Red cells are commonly without characteristic morphologic abnormalities; however, following splenectomy they may become markedly abnormal, with numerous crenated cells, lobulated cells, and target cells.[125] Establishing the diagnosis requires the demonstration of low enzyme activity.[112] Care must be taken in interpreting in vitro test results, because contamination with transfused red cells or leukocytes can increase measured enzyme activity.[101] Specialized laboratories can assess for kinetically abnormal mutant PKs.[112] Molecular diagnostic methods can be used if the likely mutation is known, as in the case of prenatal diagnosis.

Therapy

Treatment for PK deficiency remains supportive. Exchange transfusion and/or intense phototherapy may be required in the neonatal period to prevent kernicterus and its resultant sequelae, including permanent hearing loss.[92] Patients with more severe disease may require periodic or even regular red cell transfusions. Increased transfusion may be needed during pregnancy both for maternal supportive care and to prevent miscarriage.[100] Splenectomy typically leads to an increase in hemoglobin by 1 to 3 g/dL[121] and can lead to transfusion independence. In one reported case, partial splenectomy failed to ameliorate transfusion needs secondary to rapid regeneration of the spleen.[139] General recommendations include, where possible, delaying splenectomy until the patient is 3 years of age or older to reduce the risk for postsplenectomy sepsis.[112] If iron overload occurs, both pharmacologic iron chelation therapy[140] and, if the anemia is not too severe, phlebotomy,[141] can successfully reduce excess iron. Hematopoietic stem cell transplant was reportedly successful in one 5-year-old boy with PK deficiency and hemoglobin E trait.[142]

Glucose Phosphate Isomerase Deficiency

Glucose phosphate isomerase (GPI) catalyzes the interconversion of G6P and fructose 6-phosphate in the second step of glycolysis. GPI deficiency is an autosomal recessive disorder and is one of the four most common erythrocyte enzymopathies, including deficiencies of G6PD, PK, and pyrimidine 5′-nucleotidase.[143] The hemolytic anemia is of variable severity and may require chronic transfusions.[144] Hydrops fetalis has been reported.[143] Splenectomy can improve the anemia, eliminating transfusion requirements.[143,145] GPI deficiency can also be associated with neurologic impairment, including myopathy and mental retardation.[146]

Hexokinase Deficiency

Hexokinase catalyzes the initial step of glycolysis, the phosphorylation of glucose to G6P (see Fig. 42-2) and is one of the rate-limiting steps of this pathway.[107] Hexokinase deficiency is a rare cause of congenital nonspherocytic anemia. Hemolytic anemia may occur as a sole manifestation or as part of a constellation of abnormalities that can include other cytopenias, diabetes mellitus, skeletal malformations, hypogonadism, and abnormal pigmentation.[147] Severe iron overload can occur.[148] Most patients are of European descent, although an affected Chinese kindred has also been described.[147] A mouse model of generalized hexokinase deficiency has been described, with manifestations of severe hemolytic anemia, marked reticulocytosis, and extensive tissue iron deposition.[149] Splenectomy may provide benefit.[150] In contrast to PK deficiency, the defect occurs proximal to the Rapoport-Leubering shunt, and thus the concentration of 2,3-BPG is reduced, shifting the oxyhemoglobin dissociation curve to the left[115] and decreasing patient tolerance to the anemia.[116]

Phosphofructokinase Deficiency

Phosphofructokinase (PFK) catalyzes the phosphorylation of fructose 6-phosphate to fructose-1,6-bisphosphate (see Fig. 42-2).[151,152] Two of the three identified isoenzymes (muscle type [PFKM] and liver type [PFKL]) are expressed in erythrocytes. Mutations in the muscle-type PFKM isoenzyme cause type VII glycogen storage disease (Tarui disease), a rare autosomal recessive disorder. Such mutations lead to an almost complete loss of PFK activity in muscle, but only partial loss of activity in erythrocytes. Clinical manifestations of type VII glycogen storage disease may present in infancy or older adulthood and include hypotonia, exercise intolerance, and weakness.[152] The severity of the hemolytic anemia is highly variable, ranging from a mild, compensated hemolysis[153] to severe chronic nonspherocytic hemolytic anemia.[152]

ALDOLASE DEFICIENCY

Aldolase catalyzes the interconversion of fructose 1,6-diphosphate to glyceraldehyde 3-phosphate and dihydroxyacetone phosphate.[107] One of the three distinct isoenzymes, aldolase A, is present in erythrocytes, muscle, and brain. Aldolase deficiency is a very rare cause of nonspherocytic hemolytic anemia, and clinical manifestations may also include myopathy and mental retardation.[154]

Phosphoglycerokinase Deficiency

Phosphoglycerate kinase catalyzes the reversible conversion of 1,3-bisphosphoglycerate to 3-phosphoglycerate. Deficiency of this X chromosome–encoded enzyme is associated with an array of findings that can variably include hemolytic anemia, myopathy, rhabdomyolysis, mental retardation, and other neurologic symptoms.[155] Splenectomy may improve the anemia.[156]

Triose-Phosphate Isomerase Deficiency

Triose-phosphate isomerase (TPI) catalyzes the reversible interconversion of the triose phosphate isomers, dihydroxyacetone phosphate, and glyceraldehyde 3-phosphate. TPI deficiency is a rare, autosomal recessive, multisystemic disease, characterized by chronic nonspherocytic hemolytic anemia, frequent bacterial infections, and progressive neuromuscular disease.[157-159] Cardiomyopathy may also be present. Hemolytic anemia manifests before 14 months of age[157] and may be severe enough to require ongoing red cell transfusions.[160] In cases with a milder degree of anemia, intermittent transfusions may be required during acute exacerbations triggered by bacterial infection.[161] Hydrops fetalis can rarely occur.[143] The typical course involves progressive neurologic degeneration with frequent early death; however, rare adult cases with less severe involvement are reported.[162] A high prevalence of heterozygous TPI deficiency has been found in African American newborns.[163] No specific therapy for this disorder is available.

Pyrimidine 5′-Nucleotidase Deficiency

Pathobiology

Red cell pyrimidine 5′-nucleotidase type 1 (P5′NT-1) deficiency, initially described in 1974,[164] is the third most common red cell enzymopathy causing hemolytic anemia, after G6PD deficiency and PK deficiency.[91] It is transmitted as an autosomal recessive trait. Maturation of the reticulocyte results in degradation of ribosomal RNA into pyrimidine 5′ nucleoside monophosphates, which must be dephosphorylated in order to freely diffuse across the cell membrane. P5′NT-1 is a member of a family of enzymes that catalyze this dephosphorylation.[165] Two main types of 5′NT, P5′NT-1 and P5′NT-2, have been isolated from RBCs.[166] Only deficiency of P5′NT-1, encoded by a gene found on chromosome 7, is associated with hemolytic anemia. P5′NT-1 is dependent on Mg^{2+} for activity and is readily inhibited by lead[167] and other heavy metals.[168] P5′NT-1 activity levels are highest in the youngest cells.[169] Mutations in P5′NT-1 lead to the accumulation of pyrimidine nucleotides, which impede RNA breakdown. The resultant ribosomal aggregates are visible as the characteristic coarse basophilic stippling seen on the peripheral smear.[164] Characterized mutations in P5′NT-1 lead to decreased thermal stability and/or impaired catalytic ability of the enzyme,[170] although residual measured enzyme activity in some cases suggests that enzyme deficiency is at least in part compensated by other nucleotidases. Acquired P5′NT deficiency occurs in the instance of lead intoxication, manifesting as hemolytic anemia, reticulocytosis, and striking basophilic stippling.[167]

Clinical and Laboratory Manifestations

P5′NT-1 deficiency is inherited in an autosomal recessive manner, and patients are usually homozygotes, or, less commonly, compound heterozygotes.[166] The disease is characterized by mild to moderate hemolytic anemia, reticulocytosis, indirect hyperbilirubinemia, and variable hepatosplenomegaly.[171,172] The anemia is occasionally severe. Gallstones may be present, and ulcers are seen rarely.[171] Learning disabilities have been described in a few cases.[171] Iron overload occurs in both severe transfusion-dependent cases and mild cases.[173] Conversely, iron deficiency secondary to intravascular hemolysis was described in one case.[174] Homozygous P5′NT-1 deficiency inherited in combination with homozygous hemoglobin E in one described case led to a particularly severe hemolytic anemia, which responded well to splenectomy.[175]

The laboratory hallmark of the disorder is the pronounced basophilic stippling seen on the peripheral smear.[164] Thus in contrast to most cases of congenital nonspherocytic hemolytic anemia, the peripheral smear provides a rapid, inexpensive diagnostic clue to the underlying disorder. This is a sensitive but not specific finding,

because basophilic stippling can also be seen in other causes of anemia, including lead poisoning, some hemoglobin variants,[176] and sideroblastic anemia. Confirmation of the diagnosis requires demonstration of decreased P5′NT-1 activity and high concentrations of pyrimidine nucleotides in red cells.[166]

Therapy

There is no targeted therapy for this disorder. In the atypical case with severe anemia, patients may be red cell transfusion dependent.[177] In other cases, transfusions may be needed sporadically, such as during pregnancy or acute infections.[178] Splenectomy in a few cases has provided benefit,[179] but in other cases has not led to any significant improvement in the anemia.[177] Patients should be monitored for iron overload, and iron chelation may be required.

Red Cell Enzymopathies Causing Methemoglobinemia

Pathobiology

Normal hemoglobin A is composed of two α-chains and two β-chains, and each one of the globin chains carries a heme group in the center of which is a molecule of ferrous iron (Fe^{2+}). In oxyhemoglobin, each ferrous atom links reversibly to a molecule of oxygen. As is shown in the sigmoidal oxyhemoglobin association curve, the binding of oxygen is cooperative, such that the binding of the first molecule of oxygen facilitates the binding of the second molecule of oxygen. Methemoglobin occurs when the ferrous molecule is oxidized to ferric (Fe^{3+}), either in the usual course of events (Fig. 42-3) or due to inadequately controlled oxidant attack. Methemoglobin causes two sorts of problems: methemoglobin cannot bind oxygen, and, further, if a methemoglobin becomes part of the hemoglobin tetramer, the oxygen affinity is increased with a left shift in the oxyhemoglobin dissociation curve and a biologically important fall in the partial pressure of oxygen at which hemoglobin is 50% saturated with oxygen (P_{50}).[180] The combined effect of decreased oxygen-carrying capacity and decreased oxygen release may lead to a profound functional impairment,[181] particularly in the patient with underlying cardiopulmonary disease.

Methemoglobin is being formed continuously, but there are mechanisms in place that normally keep the methemoglobin level at about 1% of the total hemoglobin.[182] The most important of these is the NADH-dependent Cb5R (also known as methemoglobin reductase).[183,184] The electrons from NADH are transferred first to FAD, reducing it to $FADH_2$, which is a prosthetic group of the enzyme. $FADH_2$ then transfers these electrons to the enzyme Cb5R, which completes the transfer of electrons to Fe^{3+}, completing the reduction of methemoglobin to Fe^{2+} hemoglobin (Fig. 42-4).

There is a backup flavin-dependent methemoglobin reductase that uses the electrons catalyzed by G6PD when it reduces NADP+ to NADPH. This flavin NADPH methemoglobin reductase, lacking a physiologic electron acceptor, is of minimal physiologic importance, but becomes important when methylene blue is used in the treatment of toxic causes of methemoglobinemia, where the normal Cb5R system is inadequate. In that case the flavin NADPH-dependent methemoglobin reductase reduces methylene blue as an electron acceptor to leukomethylene blue, which then directly reduces methemoglobin (Fig. 42-5).[185]

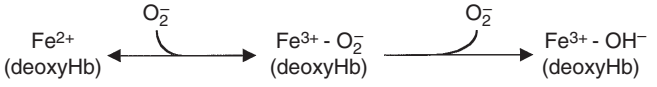

Figure 42-3 AUTO-OXIDATION OF HEMOGLOBIN. Iron is in the ferrous state (Fe^{2+}) in deoxyhemoglobin (deoxyHb). When oxygen is bound, an electron is partially transferred from the iron moiety to the bound oxygen, forming a ferric-superoxide anion complex (Fe^{3+}-O_2^-). During deoxygenation, some of the oxygen leaves as a superoxide (O_2^-) radical. The partially transferred electron is not returned to the iron moiety, leaving the iron in the ferric state (Fe^{3+}) and forming methemoglobin (metHb).

Acquired or Acute Toxic Methemoglobinemia

Most cases of methemoglobinemia are acquired, resulting from either exposure to oxidizing agents or from pathologic underlying conditions. Oxidizing agents may accelerate the rate of formation of methemoglobin up to 1000-fold[182] and eventually overwhelm the capacity of the methemoglobin reduction pathways. Numerous toxins and drugs or their metabolites have been implicated in causing methemoglobinemia (see box on Substances Associated With Methemoglobinemia), including the more common culprits, dapsone, local anesthetics (benzocaine, lidocaine, prilocaine), and derivatives of the anesthetic phenacetin. In a retrospective study of pediatric oncology patients who were treated with dapsone for the prevention of *Pneumocystis carinii* pneumonia, methemoglobinemia was documented in 32 of 167 (19.2%) patients.[186] In this study, higher dapsone dosing was associated with increased risk. In another retrospective study of 138 cases of acquired methemoglobinemia, 42% of cases were due to dapsone.[181] In this series, methemoglobinemia was mild (<8% of total hemoglobin) in the majority of cases. Five of the most severe cases were caused by topical 20% benzocaine spray. In 2006 the U.S. Food and Drug Administration (FDA) issued a public health advisory regarding the risk for methemoglobinemia with the use of benzocaine sprays.[187] In a follow-up safety announcement in 2011, the FDA reported a total of 319 cases of methemoglobinemia due to topical benzocaine sprays, including 32 life-threatening and 7 fatal cases.[188] A single spray of benzocaine, and doses well below the maximum standard allowable dose of prilocaine, particularly in the presence of predisposing factors, have been reported to lead to methemoglobinemia.[189] The FDA has recommended that benzocaine products not

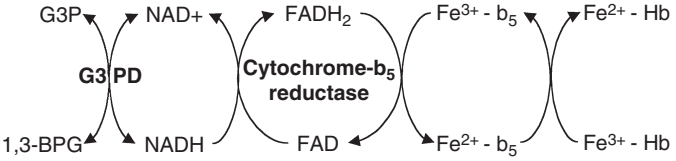

Figure 42-4 NADH-DEPENDENT METHEMOGLOBIN REDUCTION. The reduced form of nicotinamide adenine dinucleotide (NADH) is generated during glycolysis in the reaction mediated by glucose-3-phosphate dehydrogenase (G3PD). A pair of electrons from NADH is transferred to the flavin adenine dinucleotide (FAD) prosthetic group of cytochrome-b_5 reductase, reducing it to $FADH_2$. Two molecules of ferric (Fe^{3+}) cytochrome b_5 are then sequentially bound and reduced, forming ferrous (Fe^{2+}) cytochrome b_5. An ionic complex between ferrous (Fe^{2+}) cytochrome b_5 and a ferric (Fe^{3+}) subunit of a hemoglobin (methemoglobin) tetramer is formed and an electron transferred between the two hemes, creating ferrous (Fe^{2+}) hemoglobin. *1,3-BPG,* 1,3- Bisphosphoglycerate; *G3P,* glyceraldehyde 3-phosphate; *Hb,* hemoglobin; *NAD+,* nicotinamide adenine dinucleotide.

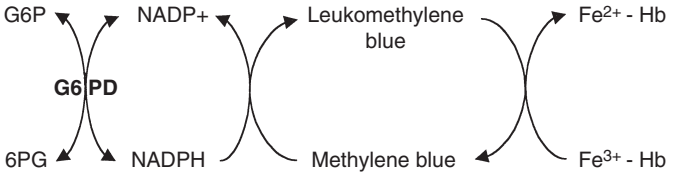

Figure 42-5 NADPH-DEPENDENT METHEMOGLOBIN REDUCTION. NADPH methemoglobin reduction can be activated by exogenously administered methylene blue. *G6P,* Glucose 6-phosphate; *G6PD,* glucose-6-phosphate dehydrogenase; *6PG,* 6-phosphogluconate; *NADP+,* oxidized form of nicotinamide adenine dinucleotide phosphate; *NADPH,* reduced form of nicotinamide adenine dinucleotide phosphate.

Substances Associated With Methemoglobinemia

- Acetaminophen (nitrobenzene derivative)
- Acetanilide
- Local anesthetics
 - Benzocaine
 - Lidocaine
 - Prilocaine
- Aniline dyes
- Celecoxib
- Dapsone
- Flutamide
- Ifosfamide
- Metoclopramide
- Nitric oxide
- Nitrites
 - Amyl nitrite
 - Isobutyl nitrite
 - Sodium nitrite
 - Nitrates (bacterial conversion to nitrites)
- Nitrobenzenes/nitrobenzoates
- Nitroethane (nail polish remover)
- Nitrofurans
- Nitroglycerin
- Paraquat/monolinuron
- Phenacetin
- Phenazopyridine (Pyridium)
- Primaquine
- Rasburicase
- Sulfamethoxazole

be used on children less than 2 years of age, such as in use of over-the counter teething medicine,[190] except under the advice and supervision of a health care professional.[188] The offending agent may be hidden, as is seen when local anesthetics are used in the preparation of cocaine.[191,192] Inhalation and/or ingestion of volatile nitrites is another recreational drug practice that can cause methemoglobinemia.[192]

Exposure to nitrates and nitrites, widely used as food preservatives and found in well water,[193] can also cause methemoglobinemia.[194] Infants less than 6 months of age may have increased susceptibility to methemoglobinemia due to low gastric pH, which allows proliferation of intestinal flora that reduces ingested nitrates to nitrites. Neonates are at particularly increased risk due to decreased Cb5R activity (50% to 60% of adult activity).[195] Homemade baby food purees of high-nitrate-containing foods such as carrots, spinach and silver beets may cause methemoglobinemia, as can acquired illnesses, including diarrheal disease in infants and sepsis.

Clinical Manifestations

Clinical manifestations develop secondary to impaired tissue oxygenation. Typical "cyanotic" slate-blue coloring of the skin and mucous membranes will be visible when 5% to 15% of the total hemoglobin is methemoglobin.[189,196] Although methemoglobin levels up to 20% or even higher may be well tolerated in some individuals, others may experience tachypnea, shakiness, altered consciousness, and signs of myocardial ischemia at methemoglobin levels of 10% to 20%.[189,190] As methemoglobin levels rise above 20% to 30%, patients can experience progressive respiratory compromise, myocardial ischemia, seizures, and coma.[189] Death typically ensues at methemoglobin levels above 70%[197] but can occur at lower levels.[189] Signs and symptoms may be potentiated by factors such as concomitant use of other oxidizing agents, age less than 6 months, anemia, or significant underlying comorbid disease. The onset of disease may be abrupt, and the clinician must maintain a high index of suspicion in at-risk situations (i.e., procedures in which topical anesthetics are used).

Laboratory Manifestations and Diagnosis

Methemoglobinemia should be suspected when the patient appears cyanotic but has a normal PaO_2 as measured by arterial blood gas assessment. The blood will typically be a dark purple to chocolate color, and the blood will not become more red on exposure to oxygen. The diagnosis of methemoglobinemia relies on analysis of its absorbance spectrum. Pulse oximetry is unreliable in the presence of methemoglobinemia, due to its light absorbance properties[198]; however, cooximetry can determine the methemoglobin fraction.[199] The presence and percentage of methemoglobin can be confirmed by use of the Evelyn-Molloy method.[200]

Therapy

Treatment is guided by the level of methemoglobinemia and patient symptoms. In the case of acute onset due to oxidizing agents or disease states, any potential offending agents should be immediately discontinued. The asymptomatic patient with methemoglobin levels of less than 20% may only need observation. If the patient is symptomatic or if methemoglobin levels are greater than 20%, intervention with methylene blue is indicated. Methylene blue is given in a dose of 1 to 2 mg/kg intravenously over 5 minutes, and the dose may be repeated after 60 minutes if necessary. Cumulative doses greater than 4 to 7 mg/kg (or even lower in infants) may cause cyanosis, dyspnea, and acute hemolysis.[201,202] Methemoglobinemia generally resolves promptly with treatment, and within 20 hours in those who receive no treatment.[189] Rebound methemoglobinemia[189] has been reported to occur after methylene blue administration, in one case several days following intentional massive nitrobenzene ingestion.[203] Therefore treated patients should be carefully monitored for recurrence of methemoglobinemia. The therapeutic effect of methylene blue is dependent on the NADPH generated by G6PD. As such, methylene blue will probably not be effective in treating toxic methemoglobinemia in patients who are also G6PD deficient and may even cause hemolysis due to its oxidant effects.[204] Patients with G6PD deficiency who require therapy can be treated with exchange transfusion.[205] Hyperbaric oxygen has also been used successfully in severe cases of methemoglobinemia.[206]

Hereditary Methemoglobinemia

Hereditary causes of methemoglobinemia are secondary to deficiency of Cb5R, very rarely described deficiency of cytochrome b_5,[207] or inheritance of an abnormal hemoglobin in hemoglobin M disease (see Chapter 41).

Cytochrome-b_5 Reductase Deficiency

Cb5R deficiency is the most common cause of congenital methemoglobinemia and is inherited in an autosomal recessive manner.[208] Cb5R is present in two forms, a soluble form present mainly in red cells[183] and a membrane-bound form found in the endoplasmic reticulum and outer mitochondrial membrane.[209,210] Type I Cb5R deficiency is characterized by a deficiency of the soluble, red cell form of Cb5R and manifests as cyanosis, fatigue, and dyspnea. This is the more common form of hereditary methemoglobinemia and is endemic in certain populations, including Navajo[211] and Athabasca[212] Native Americans and natives of Yakutsk, Siberia.[213] Compensatory polycythemia is seen only rarely. Methemoglobinemia, even up to levels of 40%, may be well tolerated.[208] The less common type II Cb5R deficiency, characterized by deficiency of the enzyme in all tissues, has a devastating clinical course, characterized, in addition to cyanosis, by progressive microcephaly, severe mental retardation, dystonia, and early death.[208,214] The types can be differentiated by the clinical phenotype, as well as by assaying enzyme activity in erythroid and nonerythroid tissues. The cyanosis can be treated with oral doses

of methylene blue (100 to 300 mg/day) or ascorbic acid (300 to 1000 mg/day in divided doses). There is currently no treatment for the neurologic manifestations of type II Cb5R deficiency.

POLYCYTHEMIA DUE TO CONGENITAL RED BLOOD CELL ENZYME DEFICIENCY

Polycythemia is defined as an absolute increase in RBC mass. Primary polycythemia refers to an inherent defect (acquired or inherited) within the RBCs that results in increased proliferation, whereas secondary polycythemia refers to a reactive process that is usually driven by elevated levels of serum erythropoietin (EPO) as a consequence of chronic tissue hypoxia or EPO-secreting tumors. The vast majority of primary and secondary polycythemias are acquired. The congenital secondary polycythemias are extremely rare and occur when germline mutations alter hemoglobin oxygen affinity or decrease the concentration of 2,3-BPG, resulting in impaired oxygen delivery to the tissues. The latter condition is a result of a congenital deficiency of the erythrocyte enzyme bisphosphoglycerate mutase (BPGM).

Epidemiology and Clinical Manifestations

Only two families with complete BPGM deficiency have been comprehensively studied because of the rarity of the condition. The first case of complete BPGM deficiency was described in 1978 in a family in France.[215] The propositus was a 42-year-old male with a hemoglobin level of 19 g/dL. He had a ruddy complexion but was otherwise clinically well. His 2,3-BPG levels were 3% of normal, and BPGM activity was undetectable.[215] Both the patient and three of his sisters were found to be compound heterozygotes for mutations in the BPGM gene.[216] A second family with complete BPGM deficiency was described in 2004 and included the first and only reported instance (to date) of a patient homozygous for a mutation in the BPGM gene. The mutation was determined to be a missense mutation near the active binding site of the enzyme.[217]

Pathobiology

2,3-BPG is an important modifier of oxygen delivery by RBCs. It binds to a central cavity of the hemoglobin tetramer and allosterically converts hemoglobin to a low oxygen affinity state, resulting in a rightward shift of the oxygen dissociation curve. Patients with chronic hypoxia have elevated levels of 2,3-BPG to facilitate oxygen unloading and increase oxygen delivery to the tissues (Fig. 42-6). BPGM is the enzyme responsible for the synthesis of 2,3-BPG via the Rapoport-Luebering shunt. BPGM is a homodimer with both synthase and phosphatase activity; its synthetic function converts 1,3-bisphosphoglycerate to 2,3-BPG, and its phosphatase activity metabolizes 2,3-BPG to 3-phosphoglycerate, an intermediate of the glycolytic pathway. A deficiency of BPGM leads to a decrease in 2,3-BPG. The ensuing increase in hemoglobin oxygen affinity results in a decrease in oxygen delivery to the tissues, which in turn leads to a compensatory polycythemia.

Diagnosis and Therapy

The diagnosis of BPGM deficiency is first suspected when a patient with an otherwise unexplained polycythemia is noted to have a decreased P_{50} on the oxygen dissociation curve and a normal hemoglobin electrophoretic profile. These studies should be followed by an assay measuring 2,3-BPG activity and, if decreased, an assay measuring BPGM activity. The condition is confirmed by demonstrating a mutation in the BPGM gene.

Due to the rarity of the condition, there is limited experience to guide treatment. Presumably the reactive polycythemia compensates for the diminished oxygen delivery to the tissues and thereby circumvents frank tissue hypoxia. These patients may, however, be more sensitive to decreases in hemoglobin and become symptomatic from what would otherwise be deemed a mild anemia.

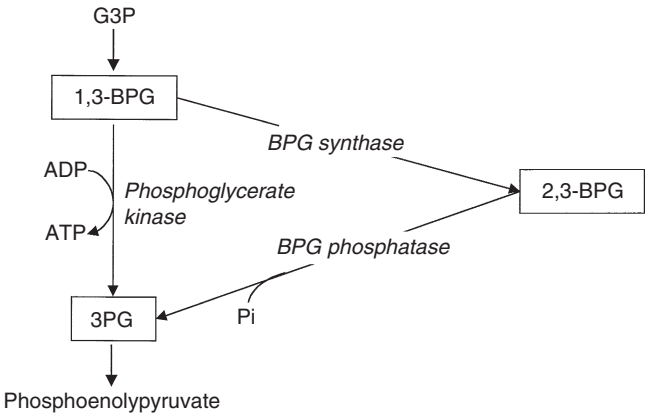

Figure 42-6 RAPOPORT-LUEBERING SHUNT. 2,3-BPG metabolism is regulated by a multifunctional enzyme, bisphosphoglycerate mutase, with both synthase (BPG synthase) and phosphatase (BPG phosphatase) activity. This reaction bypasses the formation of adenosine triphosphate (ATP) in the glycolytic pathway. *ADP,* Adenosine diphosphate; *1,3-BPG,* 1,3-bisphosphoglycerate; *2,3-BPG,* 2,3-bisphosphoglycerate; *G3P,* glyceraldehyde 3-phosphate; *3PG,* 3-phosphoglycerate; *Pi,* inorganic phosphate.

CHAPTER 43

RED BLOOD CELL MEMBRANE DISORDERS

Patrick G. Gallagher

Characterization of the structure and function of red blood cell membrane proteins and their genes (Fig. 43-1) has led to considerable advances in our understanding of the molecular pathology of membrane-associated disorders, including the definition and characterization of mutations of membrane proteins as a well-defined cause of hereditary hemolytic disease. Likewise, knowledge of the molecular mechanisms underlying changes in red blood cell deformability, structural integrity, and shape has advanced. Red blood cell shape abnormalities often provide a clue to the pathobiology and diagnosis of the underlying disorder. This chapter categorizes red blood cell membrane disorders according to the following morphologic and clinical phenotypes: (1) hereditary spherocytosis (HS); (2) hereditary elliptocytosis (HE), hereditary pyropoikilocytosis (HPP), and related disorders; (3) Southeast Asian ovalocytosis (SAO); (4) hereditary and acquired acanthocytosis; and (5) hereditary and acquired stomatocytosis (Tables 43-1 and 43-2).

VERTICAL AND HORIZONTAL INTERACTIONS OF MEMBRANE PROTEINS AND DISORDERS OF RED BLOOD CELL SHAPE

Palek et al first proposed dividing membrane protein-protein and protein-lipid interactions into two categories, vertical and horizontal interactions. Vertical interactions, which are perpendicular to the plane of the membrane, stabilize the lipid bilayer. These interactions include spectrin-ankyrin–band 3 interactions, spectrin–protein 4.1R–junctional complex proteins linkage, spectrin-ankyrin–Rh multiprotein complex linkage, and the weak interactions between the skeletal proteins and the negatively charged lipids of the inner half of the membrane lipid bilayer. Horizontal interactions, which are parallel to the plane of the membrane, support the structural integrity of erythrocytes after their exposure to shear stress. Horizontal interactions involve the spectrin heterodimer association site, where spectrin heterodimers assemble into tetramers, the principal building blocks of the membrane skeleton, and the contacts of the distal ends of spectrin heterodimers with actin and protein 4.1R within the junctional complex. Although interactions between proteins of the erythrocyte membrane are significantly more complex than can be classified by this model of horizontal and vertical interactions, the model serves as a useful starting place for understanding erythrocyte membrane protein interactions, particularly in reference to membrane-related disorders.

According to the vertical/horizontal model, HS is considered a disorder of vertical interactions (Fig. 43-2). Although the primary molecular defects in HS are heterogeneous (including deficiencies or dysfunctions of α- and β-spectrin, ankyrin, band 3, and protein 4.2), one common feature of HS red blood cells is a weakening of the vertical contacts between the skeleton and the overlying lipid bilayer membrane together with its integral proteins. Consequently the lipid bilayer membrane is destabilized, leading to release of bilayer lipids from the cells in the form of skeleton-free lipid vesicles. This lipid loss, in turn, results in membrane surface area deficiency and spherocytosis.

In most patients with HE and the related disorder HPP (see Hereditary Elliptocytosis and Related Disorders), the principal lesion involves horizontal membrane–protein associations, primarily spectrin dimer-dimer interactions. In a subset of HE patients with a deficiency or a dysfunction of protein 4.1R or glycophorin C (GPC), the horizontal defect resides in the junctional complex, where the distal ends of spectrin tetramers connect to actin, in conjunction with protein 4.1R. In patients with severely dysfunctional spectrin mutations, the weakened spectrin dimer-dimer self-association disrupts the skeletal lattice, leading to a marked skeletal instability and cell fragments. In patients with mildly dysfunctional spectrins, red blood cell shape is that of biconcave elliptocytes. It is speculated that elliptocytes are permanently deformed cells because the weakened horizontal interactions facilitate a shear stress–induced rearrangement of skeletal proteins, precluding recovery of the normal biconcave shape. This hypothesis is not applicable to all forms of elliptocytosis. For example, in SAO, the elliptocytic/ovalocytic cells containing mutant band 3 protein are rigid and "hyperstable" rather than unstable.

Acanthocytosis, Stomatocytosis, and the Bilayer Couple Hypothesis

The mechanism of acanthocytosis and stomatocytosis associated with defects of membrane proteins is much less clear. Most forms of acanthocytosis are associated with either acquired or inherited abnormalities of membrane lipids (e.g., acanthocytosis in end-stage liver disease or abetalipoproteinemia). In rare subjects with acanthocytosis, membrane protein abnormalities have been detected, but the associated mechanisms leading to acanthocyte formation are unknown. These abnormalities occur in the McLeod phenotype, the chorea-acanthocytosis syndrome, and other rare disorders. In acanthocytosis erythrocytes, agents that interact with the lipids of the inner lipid bilayer leaflet normalize the shape. These studies suggest that the shape abnormalities reflect an asymmetry in the distribution of membrane lipids between the two halves of the red blood cell lipid bilayer as predicted by the bilayer couple hypothesis. According to the bilayer hypothesis, the shape of the red blood cell reflects the ratio of the surface areas of the two hemileaflets of the bilayer. The preferential expansion of the outer leaflet leads to red blood cell crenation (echinocytosis or acanthocytosis), whereas expansion of the inner lipid bilayer produces a cup shape (stomatocytosis) and surface invaginations.

Hereditary Spherocytosis

Introduction and Epidemiology

The typical features of HS include a dominantly inherited hemolytic anemia of mild to moderate severity, spherocytosis on the peripheral blood film, and a favorable response to splenectomy. The clinical spectrum of HS is variable and includes both mild and asymptomatic forms, as well as severe forms that appear in infancy. The previously

reported HS prevalence in Western populations of 1 in 5000 persons is an underestimation, because milder forms of HS might be asymptomatic, suggesting a prevalence of 1 in 2000 individuals. HS has been reported worldwide, particularly in Japanese and African populations, but its prevalence in other ethnic groups is unknown.

Pathobiology

Two major factors are involved in HS pathophysiology: (1) an intrinsic red blood cell defect and (2) an intact spleen that selectively retains and damages abnormal HS erythrocytes. An inherited deficiency or dysfunction of proteins of the erythrocyte membrane leads to a multistep process of accelerated HS red blood cell destruction. Destabilization of the lipid bilayer facilitates a release of lipids from the membrane, leading to surface area deficiency and formation of poorly deformable spherocytes that are selectively retained and damaged in the spleen (see Fig. 43-2).

Molecular Pathology

The molecular basis of HS is heterogeneous. Based on densitometric quantitation of membrane proteins separated by polyacrylamide gel electrophoresis, HS can be divided into the following subsets: (1) isolated deficiency of spectrin, (2) combined deficiencies of spectrin and ankyrin, (3) deficiency of band 3 protein, (4) deficiency of protein 4.2, and (5) no abnormality identified.

Isolated Spectrin Deficiency

The reported mutations of isolated spectrin deficiency include defects of both α- and β-spectrin. Mutations of the β-spectrin gene have been identified in a number of patients with dominantly inherited HS associated with spectrin deficiency. A few cases have been associated with de novo β-spectrin gene mutations. With a few exceptions, these mutations are private and may be associated with decreased β-spectrin messenger ribonucleic acid (mRNA) accumulation. Mutations in the highly conserved region of β-spectrin involved in the interaction with protein 4.1R likely lead to dysfunctional binding to protein 4.1R and thereby the linkage of spectrin to actin.

In nondominantly inherited HS associated with isolated spectrin deficiency, the defect involves α-spectrin. In normal erythroid cells, α-spectrin is synthesized in large excess of β-spectrin. Thus subjects

Table 43-2 Peripheral Blood Film Evaluation in a Patient With Red Cell Membrane Disorder

Shape	Pathobiology	Diagnosis
Microspherocytes	Loss of membrane lipids leading to a reduction of surface area resulting from deficiencies of spectrin, ankyrin, or band 3 and protein 4.2 Removal of membrane material from antibody-coated red cells by macrophages Removal of membrane-associated Heinz bodies, with the adjacent membrane lipids, by the spleen	HS Immunohemolytic anemias Heinz body hemolytic anemias
Elliptocytes	Permanent red cell deformation resulting from a weakening of skeletal protein interactions (such as the spectrin dimer-dimer contact). This facilitates disruption of existing protein contacts during shear stress–induced elliptical deformation. Subsequently, new protein contacts are formed that stabilize elliptical shape Unknown	Mild common HE Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Poikilocytes/ Fragments	Weakening of skeletal protein contacts resulting from skeletal protein mutations Unknown	Hemolytic HE/HPP Iron deficiency, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndrome, thalassemias
Schistocytes, fragmented red cells	Red cells "torn'' by mechanical trauma (fibrin strands, turbulent flow)	"Microangiopathic" hemolytic anemia associated with disseminated intravascular coagulation, thrombotic thrombocytopenic purpura, vasculitis, heart valve prostheses
Acanthocytes	Uptake of cholesterol and its preferential accumulation in the outer leaflet of the lipid bilayer Selective accumulation of sphingomyelin in the outer lipid leaflet Unknown	Spur cell hemolytic anemia in severe liver disease Abetalipoproteinemia Chorea-acanthocytosis syndrome, malnutrition, hypothyroidism McLeod phenotype
Echinocytes	Expansion of the surface area of the outer hemileaflet of lipid bilayer relative to the inner hemileaflet Unknown	Hemolytic anemia associated with hypomagnesemia and hypophosphatemia in malnourished patients, pyruvate kinase deficiency; in vitro artifact of low blood storage (ATP depletion), contact with glass or elevated pH Hemolysis in long-distance runners, renal failure
Stomatocytes	Expansion of the surface area of the inner hemileaflet of the bilayer relative to the outer leaflet Unknown	Exposure of red cells to cationic anesthetics in vitro; in vivo the drug concentrations may not be sufficient to produce similar effect Alcoholism, inherited disorders of membrane permeability (hereditary stomatocytosis)
Target cells	Absolute excess of membrane lipids (both cholesterol and phospholipids: "symmetric" lipid gain), followed by an increase of cell surface area Relative excess of surface area because of a decrease in cell volume	Obstructive jaundice, liver disease with intrahepatic cholestasis Thalassemias and some hemoglobinopathies (C, D, E)

ATP, Adenosine triphosphate; *HE,* hereditary elliptocytosis; *HPP,* hereditary pyropoikilocytosis; *HS,* hereditary spherocytosis.

with one normal and one defective α-spectrin allele are asymptomatic, because α-spectrin production remains in excess of β-spectrin synthesis, allowing normal amounts of spectrin heterodimers to be assembled on the membrane. Patients who are homozygotes or compound heterozygotes for α-spectrin defects suffer from moderate to severe HS.

Combined Deficiency of Spectrin and Ankyrin

The biochemical phenotype of combined spectrin and ankyrin deficiency is the most common abnormality found in the erythrocytes of HS patients. Ankyrin represents the principal binding site for spectrin on the membrane; thus it is not surprising that ankyrin deficiency is accompanied by a proportional decrease in spectrin assembly on the membrane despite normal spectrin synthesis. Similar to HS associated with β-spectrin mutations, most ankyrin defects are private point mutations associated with decreased mRNA accumulation. In some cases, mutations of the ankyrin promoter leading to decreased ankyrin expression have been found. Approximately 15% to 20% of ankyrin gene mutations reported are de novo mutations.

A number of patients with atypical HS associated with karyotypic abnormalities involving deletions or translocations of the ankyrin gene locus on chromosome 8p have been described. Ankyrin deletions may be part of a contiguous gene syndrome with manifestations of spherocytosis, mental retardation, typical facies, and hypogonadism.

Deficiency of Band 3 Protein

Deficiency of band 3 protein is found in a subset of HS patients who present with a phenotype of a mild to moderate dominantly inherited HS. Most, if not all, of these patients also have concomitant protein 4.2 deficiency. Numerous band 3 mutations associated with HS have been reported, spread throughout both the cytoplasmic and the membrane-spanning domains.

A number of band 3 mutations clustered in the membrane-spanning domain that replace highly conserved arginines have been described. These arginines, which are all located at the cytoplasmic end of a predicted transmembrane helix, exhibit defective cellular trafficking from the endoplasmic reticulum to the plasma membrane.

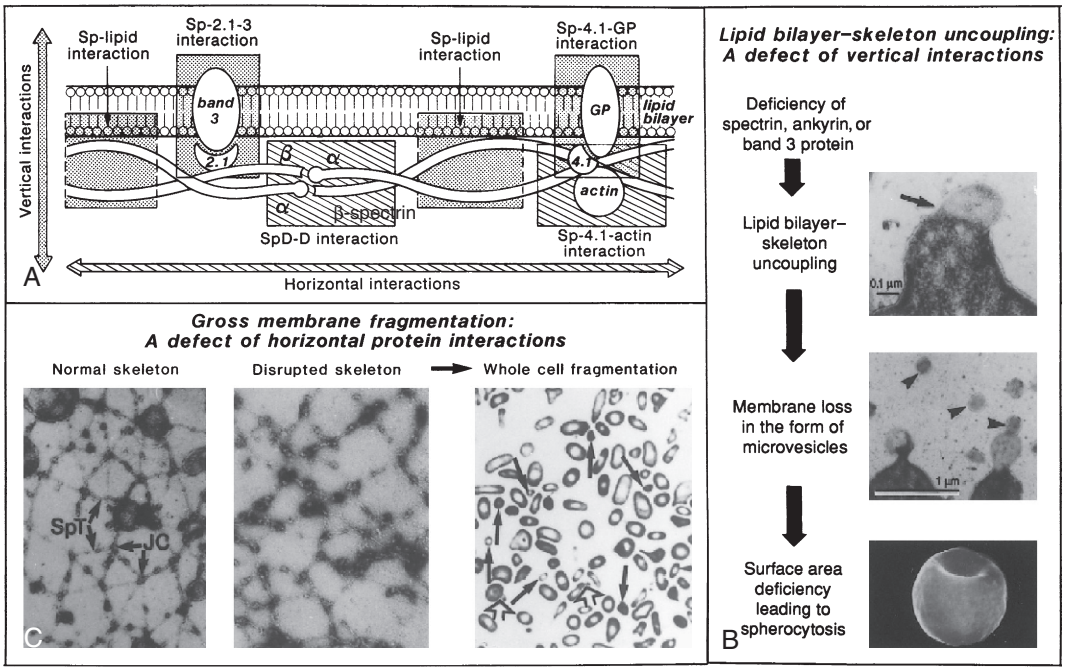

Figure 43-2 VERTICAL AND HORIZONTAL INTERACTIONS OF MEMBRANE PROTEINS AND THE PATHOBIOLOGY OF THE RED CELL LESION IN HEREDITARY SPHEROCYTOSIS AND HEREDITARY ELLIPTOCYTOSIS. **A,** In one model of the erythrocyte membrane, proteins interact in a series of horizontal and/or vertical interactions. Perturbation of these interactions leads to disorders of erythrocyte shape. **B,** A defect of vertical interactions as exemplified by the membrane lesion in hereditary spherocytosis. Deficiency of spectrin, ankyrin, or band 3 protein leads to uncoupling of the membrane lipid bilayer from the underlying skeleton *(top panel),* followed by a formation of spectrin-free microvesicles of about 0.2-0.5 mm in diameter *(arrowheads, middle panel).* These vesicles can be visualized by transmission electron microscopy, but they are not seen on examination of a peripheral blood film. The subsequent loss of cell surface area and a decrease in the surface/volume ratio lead to spherocytosis *(bottom panel).* **C,** Defect of horizontal interactions of membrane skeleton proteins as exemplified by the membrane lesion in hemolytic forms of hereditary elliptocytosis and hereditary pyropoikilocytosis. The molecular lesion of weakened self-association of spectrin heterodimers to tetramers (SpT) leads to decreased linkage of spectrin to junctional complexes (JC), representing a horizontal defect of shear stress-resisting protein interactions. It leads to a disruption of the membrane skeletal lattice and, consequently, to destabilization of the whole cell, followed by cell fragmentation, as seen as seen on peripheral blood smear.

Alleles have been identified that influence band 3 expression and that, when inherited in trans to a band 3 mutation, aggravate band 3 deficiency and worsen the clinical severity of the disease.

Deficiency of Protein 4.2

Recessively inherited HS caused by mutations in protein 4.2 is relatively common in Japan. In these cases, an almost total absence of protein 4.2 from the erythrocyte membranes of homozygous patients is detected. Protein 4.2–deficient erythrocytes can also have a decreased content of ankyrin and band 3. Protein 4.2 deficiency also occurs in association with band 3 mutations, probably as a result of abnormal binding of protein 4.2 to the cytoplasmic domain of band 3.

A detailed listing of HS mutations is available (http://research.nhgri.nih.gov/RBCmembrane/) in a mutation database maintained by the National Human Genome Research Institute and Yale University.

Molecular Basis of Surface Area Deficiency

Hereditary spherocytes are intrinsically unstable, releasing lipids under a variety of in vitro conditions, including adenosine triphosphate (ATP) depletion or exposure of cells to shear stress. The loss of membrane material occurs through the release of vesicles containing integral proteins devoid of spectrin. During in vitro incubation, the loss of membrane material is sufficient to augment the surface area deficiency, as evidenced by increased osmotic fragility of the cells after incubation. It is assumed but not proved that a similar process takes place in vivo.

The molecular basis of HS is heterogeneous; thus it is likely that surface area deficiency is a consequence of several distinct molecular mechanisms whose common denominator is either a weakening of the vertical connections between the skeleton and the lipid bilayer membrane or a weakening of the stabilizing effect of transmembrane proteins on adjacent lipid molecules of the plasma membrane. Three distinct hypothetic pathways that can lead to surface area deficiency are depicted in Fig. 43-2. In patients with isolated spectrin deficiency or a combined deficiency of spectrin and ankyrin, the loss of red blood cell surface may be caused by an uncoupling of the lipid bilayer membrane from the underlying skeleton. In normal red blood cells, the skeleton forms a nearly monomolecular submembrane layer occupying more than one-half of the inner surface of the membrane. Consequently spectrin deficiency leads to a decreased density of this network. As a result, areas of the lipid bilayer membrane that are not directly supported by the skeleton are susceptible to release from the cells in the form of microvesicles.

In HS associated with a deficiency of band 3 protein, two hypothetic pathways may lead to a loss of surface area. One mechanism may involve a loss of band 3 protein from the cells. Because band 3 protein spans the lipid bilayer membrane many times, it is likely that a substantial amount of "boundary" lipids are released together with the band 3 protein, thus leading to surface area deficiency. Another

possible mechanism may involve a formation of band 3–free domains in the membrane, followed by the formation of membrane blebs, which are subsequently released from the cells as microvesicles. Such a hypothesis is based on the observation that aggregation of intramembrane particles (composed principally of band 3) in ghosts leads to the formation of particle-depleted domains from which membrane lipids bleb off as microvesicles. Additional evidence supporting the latter model comes from the band 3 knock-out mouse model and from human, cow, and zebrafish cases of complete band 3 deficiency. Erythrocytes lacking band 3 spontaneously shed membrane vesicles, leading to spherocytosis and hemolysis.

Alterations in Cation Content and Permeability

HS red blood cells, particularly those collected from the spleen, are somewhat dehydrated and abnormally permeable to monovalent cations, presumably as a consequence of the underlying membrane defect. The cellular dehydration may be caused by activation of pathways causing a selective loss of potassium and water or a hyperactive Na^+/K^+ pump.

Entrapment of Nondeformable Spherocytes in the Spleen

The importance of the spleen in the pathophysiology of hemolysis in HS was appreciated in the original description of the disease and has been substantiated by subsequent studies. HS cells are selectively destroyed in the spleen because of their poor deformability and because of the unique anatomy of the splenic vasculature that acts as a microcirculation filter.

The poor red blood cell deformability is principally a consequence of a decreased cell surface/cell volume ratio resulting from the loss of surface material. Normal discocytes have an excess surface, which allows them to deform and pass through narrow microcirculation openings. In contrast, HS red blood cells lack this extra surface, and their poor deformability may be further impaired by cellular dehydration.

The principal sites of red blood cell entrapment in the spleen are fenestrations in the wall of splenic sinuses, where blood from the splenic cords of the red pulp enters the venous circulation. In rat spleen, the length and width of these fenestrations, 2 to 3 μm and 0.2 to 0.5 μm, respectively, are approximately half the red blood cell diameter. Electron micrographs show that very few HS red blood cells traverse these slits. Consequently the nondeformable spherocytes accumulate in the red pulp, which becomes grossly engorged.

Splenic Conditioning and Destruction

Once trapped in the spleen, HS erythrocytes undergo additional damage or conditioning with further loss of surface area and an increase in cell density, as is evident in cells removed from the spleen at splenectomy. Some of these conditioned red blood cells reenter the systemic circulation, as revealed by the "tail" of the osmotic fragility curve, indicating the presence of a subpopulation of cells with a markedly reduced surface area. After splenectomy, this red blood cell population disappears.

Contributions to conditioning may include a relatively low pH in the spleen as well as in the sequestered red blood cells that may further compromise the poor HS red blood cell deformability, and contact of red blood cells with macrophages that may inflict additional damage on the red blood cell membrane. The conditioning effect of the spleen appears to represent a cumulative injury. The average residence time of HS red blood cells in the splenic cords is between 10 and 100 minutes compared with 30 to 40 seconds for normal red blood cells, and only 1% to 10% of blood entering the spleen is temporarily sequestered in the congested cords, whereas the remaining 90% of blood flow is rapidly shunted into the venous circulation.

Inheritance

The HS genes are assigned to several chromosomes, including chromosome 1 (α-spectrin), chromosome 8 (ankyrin), chromosome 14 (β-spectrin), chromosome 15 (protein 4.2), and chromosome 17 (band 3). In approximately two-thirds of HS patients, inheritance is autosomal dominant. In the remaining patients, inheritance is nondominant. In many of these patients, HS is caused by a de novo mutation, which is inherited in an autosomal recessive fashion in subsequent generations. Recessively inherited HS cases manifesting with severe hemolytic anemia have been reported. The majority of the affected patients were found to be severely deficient in red blood cell spectrin, associated with α-spectrin defects. The remaining cases characterized by a recessive inheritance pattern are caused by a defect in protein 4.2, a deficiency that is associated with relatively mild hemolysis.

Only a few cases of homozygous HS have been reported. These patients have a severe hemolytic anemia, whereas their mostly consanguineous parents have a mild to moderate form of the disease or are asymptomatic.

Although the clinical severity of HS is highly variable among different kindreds, in general it is relatively uniform within a given family, in which HS is typically inherited as an autosomal dominant disorder. However, HS kindreds have been described in which there was great variability in the clinical severity of affected family members. Several explanations might account for these observations, including variable penetrance of the genetic defect, a de novo mutation, presence of a mild recessive HS in the kindred, presence of a modifier allele that influences the expression of a membrane protein, or a tissue-specific mosaicism of the defect.

Clinical Manifestations

Typical Forms

The typical HS patient is relatively asymptomatic. As noted in the earliest descriptions of HS, mild jaundice can be the only symptom of the disease. Splenomegaly gradually develops in most patients, with the spleen occasionally reaching large dimensions. Anemia is usually mild to moderate but may be absent because of compensatory bone marrow hyperplasia.

Mild Forms and Carrier State

In some families, anemia is absent, the reticulocyte count is normal or only minimally elevated, laboratory evidence of hemolysis is minimal or absent, and the changes in red blood cell shape can be mild, escaping detection on the peripheral blood film. The presence of HS is detected only by osmotic fragility testing or during evaluation of a relative with a more symptomatic form of the disease. Some patients are first diagnosed during transient viral infections such as infectious mononucleosis or parvovirus infection, during pregnancy, or even in the seventh to ninth decades of life as the bone marrow's ability to compensate for hemolysis wanes.

Severe and Atypical Forms

The relatively uncommon patients with nondominant forms of HS can present with a severe life-threatening hemolysis early in life. Some patients can be transfusion dependent during early infancy and childhood. The underlying molecular defects include severe spectrin or band 3 deficiency.

Hereditary Spherocytosis and Nonerythroid Manifestations

In most HS cases, the clinical manifestations are confined to the erythroid lineage, probably because many of the nonerythroid

counterparts of the red blood cell membrane proteins (e.g., spectrin and ankyrin) are encoded by separate genes or because some proteins (e.g., protein 4.1R, β-spectrin, ankyrin) are subject to tissue-specific alternative splicing. However, several HS kindreds have been reported with a cosegregating neurologic or muscular abnormality, such as a degenerative disorder of the spinal cord, cardiomyopathy, or mental retardation. The observation that both erythrocyte ankyrin and β-spectrin are also expressed in muscle, brain, particularly the cerebellum, and spinal cord raises the possibility that these HS patients may have a defect in one of these proteins. This hypothesis is further supported by studies of nb/nb mice, a mouse model of HS caused by an ankyrin mutation. These mice develop a neurologic syndrome with a progression that coincides with the loss of ankyrin from the Purkinje cells of the cerebellum.

Mutations of band 3 without HS have been described in patients with distal renal tubular acidosis. With a few rare exceptions, most patients with heterozygous mutations of band 3 and HS have normal renal acidification.

Laboratory Manifestations

Most HS patients have either a mild to moderate anemia or no anemia at all, reflecting the facts that the hemolytic rate can be very mild and that the hemolysis is fully compensated for by increased red blood cell production, as evidenced by reticulocytosis. Some patients, however, particularly those with nondominantly inherited HS, are severely anemic, with hemoglobin concentrations as low as 4 to 6 g/dL.

Despite the increased percentage of reticulocytes with a larger volume than mature red blood cells, the mean corpuscular volume (MCV) of HS red blood cells is often low normal or even slightly decreased, and the mean corpuscular hemoglobin concentration (MCHC) is usually increased (>35 g/dL), together reflecting mild cellular dehydration.

The finding of an MCHC greater than 35.4 g/dL combined with a red blood cell distribution width (RDW) of less than14% has been found to be an excellent screening test for HS. Another screening method measures MCV by light scattering and provides a histogram of hyperdense erythrocytes (MCHC >40 g/dL) claimed to identify nearly all HS patients. These hyperdense erythrocytes can be detected with newer laser-based blood counters or using aperture impedance analysis available in many clinical laboratories.

Evidence of accelerated red blood cell destruction, as indicated by increased lactate dehydrogenase and unconjugated bilirubin levels and by decreased haptoglobin, as well as by reticulocytosis, is present in typical HS patients. However, these abnormalities can be absent in individuals with a mild form of the disease.

Blood Film

In a typical case of HS, spherocytes are readily identified by their characteristic shape on the peripheral blood film (Fig. 43-3). They lack central pallor, their mean cell diameter is decreased, and they appear more intensely hemoglobinated, which reflects both altered red blood cell geometry and increased cell density. In a three-dimensional view, some spherocytes have a spherostomatocytic shape that is occasionally appreciated on the peripheral blood film. In mild forms of the disease, the peripheral blood smear can appear normal because the loss of surface area can be too small to be appreciated by blood smear evaluation; the cells appear as "fat" disks rather than as true spherocytes.

Additional morphologic features have been described in some HS patients (see Fig. 43-3). A subset of HS patients whose red blood cells are deficient in band 3 protein have some pincer-like red blood cells on the peripheral blood film, a finding that is both sensitive and specific for this HS subset. These pincer-like cells disappear after splenectomy. Surface spiculations or acanthocytic spherocytes have been described in cases of HS associated with defects in β-spectrin. Frequent sphero-ovalocytes and stomatocytes have been reported in Japanese patients with protein 4.2 deficiency.

Osmotic Fragility

The osmotic fragility test (Fig. 43-4) measures the in vitro lysis of red blood cells suspended in solutions of decreasing osmolarity. The normal red blood cell membrane is unstretchable and is virtually freely permeable to water. Thus the cell behaves as a nearly perfect osmometer in that it increases its volume in hypotonic solutions progressively until a "critical hemolytic volume" is reached. At this point, the red blood cell membrane ruptures, and hemoglobin escapes into the supernatant solution. As a result of the loss of membrane and the ensuing surface area deficiency, the critical hemolytic volume of spherocytes is considerably lower than that of normal red blood cells. Consequently these cells hemolyze more than normal red blood cells when suspended in hypotonic sodium chloride solutions. However, a finding of increased osmotic fragility is not unique to HS and is also present in other conditions associated with spherocytosis on the peripheral blood film, such as autoimmune hemolytic anemia.

The slight dehydration of hereditary spherocytes (which in other conditions is associated with decreased osmotic fragility) has no appreciable effect on HS osmotic fragility because of the overriding effect of the markedly diminished cell surface area. In fact, the densest, most dehydrated cells exhibit the greatest increase in osmotic fragility.

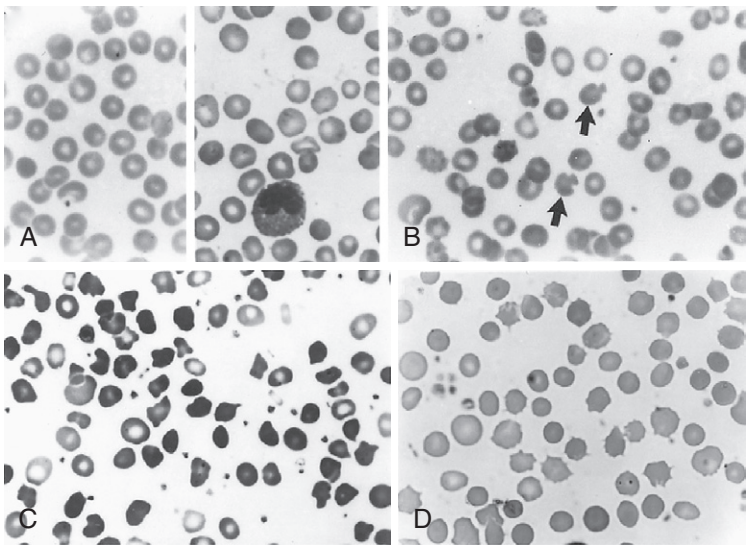

Figure 43-3 BLOOD FILMS FROM PATIENTS WITH HEREDITARY SPHEROCYTOSIS (HS) OF VARYING SEVERITY. **A,** Two blood films of typical moderately severe HS with a mild deficiency of red blood cell spectrin and ankyrin. Although many cells have a spheroidal shape, some retain a central concavity. **B,** HS with pincer-like red blood cells *(arrows),* as typically seen in HS associated with band 3 deficiency. Occasional spiculated red blood cells are also present. **C,** Severe atypical HS caused by a severe combined spectrin and ankyrin deficiency. In addition to spherocytes, many cells have irregular contour. **D,** HS with isolated spectrin deficiency caused by a β-spectrin mutation. Some of the spherocytes have prominent surface projections resembling spheroacanthocytes.

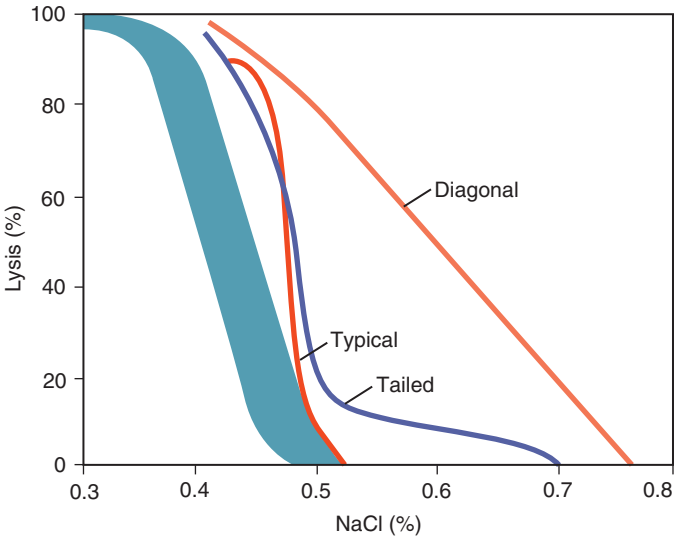

Figure 43-4 CHARACTERISTIC OSMOTIC FRAGILITY CURVES IN HEREDITARY SPHEROCYTOSIS (HS). The typical curve of increased osmotic fragility is the most common finding. The tailed curve reveals a second population (a tail) of very fragile erythrocytes conditioned by the spleen. This tail disappears after splenectomy. The diagonal curve is seen in patients with severe HS. *(Modified from Dacie J: Hereditary spherocytosis (HS). In* The haemolytic anaemias, *ed 3, vol 1, Edinburgh, 1985, Churchill Livingstone, p 134.)*

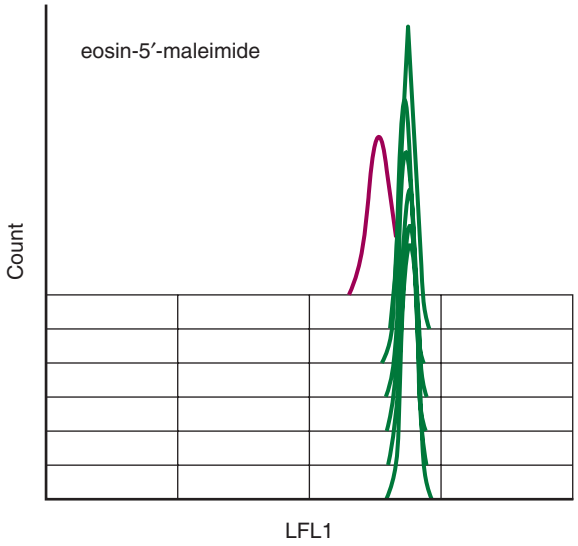

Figure 43-5 A flow cytometric test that measures the fluorescence intensity of intact red blood cells labeled with the dye eosin-5′-maleimide, which reacts with band 3 protein, has been shown to be useful as a first-line test for the diagnosis of hereditary spherocytosis. Shown is log fluorescence (LFL1) versus count with six normal controls *(green)* and a patient with hereditary spherocytosis *(red)*.

The osmotic fragility curve often reveals uniformly increased osmotic fragility. A "tail" of the osmotic fragility curve can be present in nonsplenectomized HS subjects, indicating a subpopulation of particularly fragile red blood cells conditioned by splenic stasis. This subpopulation of cells disappears after splenectomy. In subjects with mild HS, osmotic fragility can be normal and abnormalities can be found only after incubation that further augments the loss of surface area; however, the sensitivity of the incubated osmotic fragility test can be outweighed by a loss of its specificity. The relative contributions of cell dehydration and surface area deficiency can be accurately determined by osmotic gradient ektacytometry, available only in specialized laboratories.

Eosin-5′-Maleimide Binding

The observation that most spherocytes are deficient in band 3 and that eosin-5′-maleimide (EMA) covalently binds band 3 and Rh-related proteins with a 1:1 stoichiometry has been used as the basis for a screening test for HS. The binding of fluorescently-labeled EMA to erythrocytes is followed by flow cytometric quantitation. The intensity of EMA binding is decreased in HS erythrocytes (Fig. 43-5). This technique appears to have both high sensitivity and specificity. Like osmotic fragility, other erythrocyte abnormalities such as abnormalities of erythrocyte hydration and variants of dyserythropoietic anemia can also yield abnormal results. In cases of mild HS (e.g., most of the patient's erythrocytes are phenotypically normal), results may be normal or indeterminate. EMA binding studies are relatively straightforward to perform and provide results within a few hours. The test is gaining popularity as more diagnostic laboratories obtain experience with its use.

Autohemolysis and Other Tests

Red blood cell autohemolysis, the spontaneous hemolysis of red blood cells incubated under sterile conditions without glucose, was previously advocated as a sensitive test for the detection of HS. This test is being used less frequently and is probably no more sensitive than the incubated osmotic fragility test. Other tests described in the literature such as the glycerol lysis test, the pink test, hypertonic cryohemolysis, and the skeleton gelation test, are infrequently performed in diagnostic laboratories in the United States. The former two tests, which employ glycerol to retard the osmotic swelling of red blood cells, are preferred by some laboratories because they are easy to perform and can be adapted to microsamples. Cryohemolysis testing in particular remains popular in Europe.

Detection of the Underlying Molecular Defect

Because the most common finding in erythrocytes of patients with HS is a deficiency of one or more of the membrane proteins, initial studies often include sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS-PAGE) solubilized red blood cell membrane proteins followed by densitometric quantitation. The results are expressed as ratios of individual red cell membrane proteins to band 3. This technique reveals abnormalities in approximately 70% to 80% of patients, defining the distinct biochemical phenotypes discussed previously. Direct quantitation of membrane proteins by radioimmunoassay is superior to densitometric quantitation and permits accurate measurement of the copy number of the individual proteins per red blood cell.

Subsequent strategies to search for the underlying defect are complex. Studies of protein function, readily employed in the detection of spectrin mutations in cases of HE and HPP (see Membrane Effects), have been disappointing in detecting abnormalities in HS, with the exception of HS characterized by a weakened β-spectrin–protein 4.1R interaction. Studies of membrane protein synthesis and assembly, using either reticulocytes or erythroblasts derived from peripheral blood burst-forming units in vitro, have been used, but they are insensitive in detecting mild to moderate abnormalities in membrane protein synthesis and assembly and are technically cumbersome to perform.

Genetic linkage analysis has been employed in cases of HS, but it suffers from the disadvantages of the need to study large kindreds and its lack of usefulness in studying patients with de novo mutations. Because of the large sizes of the HS genes, mutation-screening techniques have been developed. Many of these employ polymerase chain reaction–based strategies, including single-strand conformational

polymorphism analyses, denaturing high-performance liquid chromatography, and direct nucleotide sequence analyses. Application of recently developed ultrahigh throughput sequencing techniques will overcome these technical obstacles to HS genetic diagnosis.

Complications

Gallstones

Bilirubin stones are found in approximately 50% of patients with HS, often even in those with a very mild form of the disease. Gallstones have occasionally been detected during infancy, but they are most likely to occur in children and young adults. The coinheritance of Gilbert syndrome markedly increases the risk for gallstones in HS patients. Because of the high incidence of gallstones, HS patients should be periodically examined by ultrasonography for the presence of gallstones, beginning early in childhood.

Crises

True hemolytic crises are relatively rare and only occasionally reported in association with infections. Aplastic crises during viral infections are largely attributable to infection by parvovirus B19. This infection (erythema infectiosum, fifth disease) manifests with fever, chills, lethargy, malaise, nausea, vomiting, abdominal pain with occasional diarrhea, respiratory symptoms, muscle and joint pains, and a maculopapular rash on the face (slapped cheek appearance), trunk, and extremities. The virus selectively infects erythroid precursors and inhibits their growth. The ensuing anemia, often profound, can be the first manifestation of HS. Multiple family members with undiagnosed HS who are infected with parvovirus have developed aplastic crises at the same time. Infection with parvovirus is a particular danger to susceptible pregnant women because it can infect the fetus, leading to fetal anemia, hydrops fetalis, and fetal demise.

Rarely, at least in developed countries, patients present with megaloblastic crises caused by folate deficiency. This typically occurs in patients with increased folate demands, such as those recovering from an aplastic crisis, pregnant women, and older adults. Megaloblastic crisis in pregnancy has been reported as the first manifestation of HS. Folate supplementation is recommended for patients with moderate to severe HS.

Other Complications

In patients with more severe forms of HS, other complications include gout, leg ulcers, or chronic dermatitis of the legs that heal after splenectomy. Symptoms of expanded erythroid space, including paravertebral or renal pelvic masses of extramedullary hematopoiesis, which can mimic an underlying neoplasm, may occur. Several cases of hemochromatosis in HS patients have been reported. In some, iron overload resulted from repeated transfusions; in others, the patients had two genetic defects, one involving HS and the other involving a hemochromatosis carrier state. Other rare complications include thrombosis, pulmonary hypertension, spinocerebellar degenerative syndromes, movement disorders, myopathy, and hypertrophic cardiomyopathy.

More than a dozen cases of HS and hematologic malignancy, including myeloproliferative disorders, multiple myeloma, and leukemia, have been reported. It is unknown if long-standing hematopoietic stress predisposes to the development of these secondary disorders or if they occurred randomly.

Differential Diagnosis

Because of the relatively asymptomatic presentation of HS, this diagnosis should be considered during an evaluation for unexplained splenomegaly, unconjugated hyperbilirubinemia of unknown cause, gallstones at a young age, severe anemia during pregnancy, or transient anemia during acute infections. The diagnosis of HS can be missed in mild forms of the disease, because spherocytosis might not be apparent on the peripheral blood film. Autoimmune hemolytic anemia should be ruled out by negative results of a Coombs test.

More typical forms of HS, characterized by relatively uniform spherocytosis with increased MCHC, are usually easily distinguished from other disorders manifesting with spherocytosis, such as immune hemolytic anemias and unstable hemoglobins. In some patients, the spherostomatocytes in the rare Rh-null syndrome and the intermediate syndromes of hereditary stomatocytosis can be confused with HS red blood cells.

Spherocytosis is transiently improved, and both the osmotic fragility and hemolysis are normalized in patients with obstructive jaundice. This is because of an expansion of red blood cell surface area that follows an increased uptake of phospholipids and cholesterol from the abnormal plasma lipoproteins. In normal red blood cells, this leads to target cell formation; in HS, spherocytes are transformed to discocytes. Spherocytosis and the increased osmotic fragility of HS red cells are likewise improved by iron deficiency, but the red blood cell life span remains shortened. In addition, coexistence of β-thalassemia trait and HS partially corrects the HS phenotype.

Therapy and Prognosis

Splenectomy

Splenectomy is curative in almost all patients with typical forms of HS, because red blood cell survival is normalized, and anemia and hyperbilirubinemia are corrected. Spherocytosis and the increase in osmotic fragility persist, but the tail of the osmotic fragility curve, indicating the presence of a subpopulation of cells conditioned by the spleen, disappears. In patients with severe, nondominantly inherited HS, splenectomy produces a dramatic clinical improvement, but hemolysis is only partially corrected.

Several weeks to months before splenectomy, patients should be immunized with polyvalent vaccine against pneumococcus as well as vaccines against *Haemophilus influenzae* type b and meningococcus.

Indications for Splenectomy

Risks and benefits should be considered carefully in HS patients before splenectomy is performed (see box on Splenectomy for Hereditary Spherocytosis). A multitude of factors influence the decision for splenectomy in HS patients, including the risk for overwhelming postsplenectomy sepsis, the emergence of penicillin-resistant pneumococci, and the potentially increased risk for cardiovascular disease and pulmonary hypertension later in life. Indications for splenectomy include growth retardation, skeletal changes, symptomatic hemolytic disease, anemia-induced compromise of vital organs, the development of leg ulcers, or the appearance of extramedullary hematopoietic tumors. Whether to perform splenectomy in patients with moderate HS without any of these factors remains controversial.

Because of an increased frequency of postsplenectomy infection in young children, most practitioners avoid splenectomy in infancy and early childhood.

Operative Considerations

When splenectomy is warranted, laparoscopic splenectomy has become the procedure of choice in many centers. Laparoscopic splenectomy has been associated with less postoperative discomfort, a quicker return to preoperative diet and activities, a shorter hospitalization time, decreased costs, and smaller scars. Early complications of splenectomy include local infection, bleeding, and pancreatitis. In general, the morbidity rate of splenectomy is lower in patients with HS than with other hematologic diseases. However, the benefits of

Splenectomy for Hereditary Spherocytosis

Splenectomy is a permanently curative treatment in most cases of hereditary spherocytosis (HS). Thus for years splenectomy was recommended for all HS patients regardless of the severity of anemia, gall bladder disease, or other symptoms. However, increasing concerns regarding overwhelming postsplenectomy infection (OPSI), the emergence of penicillin-resistant pneumococci, and increased risk for cardiovascular diseases have tempered these recommendations. When considering splenectomy, health care providers, the patient, and the patient's family should review and consider the risks and benefits. Individual factors that may pose additional risk, such as distance from medical care in case of febrile illness and residence in or travel to areas where parasitic diseases such as malaria or babesiosis occur, should be considered. Expert opinions vary on indications for splenectomy. There are no studies to guide practice. However, because the risk for OPSI is highest in infancy and childhood, most agree it is best to avoid total splenectomy in early childhood.

Benefits

Anemia ameliorated
Risk for hemolysis-associated gall bladder disease eliminated
Risk for aplastic crisis eliminated

Risks

OPSI—especially with encapsulated organisms (*Streptococcus pneumoniae, Neisseria meningitides,* and *Haemophilus influenzae*)
Increased risk for thrombotic complications
Increased risk for vascular complications (pulmonary hypertension, cardiovascular disease)

Indications for Splenectomy

Expert opinions vary
Severe, symptomatic spherocytosis
Growth failure, skeletal changes, leg ulcers, and extramedullary hematopoietic tumors (signs of severe anemia)
Older patients with vascular compromise of vital organs
Moderate HS with compensated, asymptomatic anemia: controversial; decision should be individualized

surgery must be weighed against possible complications, such as postsplenectomy infections. Although these complications are rare and their frequency is likely to diminish further with appropriate vaccinations, the indiscriminate performance of splenectomy in all HS patients with splenomegaly is unwarranted.

Subtotal (Partial) Splenectomy

Partial splenectomy was developed for infants and young children with severe HS, anemia, and poor growth with the goals of palliating anemia and decreasing transfusion requirements while preserving splenic function. More recently some have advocated expanding the procedure to all patients being splenectomized for HS. The goal of the operation is to decrease hemolysis while maintaining splenic phagocytic function. In initial cohorts of patients treated with partial splenectomy, stable increases in hemoglobin levels with decreased reticulocyte counts have been observed. The volume of splenic tissue left behind ranges from 10 to 30 mL. Although initial data are promising, it is not clear whether the remaining splenic tissue will effectively prevent postsplenectomy sepsis. In addition, regrowth of the splenic remnant has been reported in many patients, which can eventually lead to recurrence of HS and another operative procedure.

There are no specific data to support the use of prophylactic antibiotics postsplenectomy. Some practitioners avoid the prescription of prophylactic antibiotics, others recommend prophylactic antibiotics for at least 5 years postsplenectomy, and others recommend their use for life.

Postsplenectomy Failures

Postsplenectomy failures are caused either by the presence of an accessory spleen missed during surgery (accessory spleens were found in 17% to 39% of all patients) or by the presence of another superimposed red blood cell disorder such as pyruvate kinase deficiency. The recurrence of hemolytic anemia several years after splenectomy should raise the suspicion of development of splenunculi, resulting from autotransplantation of splenic tissue during surgery. The presence of an accessory spleen or splenunculus is suggested by the absence of both Howell-Jolly bodies and the "pitted" cells with crater-like surface indentations readily seen by interference contrast microscopy. A definitive confirmation of splenosis is made by a radiocolloid liver-spleen scan or by a scan using chromium (Cr)-labeled heated red blood cells, which are taken up by the ectopic splenic tissue.

Genetic Counseling

After a patient is diagnosed with HS, family members should be examined for the presence of HS. A history, physical examination for splenomegaly, complete blood count with indices, reticulocyte count, examination of the peripheral blood smear for spherocytes, and biochemical evaluation including bilirubin and haptoglobin levels should be obtained for available close relatives.

Future Directions

Advances in ultrahigh throughput deoxyribonucleic acid (DNA) sequencing methodology will greatly facilitate precise genetic diagnosis in cases of suspected inherited membrane-associated disorders. The technique of exome sequencing has rapidly developed into an effective tool for the identification of disease-causing variants in genetic disease, particularly monogenic disorders. It can be applied to disorders with recessive or dominant inheritance or de novo occurrence, and it obviates the need for linkage analysis in large numbers of individuals. As more patients are studied, it is likely that new HS-associated loci will be discovered, specific mutations will provide insight into the structure and function of associated membrane protein genes, and our understanding of genotype-phenotype relationships, particularly those with variable influence on disease severity, will be extended.

HEREDITARY ELLIPTOCYTOSIS AND RELATED DISORDERS

Introduction and Epidemiology

Hereditary elliptocytosis designates a group of inherited disorders that have in common the presence of elliptical red blood cells on peripheral blood films. Elliptocytosis was first described by Dresbach in 1904, and its heritability was firmly established by Hunter. Subsequent reports have revealed a considerable heterogeneity of clinical expression and have defined several distinct syndromes, including HPP and SAO.

Hereditary elliptocytosis is common in people of African and Mediterranean ancestries. In the U.S. population, the prevalence of HE is approximately 3 to 5 per 10,000. The true incidence of HE is unknown because its clinical severity is heterogeneous and most patients are asymptomatic without anemia. HE is considerably more frequent in areas of endemic malaria. In equatorial Africa, the prevalence of common HE has been estimated at between 0.6% and 1.6%.

Worldwide, HE appears to be more common among people of African origin. In Southeast Asian populations, the prevalence of SAO, a variant of HE, is as high as 30%.

The molecular basis of HE remained obscure until a defect of membrane skeletal proteins was suggested. Subsequently defects in the erythrocyte membrane proteins α-spectrin, β-spectrin, protein 4.1R, GPC, and band 3 were described.

On the basis of red blood cell morphologic characteristics, HE can be divided into three major groups (Fig. 43-6). Common HE, a dominantly inherited condition, is morphologically characterized by biconcave elliptocytes and, in some patients, rod-shaped cells. The clinical severity of common HE is highly variable, ranging from an asymptomatic condition to a severe recessively inherited hemolytic anemia, including hemolytic HE and HPP, in which the blood film reveals numerous red blood cell fragments, microspherocytes, and poikilocytes. Spherocytic HE, also called hemolytic ovalocytosis, is a much less common condition in which both round "fat" ovalocytes and spherocytes are present on the blood film. SAO, a disorder highly prevalent in the malaria belt of Southeast Asia and the Pacific, is characterized by rigid, spoon-shaped cells that have either a longitudinal slit or a transverse ridge.

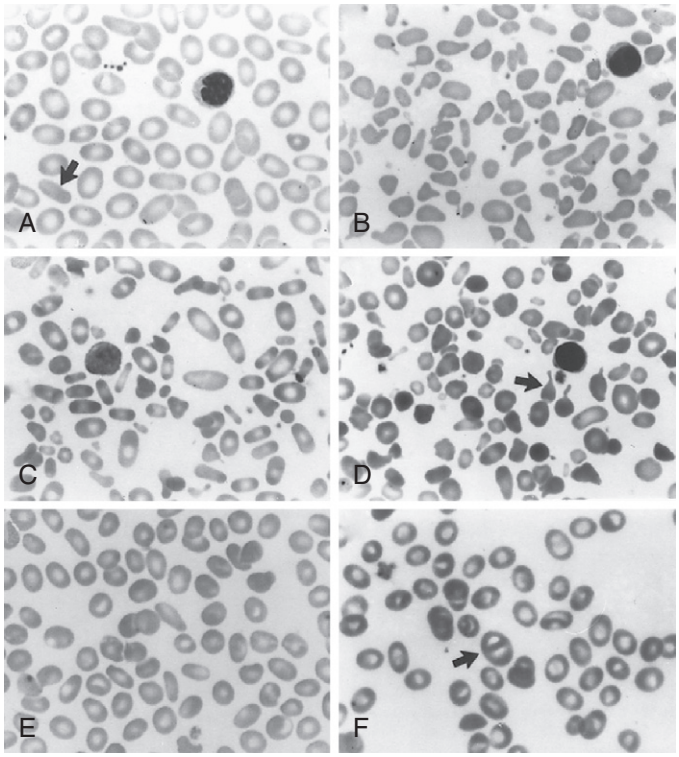

Figure 43-6 BLOOD FILMS OF SUBJECTS WITH VARIOUS FORMS OF HEREDITARY ELLIPTOCYTOSIS (HE). **A,** Simple heterozygote with mild common HE. Note the predominant elliptocytosis with some rod-shaped cells *(arrow)* and virtual absence of poikilocytes. **B,** Simple heterozygote with severe common hemolytic elliptocytosis. Note the numerous small fragments and poikilocytes. **C,** "Homozygous" common HE because of doubly heterozygous state for two mutant α-spectrins. Both parents have mild HE. Note the many elliptocytes as well as numerous fragments and poikilocytes. **D,** Hereditary pyropoikilocytosis. The patient is a double heterozygote for a structural α-spectrin mutant and a presumed α-spectrin synthetic defect. Note the prominent microspherocytosis, micropoikilocytosis, and fragmentation. Only few elliptocytes are present. Some poikilocytes are in the process of budding *(arrow)*. **E,** Spherocytic HE (hereditary ovalocytosis). Most red blood cells are oval rather than truly elliptical. Many oval cells are "fat," lacking a central concavity, the feature distinguishing spherocytic HE from common HE. **F,** Southeast Asian ovalocytosis. Most cells are oval, some containing either a longitudinal slit or a transverse ridge *(arrow)*.

Pathobiology of Common Hereditary Elliptocytosis

The possibility that the primary lesion of HE and HPP erythrocytes resides in the proteins of the red blood cell membrane skeleton was first raised by the findings of thermal instability of HPP spectrin, retention of the elliptical shape in HE membrane skeletons, disintegration of membrane skeletons after exposure to shear stress, defective self-association of spectrin dimers to tetramers, altered susceptibility of spectrin to tryptic digestion, and a deficiency of the membrane skeleton proteins spectrin and protein 4.1R. Gene cloning and determination of the primary structure of these proteins was soon followed by reports of mutations in the genes encoding erythrocyte membrane proteins.

Spectrin Mutations

The most common defects in HE, found in approximately two-thirds to three-quarters of all patients, are mutations of α- or β-spectrin. Both α- and β-spectrin are elongated flexible molecules consisting of triple-helical repeats connected by nonhelical segments. These polypeptides are associated side to side in an antiparallel position, forming a flexible, rod-like αβ heterodimer in which the NH_2-terminal of α-spectrin and the COOH-terminal of β-spectrin form the head region of the heterodimer. Spectrin heterodimers associate head to head to form spectrin tetramers, the major structural subunits of the membrane skeleton. Spectrin tetramers in turn are interconnected into a highly ordered two-dimensional lattice through binding, at their distal ends, to actin oligomers with the aid of protein 4.1R.

The contact site between the α- and β-spectrin chains of the opposed heterodimers is a combined "atypical" triple-helical repetitive segment in which the first two helices are contributed by the COOH-terminal of β-spectrin, whereas helix 3 is the first helical segment of α-spectrin. Spectrin dimer-tetramer interconversion is governed by a simple thermodynamic equilibrium that under physiologic conditions strongly favors spectrin tetramers. Most α-spectrin defects are at or near the NH_2-terminal of α-spectrin, which is involved in the heterodimer contact (the αI domain defined by limited tryptic peptide mapping; see the discussion under Laboratory Manifestations), and impair the self-association of spectrin into tetramers. Most α-spectrin mutations are point mutations. These mutations create abnormal proteolytic cleavage sites that typically reside in the third helix of a repetitive segment and give rise to abnormal tryptic peptides on two-dimensional tryptic peptide maps of spectrin.

Elliptocytogenic β-spectrin mutations are COOH-terminal point mutations or truncations that disrupt the formation of the combined β triple-helical repetitive segment and consequently the self-association of spectrin heterodimers to tetramers. All of these mutations open a proteolytic cleavage site residing in the third helix of the combined repetitive segment, which gives rise to a 74-kDa αI peptide.

Although most spectrin mutations reside in the vicinity of the αβ-spectrin self-association site, a few mutations remote from the self-association site have been described. These mutations are asymptomatic in the simple heterozygous state but cause hemolytic anemia, which can be severe, in homozygous patients. Unlike mutations located in the self-association contact site, which are predicted to disrupt the conformation of the local protein structure, mutations outside this region are predicted to perturb long-range protein-protein interactions, disrupting the positively coupled, cooperative interactions of αβ spectrin self-association, spectrin-ankyrin interactions, and ankyrin–band 3 interactions. One HE-associated mutation in a linker region remote from the self-association contact site disrupted the stability propagated from one spectrin repeat to the next.

Protein 4.1R Mutations

Another group of elliptocytogenic mutations, although much less common than spectrin mutations, are quantitative or qualitative

defects of protein 4.1R. Protein 4.1R is a multifunctional protein that contains several important sites of protein interactions, including the spectrin-binding domain, where 4.1R binds to the distal end of the spectrin αβ heterodimer, markedly increasing the binding of spectrin to oligomeric actin, and the basic NH_2-terminal domain, where 4.1R interacts with GPC, phosphatidylinositol, and phosphatidylserine, facilitating the attachment of the distal end of spectrin to the membrane.

Studies of 4.1R mRNA from normal red blood cells revealed 4.1R isoforms resulting from complex tissue- and developmental stage–specific patterns of alternate mRNA splicing. Alternate translation initiation sites are present in the protein 4.1R mRNA. When an upstream AUG is used, isoforms greater than 80 kDa are synthesized. During erythropoiesis, this upstream AUG is spliced out and a downstream AUG is used, leading to the production of the 80-kDa mature erythroid protein 4.1R isoform. On SDS-PAGE, protein 4.1R is resolved into two bands of different sizes: 4.1a and 4.1b. The larger band, 4.1a, is typically found in normal red blood cells, whereas the shorter one, 4.1b, represents the major isoform of reticulocytes. The 4.1b isoform is converted into the 4.1a isoform by deamidation of Asn 502.

A partial deficiency of protein 4.1R is associated with mild, dominantly inherited HE, whereas a complete deficiency (a homozygous state) leads to a severe hemolytic disease. Homozygous protein 4.1R(–) erythrocytes fragment more rapidly than normal at moderate sheer stresses, an indication of their intrinsic instability. Membrane mechanical stability can be restored by reconstituting the deficient red blood cells with protein 4.1R or the protein 4.1R/spectrin/actin-binding site. Homozygous protein 4.1R(–) erythrocytes also lack p55 and have only 30% of the normal content of GPC. These homozygous protein 4.1R(–) erythrocytes, as well as GPC-deficient Leach erythrocytes, demonstrate decreased invasion and growth of *Plasmodium falciparum* in vitro.

Mutations associated with protein 4.1R deficiency have included deletions that include the exon encoding the erythroid transcription start size and mutations of the transcription initiation codon. Qualitative defects of protein 4.1R protein include deletions and duplications of the exons encoding the spectrin-binding domain, leading either to truncated or elongated forms of protein 4.1R. Electron microscopic studies of homozygous protein 4.1R(–) erythrocyte membranes revealed a markedly disrupted skeletal network with disruption of the intramembrane particles, suggesting that protein 4.1R plays an important role in maintenance not only of the skeletal network but also of the integral proteins of the membrane structure.

Glycophorin C Deficiency

GPC has been found absent because of a variety of molecular defects. In contrast to other forms of HE, which are dominantly inherited, heterozygous carriers are asymptomatic, with normal red blood cell morphology, and homozygous subjects have no anemia and only mild elliptocytosis apparent on the peripheral blood film.

GPC deficiency with elliptocytosis, the so-called Leach phenotype, caused by reduced expression of GPC, should be distinguished from the immunochemically defined phenotypes Gerbich and Yus, in which abnormal glycoproteins are formed that can functionally substitute for normal GPC and preserve the normal red blood cell shape. The Leach phenotype is usually caused by a large deletion of genomic DNA (~7 kb) that removes exons 3 and 4 from the GPC/glycophorin D locus. In one patient, the Leach phenotype was caused by a frameshift mutation.

GPC-deficient subjects are also partially deficient in protein 4.1R and lack p55, presumably because these proteins form a complex and recruit or stabilize each other on the membrane. It has been speculated that the protein 4.1R deficiency in Leach erythrocytes is the cause of the elliptocytic shape. In contrast, subjects deficient in glycophorin A, the major transmembrane glycoprotein, are asymptomatic.

Membrane Effects

Most of the elliptocytogenic mutations of spectrin reside within, or in the vicinity of, the spectrin heterodimer self-association site, disrupting this region and consequently disrupting the two-dimensional integrity of the membrane skeleton (Fig. 43-7). These defects are detected by ultrastructural examination of the membrane skeleton, which reveals disruption of a normally uniform hexagonal lattice. Consequently membrane skeletons are mechanically unstable, as are whole cell membranes and the cells. In patients with severely dysfunctional spectrin mutations or patients homozygous or doubly heterozygous for spectrin mutations, the membrane instability is sufficient to cause red blood cell fragmentation with hemolytic anemia under conditions of normal circulatory shear stress.

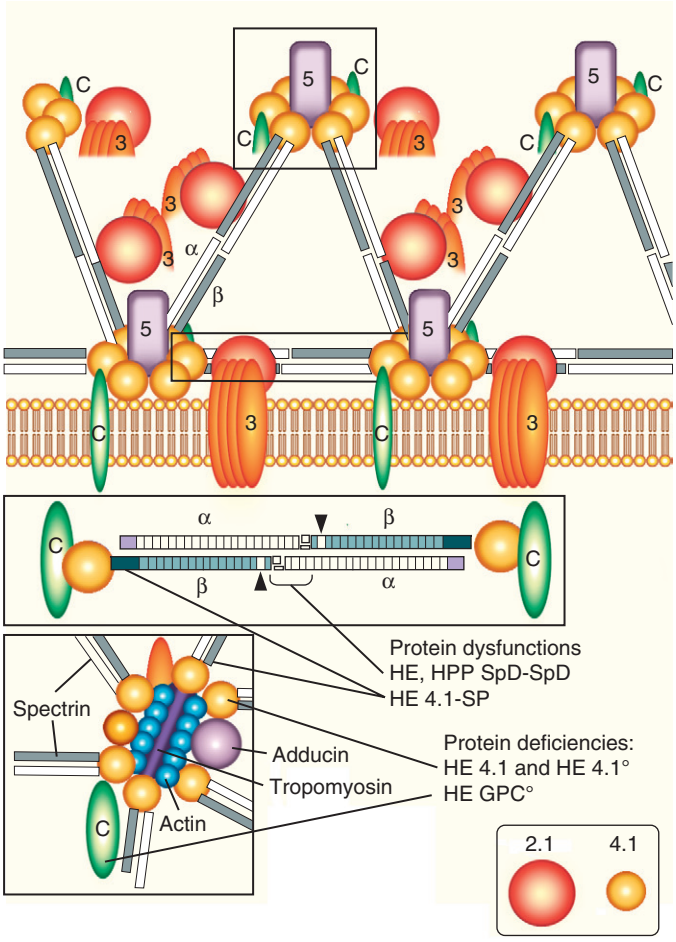

Figure 43-7 SCHEMATIC REPRESENTATION OF THE MOLECULAR ASSEMBLY OF THE MEMBRANE SKELETON AND THE MOLECULAR DEFECTS IN HEREDITARY ELLIPTOCYTOSIS (HE) AND HEREDITARY PYROPOIKILOCYTOSIS (HPP). Spectrin is composed of α- and β-spectrin heterodimers (SpD) that associate in their head regions into tetramers. At their distal ends, SpD bind to the junctional complexes of oligomeric actin (band 5 *[5]*) and protein 4.1. Additional proteins found in the junctional complex, such as adducin and tropomyosin, are shown in the lower enlarged area. The membrane skeleton is attached to transmembrane proteins by interactions of β-spectrin with ankyrin (protein 2.1; *[black arrowhead]* designates the ankyrin-binding site in β-spectrin), which in turn binds to the cytoplasmic domain of band 3 *(3),* and by linkage of protein 4.1 to glycophorin C (GPC). The known protein dysfunctions in HE and HPP include (1) defects of the SpD head region because of a mutation of either α- or β-spectrin, causing impaired assembly of SpD into tetramers, and (2) defects of proteins of the junctional complex such as a qualitative or quantitative defect of protein 4.1R or GPC. *SP,* Spectrin.

The pathobiology of the elliptocytic shape is less clear. Red blood cell precursors in common HE are round, and the cells become progressively more elliptical as they age in vivo. Red blood cells subjected to shear stress in vitro, or red blood cells flowing through microcirculation in vivo, have an elliptical or parachute-like shape, respectively. It is possible that elliptocytes and poikilocytes are permanently stabilized in their abnormal shape because the weakened spectrin heterodimer contacts facilitate skeletal reorganization, which follows axial deformation of cells resulting from application of a prolonged or excessive shear stress. This reorganization is likely to involve breakage of the unidirectionally stretched protein connections followed by the formation of new protein contacts that preclude the recovery of a normal biconcave shape. This process has been shown to account for permanent deformation of irreversibly sickled cells.

In HPP, the recessively inherited form of HE characterized by severe hemolysis, red blood cells have two abnormalities. They contain a mutant spectrin that characteristically disrupts spectrin heterodimer self-association, and they are also partially deficient in spectrin, as evidenced by a decreased spectrin/band 3 ratio. In some HPP cases, this biochemical phenotype is a consequence of a double heterozygous state for an elliptocytogenic α-spectrin mutation and a defect involving reduced α-spectrin synthesis. Such synthetic defect of α-spectrin is fully asymptomatic in the heterozygous carrier, because under normal conditions, the synthesis of α-spectrin is approximately three to four times greater than that of β-spectrin.

When present in conjunction with an elliptocytogenic mutation of α-spectrin, such a synthetic defect augments the expression of the mutant spectrin. Because the elliptocytogenic α-spectrin mutants are often unstable, the combination of the two defects leads to spectrin deficiency in the cells. Other HPP subjects are homozygous or doubly heterozygous for one or two elliptocytogenic spectrin mutations, respectively. In such cases, the spectrin deficiency may be a consequence of spectrin instability that reduces the amount of spectrin available for membrane assembly. Furthermore, in red blood cells containing a high fraction of unassembled dimeric spectrin, the spectrin deficiency may in part be related to the stoichiometric ratio of one ankyrin copy per one spectrin tetramer (i.e., two spectrin heterodimers). Consequently only approximately one-half of spectrin heterodimers succeed in attaching to the ankyrin-binding sites. The phenotype of HPP, characterized by the presence of fragments and elliptocytes, together with evidence of red blood cell surface area deficiency (as reflected by the presence of microspherocytes on the peripheral blood film), suggests that the membrane dysfunction involves both vertical interactions (a consequence of spectrin deficiency) and horizontal interactions involving the elliptocytogenic spectrin mutation.

The red blood cell lesion in protein 4.1R deficiency shows similarities in regard to cell shape and membrane stability to the elliptocytogenic mutations of spectrin, suggesting that the deficiency principally affects the spectrin-actin contact (see Fig. 43-7) rather than the skeleton attachment to GPC via protein 4.1R (a vertical interaction).

The molecular basis of elliptocytosis and the mechanical instability of GPC-deficient red blood cells are not fully understood. However, recent studies suggest that the deficiency of GPC is not directly responsible for the altered mechanical properties. Instead, the mechanical instability appears to be related to a concomitant partial deficiency of protein 4.1R, as evidenced by a full correction of membrane instability by introduction into the cells of protein 4.1R or its spectrin-binding peptide, which facilitates the contact of β-spectrin to actin. The superimposed deficiency of protein 4.1R is likely to be related to the fact that GPC serves as an attachment site for protein 4.1R to the membrane, recruiting protein 4.1R to the red blood cell membrane. The effects of these defects on the mechanical stability of GPC–deficient cells appear to be relatively minor, because GPC–deficient subjects have no detectable hemolytic anemia and the mechanical properties of the red blood cells are normal when tested by micropipette aspiration.

Inheritance

In most patients, HE is inherited as an autosomal dominant disorder. The clinical severity is highly variable among different kindreds (reflecting heterogeneous molecular lesions) and, to a lesser extent, within a given kindred, presumably because of other genetic or acquired defects that modify disease expression. Occasionally HE is inherited as an autosomal recessive condition from an asymptomatic parent who carries the same molecular defect of spectrin as the HE offspring. In one kindred with a submicroscopic chromosome X deletion, inheritance was X-linked.

The inheritance of the related disorder HPP is autosomal recessive: one of the parents carries the α-spectrin mutation and either is asymptomatic or has mild HE, whereas the other parent is fully asymptomatic and has no abnormalities detectable by current biochemical approaches. However, several HPP patients have recently been studied who were doubly heterozygous for two α-spectrin mutations; in the heterozygous parents, these mutations were either silent or expressed as mild HE.

Clinical Manifestations

In view of the striking molecular heterogeneity of common HE, it is not surprising that the clinical spectrum of this disorder is variable, ranging from an asymptomatic trait without hemolysis to a life-threatening hemolytic anemia.

Mild Hereditary Elliptocytosis and Asymptomatic Carrier State

In most of these subjects, HE is found accidentally during evaluation of the peripheral blood film. Although some HE subjects have a mild compensated hemolytic anemia, others do not have any evidence of hemolysis, their red blood cell survival is normal, and the peripheral blood film may reveal only modest (≥15%) elliptocytosis. The molecular basis of mild HE is heterogeneous, and the reported molecular defects include both α- and β-spectrin mutations, partial deficiency of the 4.1R protein, and the absence of GPC. Some individuals carrying the spectrin mutation are completely asymptomatic, including normal red blood cell morphologic features; this is often the case in one of the parents of a patient with HPP.

Hereditary Elliptocytosis With Sporadic Hemolysis

Worsening of hemolysis together with the appearance of poikilocytes on the peripheral blood film has been reported in patients with hypersplenism, infections, or vitamin B_{12} deficiency, as well as in those with microangiopathic hemolysis such as disseminated intravascular coagulation or thrombotic thrombocytopenic purpura. In the latter two conditions, worsening hemolysis can be caused by microcirculatory damage superimposed on the underlying mechanical instability of the red blood cells.

Hereditary Elliptocytosis With Neonatal Poikilocytosis

Neonatal offspring of parents with mild HE present with symptomatic hemolytic anemia and a marked poikilocytosis. During the first year of life, the hemolysis and poikilocytosis abate, and the clinical picture transforms into that of mild HE. Such patients typically carry one mutant α-spectrin allele. The severity of the molecular defect, in terms of the percentage of spectrin dimers and the amount of mutant spectrin in the cells, is the same in the neonatal period as it is later in life. The worsening of hemolysis in the neonatal period has been attributed to the presence of fetal hemoglobin, which binds poorly to 2,3-diphosphoglycerate (2,3-DPG). The ensuing elevation of free

2,3-DPG levels has a marked destabilizing effect on the spectrin–protein 4.1R–actin interaction, thereby further destabilizing the membrane skeleton.

Hereditary Elliptocytosis With Chronic Hemolysis

Patients with HE with chronic hemolysis present with moderate to severe hemolytic anemia with elliptocytes and poikilocytes on peripheral blood film; some require splenectomy. In some of the kindreds, the hemolytic HE has been transmitted through several generations. In some kindreds, not all of the HE subjects have chronic hemolysis; some have a mild hemolysis only, presumably because of another genetic factor modifying the disease expression.

Homozygous and Compound Heterozygous Hereditary Elliptocytosis

Several HE individuals have been described who were apparent homozygotes for the HE gene. These individuals were found to be either homozygotes or compound (double) heterozygotes for one or two α- or β-spectrin mutations. The clinical severity is variable, from a relatively mild hemolytic anemia to a severe, life-threatening disease, depending on the severity of the underlying molecular defect, and in some cases is indistinguishable from HPP.

Hereditary Pyropoikilocytosis

It is now established that HPP represents a subtype of common HE, as evidenced by the coexistence of both HE and HPP in the same family and by the presence of the same molecular defect of spectrin. Unlike HE subjects carrying the spectrin mutation, the red blood cells of HPP subjects are also partially deficient in spectrin. Typically one parent of the HPP offspring carries an α-spectrin mutation, whereas the other parent is fully asymptomatic and has no detectable biochemical abnormality. In many such patients the asymptomatic parent carries a silent "thalassemia-like" defect of spectrin synthesis, enhancing the relative expression of the spectrin mutant and leading to a superimposed spectrin deficiency in the HPP offspring. Subsequent studies of the original HPP kindred revealed that defective spectrin synthesis from the null allele was caused by a splicing mutation of the α-spectrin gene. Some HPP subjects inherited two α-spectrin mutations; either their parents were hematologically normal or one had mild HE. In these HPP subjects, spectrin deficiency may be related to instability of the mutant spectrin. The thermal instability of spectrin originally reported as diagnostic of HPP is not unique for this disorder; it is also found in HE subjects carrying this α-spectrin mutation, in the homozygous and in the heterozygous states. HPP is seen predominantly in black subjects, but it has also been diagnosed in Arabs and whites.

Molecular Determinants of Clinical Severity

The severity of hemolysis in common HE often varies not only among different kindred but within a given family as well. The two principal determinants of severity of hemolysis are the spectrin content of the cells and the percentage of dimeric spectrin in the crude spectrin extract. The fraction of dimeric spectrin in such extracts in turn depends on several factors. The first of them is the degree of dysfunction of the mutant spectrin. Typically mutations that are either within or near the combined αβ triple-helical repetitive segment representing the spectrin heterodimer self-association site produce a more severe clinical phenotype and a more severe defect of spectrin function than those seen with point mutations in the more distant triple-helical repeats. Second, the percentage of the dimeric spectrin depends on the fraction of the mutant spectrin in the cells, which in turn is determined by the gene dose (e.g., simple heterozygote versus homozygote or double heterozygote) or the presence of other genetic defects such as the presence, in trans, of a defect leading to a reduced α-spectrin synthesis in some subjects with HPP.

The low-expression α-spectrin allele α^{LELY} is the best-characterized abnormality affecting spectrin content and clinical severity. Initially a polymorphism of the αV domain, $\alpha^{V/41}$, was identified in HE patients who, when they inherited $\alpha^{V/41}$ in trans, had more severe HE than expected. Subsequently an amino acid substitution of exon 46, Leu1857Val, and partial skipping of exon 46, linked to the $\alpha^{V/41}$ polymorphism, were identified as the characteristics of the α^{LELY} allele. These abnormalities are located within the site at which spectrin monomers assemble into heterodimers (the spectrin heterodimer nucleation site). In vitro studies suggest that the inability of α-spectrin chains to assemble into the mature membrane skeleton is because of a combination of decreased αβ dimer-binding affinity and increased proteolytic cleavage of the mutant α-spectrin chains. The presence of α^{LELY} in trans diminishes the propensity of the otherwise normal allele to associate with the corresponding β-chain, favoring the attachment of the elliptocytogenic α-spectrin allele. Conversely, coexistence of the α-spectrin mutation in cis and the mutation involving the α-spectrin nucleation site diminishes the propensity of the mutant allele to be incorporated into the spectrin heterodimer, thereby ameliorating the clinical severity of this mutation. The α^{LELY} allele is clinically silent by itself, even when inherited in the homozygous state, probably because α-spectrin is normally synthesized in threefold to fourfold excess.

Laboratory Manifestations

Blood Film and Laboratory Evidence of Hemolysis

A careful blood smear evaluation is essential for the diagnosis of HE and for the classification of the disorder into the three major subtypes outlined earlier (see Hereditary Elliptocytosis and Related Disorders, Introduction and Epidemiology and Fig. 43-6). In patients in whom elliptocytosis is the only morphologic abnormality, hemolysis is characteristically minimal or absent, with the exception of spherocytic elliptocytosis, in which the presence of round "fat" ovalocytes is associated with accelerated red blood cell destruction. In patients with hemolytic forms of common HE, poikilocytosis is characteristically found on the blood film. In severe forms of HE, particularly in homozygous HE, many red blood cells circulate as cell fragments, producing a marked decrease in MCV. The finding of red blood cell fragments together with a striking microspherocytosis and often only occasional elliptocytes is characteristic of HPP (see Fig. 43-6).

Osmotic and Thermal Fragility

Osmotic fragility is increased in HPP, in spherocytic elliptocytosis, and in HE subjects with poikilocytosis apparent on the peripheral blood film. In patients with a mild common HE without poikilocytosis on the peripheral blood film, osmotic fragility is normal.

Thermal instability of red blood cells was originally reported as a characteristic feature of HPP. It reflects thermal instability of the mutant spectrin: In normal red blood cells, spectrin is denatured and red blood cells fragment at 50° C. HPP red blood cells fragment and their spectrin denatures at 41° C. However, the diagnostic value of this test is limited, because thermal instability of red blood cells is also noted in HE red blood cells containing mutant spectrin. In contrast, an occasional patient with otherwise typical HPP may have normal thermal stability of red blood cells and spectrin. Red blood cells in common HE have unstable membranes and membrane skeletons when subjected to shear stress.

Electrophoretic Separation of Solubilized Membrane Proteins

In HE and HPP, SDS-PAGE can reveal proteins of abnormal mobility, the origin of which can be subsequently identified by Western blotting (e.g., truncated α- or β-spectrins in HE and HPP, or elongated or truncated forms of the 4.1R protein, and a partial or, rarely, complete deficiency of the 4.1R protein in HE). In HPP, SDS-PAGE reveals a partial deficiency of spectrin, as indicated by a decreased spectrin/band 3 ratio. Spectrin deficiency, in conjunction with an elliptocytogenic spectrin mutation affecting the spectrin heterodimer contact, is invariably found in cases of HPP.

Nondenaturing Gel Electrophoresis of Low-Ionic-Strength Spectrin Extract

Analysis of the ratio of tetrameric and dimeric spectrin in the low-ionic-strength extracts reveals the most common functional abnormality in HE (i.e., weakened self-association of spectrin heterodimers into tetramers). Because the spectrin dimer-tetramer interconversion has a high activation energy, it is kinetically immobilized at near 0° C. Consequently the percentage of spectrin dimers and tetramers in the 0° C crude spectrin extract reflects the relative distribution of these species in the red blood cell membrane in situ. Mutations of α- or α-spectrin residing within or near the αβ-spectrin heterodimer self-association site invariably lead to an increase in the fraction of dimeric spectrin in the crude 0° C spectrin extract.

Tryptic Peptide Mapping of Spectrin and the Detection of the Underlying DNA Defect

Tryptic digestion of spectrin followed by electrophoretic separation gives rise to highly reproducible tryptic peptide patterns. Among these peptides, the 80-kDa αI domain peptide representing the self-association site of the normal α-spectrin is among the most prominent. Nearly all α- or β-spectrin mutations reported are associated with a formation of tryptic peptides of abnormal size and mobility that are generated from the normal 80-kDa αI domain peptide. The cleavage sites of the most common abnormal tryptic peptides are found in the third helix of a given triple-helical repetitive segment. The reported mutations reside in the vicinity of these cleavage sites either in the same helix or, less commonly, in helix 1 or 2 of a given repetitive segment. Consequently tryptic peptide mapping remains a powerful tool with which to map the site of the underlying spectrin mutation, which can be subsequently defined by polymerase chain reaction amplification and sequencing of the respective region of the genomic DNA or complementary DNA (cDNA).

Differential Diagnosis

Various acquired and inherited conditions can be associated with elliptocytosis and poikilocytosis, including iron deficiency, thalassemias, megaloblastic anemias, myelofibrosis, myelophthisic anemias, myelodysplastic syndromes, and pyruvate kinase deficiency. The percentage of elliptocytes in these conditions is seldom greater than 60%. However, this is not diagnostically useful, because some HE subjects can have a relatively low percentage of elliptocytes. In normal subjects the percentage of elliptocytes is not greater than 5%, although in earlier reports it was listed as high as 15%. Previous diagnostic criteria of HE, based on the percentage of elliptocytes, such as 25%, 33%, or 40%, and their axial ratio, do not appear useful. The most reliable differentiation of HE from the other conditions mentioned is based on a positive family history rather than on the percentage of elliptocytes.

Therapy and Prognosis

As in the case of HS, red blood cells from patients with more severe forms of HE are retained by the spleen, producing a marked engorgement of splenic pulp. Consequently patients with symptomatic hemolysis benefit from splenectomy. This procedure is virtually never indicated in heterozygotes with autosomal dominant HE because most do not have clinically significant hemolytic anemia. If hemolysis is still active after splenectomy, folate should be administered daily. Recommendations for antibiotic prophylaxis, immunizations, and monitoring for intercurrent illnesses are similar to those noted earlier for HS patients before and after splenectomy. Serial interval ultrasonographic investigations to detect gallstones should be performed in patients with significant hemolysis.

Spherocytic Elliptocytosis

Spherocytic elliptocytosis, which shares features of HS and HE, has been designated spherocytic HE, HE with spherocytosis, or hereditary hemolytic ovalocytosis. The diagnosis is based on the simultaneous presence of elliptical red blood cells and spherocytes or "fat," round sphero-ovalocytes in the peripheral blood film (see Fig. 43-6). In contrast to common HE, cells of other shapes, such as rod-shaped cells, poikilocytes, and fragments, are absent. Importantly, hemolysis, despite relatively mild alterations in red blood cell morphologic features, and increased osmotic fragility are the main diagnostic features distinguishing this disorder from common HE.

The molecular basis of spherocytic HE is unknown. However, patients with mutations, particularly truncations at the C-terminal of β-spectrin, have many of the clinical features of spherocytic HE and probably represent an example of this disorder. Patients who lack GPC have rounded, smooth elliptocytes and could be classified as having a mild, recessively inherited variant of spherocytic HE. Finally, some patients with recessively inherited defects of protein 4.2 can display some features of spherocytic HE, particularly mild ovalostomatocytosis.

Southeast Asian Ovalocytosis

Southeast Asian ovalocytosis is characterized by the presence of oval red blood cells, many containing one or two transverse ridges or a longitudinal slit (see Fig. 43-6). The condition is widespread in certain ethnic groups of Malaysia, Papua New Guinea, the Philippines, and Indonesia. Numerous functional abnormalities of ovalocytes have been reported, including increased red blood cell rigidity, decreased osmotic fragility, increased thermal stability, resistance to shape change by echinocytogenic agents, and a reduced expression of many red blood cell antigens. A remarkable feature of ovalocytes is their resistance to in vitro invasion by several strains of malaria parasites, including *Plasmodium falciparum* and *Plasmodium knowlesi*. Moreover, in areas of endemic malaria, the ovalocytic subjects have reduced numbers of intracellular parasites in vivo. In these regions there is a decrease in the prevalence and in the disease severity of malaria in patients with SAO compared with control subjects.

All SAO individuals are heterozygotes for two band 3 gene mutations in cis: the deletion of nine codons encoding amino acids 400 through 408 from the boundary of the cytoplasmic and membrane domains of band 3, and the 56 Lys to Glu substitution. The 56 Lys to Glu substitution represents an asymptomatic polymorphism known as band 3 Memphis. The SAO phenotype is associated with a tighter binding of band 3 to ankyrin, increased tyrosine phosphorylation of the band 3 protein, inability to transport sulfate anions, and a markedly restricted lateral and rotational mobility of band 3 protein in the membrane.

Laboratory Manifestations

The finding of 30% or greater of oval red blood cells on the peripheral blood film, some containing a central slit or a transverse ridge, in the context of a notable absence of clinical and laboratory evidence of hemolysis in a subject from the ethnic groups noted earlier is highly suggestive of the diagnosis. A useful screening test is the demonstration of the resistance of ovalocytes or their ghosts to changes in shape produced by treatments that produce spiculation in normal cells, such as metabolic depletion or exposure of ghosts to salt solutions. In contrast to normal red blood cells, which form spicules in response to such stimuli, SAO red blood cells or ghosts do not change shape after these treatments. The mechanism of this resistance to changes in shape is not clear, and it may reflect the high rigidity of the red blood cell membrane.

Because the underlying cause of SAO is the deletion of 27 bases from the band 3 gene, isolation of genomic DNA or reticulocyte cDNA with subsequent amplification of the deletion-containing region appears to be the most specific test for establishing the diagnosis of SAO. Interestingly, this mutation appears to be lethal in the homozygous state, because large screens of individuals from indigenous areas have only identified heterozygotes.

Molecular Basis of Southeast Asian Ovalocytosis Membrane Rigidity and Malaria Resistance

The red blood cells of SAO are unique among axially deformed cells in that they are rigid and hyperstable rather than unstable. The SAO mutation is the first example of a defect of an integral membrane protein leading to red blood cell membrane rigidity, an observation previously attributed to properties of the membrane skeleton. The basis of the increased rigidity is unclear.

The molecular basis of malaria resistance of SAO red blood cells is likely related to altered properties of the band 3 protein, which serves as one of the malaria receptors, as evidenced by the inhibition of in vitro invasion by band 3–containing liposomes. In normal red blood cells, the invasion process is associated with a marked membrane remodeling that involves redistribution of intramembrane particles that contain band 3 protein. Such particles cluster at the site of parasite invasion, forming a ring around the orifice through which the parasite enters the cell. The invaginated red blood cell membrane, which surrounds the invading parasite, is free of intramembrane particles. The reduced lateral mobility of band 3 protein in SAO red blood cells may preclude band 3 receptor clustering, thereby preventing the attachment of the parasites to the cells. Decreased exchange of anions across the red blood cell membrane has also been proposed to contribute to the resistance of ovalocytes to malaria invasion. In addition, SAO red blood cells consume ATP at a higher rate than normal cells, and the partial depletion of ATP levels in ovalocytes has been suggested to account, at least in part, for the resistance of these cells to malaria invasion in vitro.

Acanthocytosis and Related Disorders

Acanthocytes (from the Greek *acantha,* "thorn") or spur cells are red blood cells with prominent thorn-like surface protrusions that vary in width, length, and surface distribution. Spur cells must be distinguished from echinocytes (Greek *echinos,* "sea urchin") or burr cells, characterized by multiple small projections that are uniformly distributed throughout the cell surface (Fig. 43-8). Acanthocytes should also be distinguished from keratocytes ("horn" red cells) that have few massive protuberances.

Acanthocytosis was first described in cases of abetalipoproteinemia and subsequently in severe liver disease, the chorea-acanthocytosis syndrome, the McLeod blood group phenotype, and other

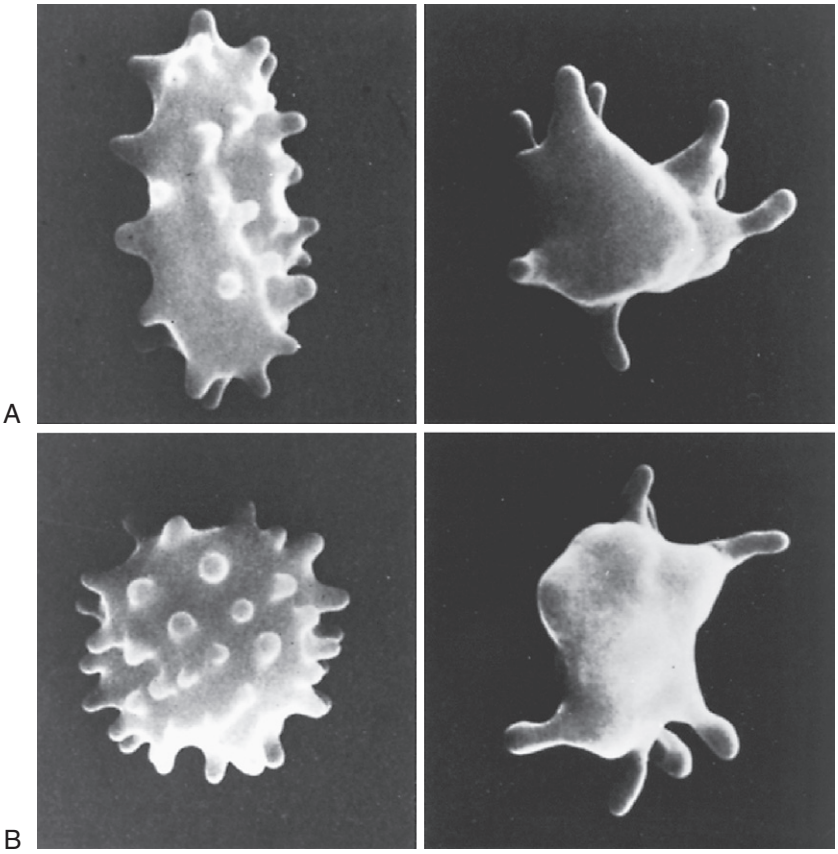

Figure 43-8 MORPHOLOGIC DIFFERENCES BETWEEN ACANTHOCYTES **(A)** AND ECHINOCYTES **(B)** AS DEMONSTRATED BY SCANNING ELECTRON MICROSCOPY. *(Modified from Bessis M:* Red cell shapes: An illustrated classification and its rationale, *New York, 1973, Springer-Verlag.)*

conditions. The molecular mechanisms leading to acanthocytosis in abetalipoproteinemia and severe liver disease have been extensively studied and have been attributed to changes in composition of membrane lipids and their altered distribution between the two hemileaflets of the lipid bilayer.

Spur Cell Hemolytic Anemia of Severe Liver Disease

Spur cell hemolytic anemia is an uncommon ominous complication of severe liver disease that is manifested by rapidly progressive hemolytic anemia and acanthocytes on the peripheral blood smear.

Pathobiology

The human red blood cell membrane contains nearly equal amounts of free (unesterified) cholesterol and phospholipids. The free cholesterol in the plasma readily equilibrates with the red blood cell membrane cholesterol pool. This is in contrast to esterified cholesterol, which cannot be transferred from plasma into the red blood cell membrane. The plasma of patients with severe liver disease contains abnormal lipoproteins that have a high free cholesterol/phospholipid ratio. The excess free cholesterol readily partitions into the red blood cell membrane, leading to a marked increase in free cholesterol in the cells. Consequently normal cells can develop a spur cell shape after their transfusion into a patient with severe liver disease or after incubation with the liver disease patient's plasma or cholesterol-enriched liposomes.

Spur cell formation involves two steps (Fig. 43-9). The first step is evident in red blood cells of splenectomized subjects with spur cell hemolytic anemia: Red blood cells have an expanded surface area with irregular contour and targeting, reflecting accumulation of free cholesterol in the membrane. This extra cholesterol accumulates preferentially in the outer bilayer leaflet, as suggested by findings of increased accessibility of cholesterol to cholesterol oxidase and a selective decrease in lipid fluidity of the outer hemileaflet of the lipid bilayer.

The second step in acanthocyte formation involves red blood cell remodeling by the spleen. As a result, red blood cells become spheroidal, and the surface projections are considerably longer and more irregular (see Fig. 43-9). The end result of these processes is poorly deformable red blood cells with long bizarre projections that are readily trapped in the spleen, which is often markedly enlarged because of passive congestion as a result of underlying portal hypertension. Cholesterol also alters membrane permeability and interacts with several membrane skeletal proteins, but the role of these changes in spur cell lesions is unclear.

Clinical Manifestations

Most patients with chronic liver disease have a mild to moderate anemia related to gastrointestinal blood loss, iron and folic acid deficiencies, or hemodilution or as a direct effect of alcohol on red blood cell precursors. Peripheral blood smears from these patients often reveal target cells that are particularly prominent in obstructive jaundice.

In some patients, particularly those with end-stage liver disease, anemia rapidly worsens and spur cells appear in high percentage in the peripheral blood. This is accompanied by worsening jaundice, rapid deterioration of liver function, hepatic encephalopathy, and hemorrhagic diatheses. A similar clinical syndrome has been described in patients with advanced metastatic liver disease, cardiac cirrhosis, Wilson disease, fulminant hepatitis, and infantile cholestatic liver disease. The development of spur cell hemolytic anemia is an ominous sign in most patients, predicting a survival seldom exceeding weeks to months. In theory, splenectomy could provide a marked improvement, because the spleen is the major sequestration site of nondeformable acanthocytes; in reality, splenectomy is seldom considered because of severity of the underlying liver disease.

Abetalipoproteinemia

Bassen and Kornzweig first described an association of acanthocytosis with atypical retinitis pigmentosa, progressive ataxic neurologic disease, and a "celiac disease" later attributed to fat malabsorption. Subsequently several investigators reported a congenital absence of β-lipoprotein, accounting for the diverse manifestations of the disorder.

Pathobiology

Abetalipoproteinemia is an autosomal recessive disorder found in people of diverse ethnic backgrounds. The primary molecular defect involves a congenital absence of β-apolipoprotein in plasma. The B apoproteins (B100 and B48) are generated by alternate transcription of a single gene residing on the short arm of chromosome 2. Their

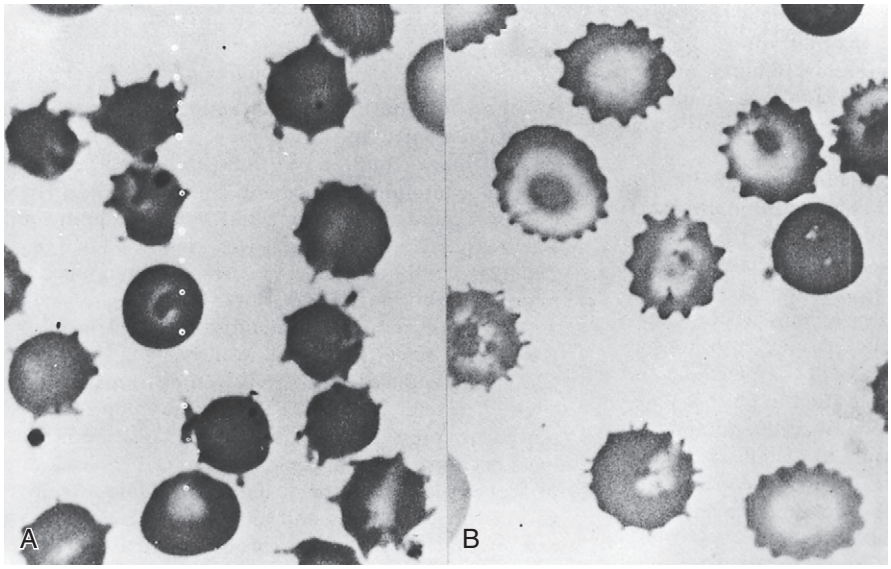

Figure 43-9 BLOOD FILM OF A PATIENT WITH LIVER CIRRHOSIS AND SPUR CELL ANEMIA BEFORE **(A)** AND AFTER **(B)** SPLENECTOMY. The latter smear demonstrates the effect of cholesterol acquisition leading to targeting (indicating increase in surface area) and irregularities in cell contour. The conditioning effect of the spleen **(A)** is demonstrated by the spheroidal shape of the cells and the remodeling of the spicules. *(From Cooper RA, Kimball DB, Durocher JR: The role of the spleen in membrane conditioning and hemolysis of spur cells in liver disease.* N Engl J Med *290:1279, 1974.)*

deficiency is secondary to defective cellular secretion of the apoprotein by liver cells, caused either by aberrant posttranslational processing or by defective aposecretion. In some patients this is because of qualitative or quantitative defects in the microsomal triglyceride transfer protein, which catalyzes the transport of triglyceride, cholesterol ester, and phospholipid from phospholipid surfaces. Microsomal triglyceride transfer protein is the only tissue-specific component, other than apolipoprotein B, required for secretion of apolipoprotein B–containing lipoproteins. As a result, apoprotein B is absent in plasma, as are the individual lipoprotein fractions that contain this apoprotein. These lipoprotein fractions include chylomicrons and very-low-density lipoproteins that transport triglycerides, as well as the low-density lipoproteins that are products of very-low-density lipoproteins and transport cholesterol. Consequently, preformed triglycerides are not transported from the intestinal mucosa, and they are nearly absent in the plasma. Plasma cholesterol and phospholipids are markedly reduced, with a relative increase in sphingomyelin at the expense of lecithin.

As is the case in acanthocytosis of liver disease, the acanthocytic lesion is acquired from the plasma. Erythrocyte precursors are of normal shape, and the acanthocytic lesion develops as the cells mature and age in the circulation. Normal cells acquire this shape when transfused into the recipient.

The most striking abnormality of red blood cell membrane lipids involves a net increase in sphingomyelin. Because plasma lipids readily exchange with the lipids of the red blood cell membrane, it is likely that this change simply mirrors the alterations in plasma lipid composition. In contrast to red blood cells in spur cell anemia of severe liver disease, the content of membrane cholesterol is normal or only slightly increased.

The role of membrane lipids in the acanthocyte shape transformation was first established by findings of restoration of biconcave shape after extraction of lipids from the cell membrane by detergents. The molecular basis of the acanthocytic shape is unknown, but several indirect observations suggest that it is related to an increase of the surface area of the outer hemileaflet of the lipid bilayer relative to the inner leaflet. Several other abnormalities have been noted in abetalipoproteinemia, including a decrease in plasma lecithin cholesterol transferase activity and an increased susceptibility of membrane and plasma lipids to oxidation as a result of malabsorption-induced deficiency of vitamin E. The contributions of these abnormalities to the acanthocyte red cell lesions are unknown.

Clinical Manifestations

This autosomal recessive disease can become evident in the first few months of life, manifested by fat malabsorption with normal absorption of other nutrients. Intestinal biopsy is diagnostic, revealing engorgement of mucosal cells with lipid droplets. Other features include retinitis pigmentosa and a progressive ataxia with intention tremors that usually develops at 5 to 10 years of age, progressing to death in the second or third decade of life. The hematologic manifestations are mild and include mild normocytic anemia with acanthocytosis (50% to 90%) and normal or slightly elevated reticulocyte counts. Occasional patients can have more severe anemia resulting from the nutritional deficiencies (iron and folate) that accompany fat malabsorption. The treatment includes dietary restriction of triglycerides and supplementation with the lipid-soluble vitamins A, K, D, and E. Vitamin E can stabilize or even improve both the retinal and neuromuscular abnormalities.

Autosomal recessive abetalipoproteinemia should be distinguished from the homozygous form of familial hypobetalipoproteinemia. Although the clinical presentation of both disorders is similar, the latter disorder is milder, and the parents have occasional acanthocytes on the peripheral blood film, and their plasma low-density lipoprotein levels are decreased. The molecular lesions in familial hypobetalipoproteinemia involve a variety of apoprotein B gene mutations, leading to aberrant apoprotein B gene transcription or translation.

Varying degrees of acanthocytosis without anemia have also been described with isolated deficiency of apoprotein B100.

Neuroacanthocytosis Syndromes

The neuroacanthocytosis syndromes are a group of degenerative neurologic disorders with phenotypic and genetic heterogeneity that share the feature of acanthocytes on peripheral blood smear. These disorders include chorea-acanthocytosis, the X-linked McLeod syndrome (see McLeod phenotype), and several other neurodegenerative diseases, including Huntington disease-like 2 caused by mutations in junctophilin-3 and pantothenate kinase–associated neurodegeneration (formerly known as Hallervorden-Spatz syndrome and its allelic variant syndrome—hypobetalipoproteinemia, acanthocytosis, retinitis pigmentosa, pallidal degeneration [HARP]) caused by mutations in pantothenate kinase 2.

Chorea-acanthocytosis syndrome is an autosomal recessive syndrome of adult onset that is manifest by multiple neurologic abnormalities, including limb chorea, progressive orofacial dyskinesia with tics, tongue-biting neurogenic muscle hypotonia, and atrophy. The hematologic manifestations are minimal and include a variable percentage of acanthocytes on the peripheral blood film without anemia and normal or only slightly decreased red blood cell survival. The mechanism of acanthocytosis in this syndrome is unknown. Studies of plasma and red blood cell membrane lipids have revealed a high content of unsaturated fatty acids, presumably accounting for reduced red blood cell membrane fluidity. Additional abnormalities of uncertain significance include an uneven distribution of intramembrane particles, impaired phosphorylation of the erythrocyte actin-bundling protein dematin, abnormal accumulation of transglutaminase products, and altered function and structure of band 3.

Mutations have been identified in the chorein gene (also known as CHAC or VPS13A—vacuolar protein sorting 13 homolog A) in many affected patients. Chorein does not belong to any known human gene family, and computer searches have not identified any known structural motifs or domains. The function of the chorein gene product remains unknown in either erythrocytes or the brain. In yeast, a chorein homologue is involved in protein sorting and transport.

McLeod Phenotype

The McLeod syndrome is characterized by a mild compensated hemolytic anemia with a variable percentage of acanthocytes on the peripheral blood film and, in some patients, late-onset myopathy or chorea. The McLeod blood group phenotype is an X-linked anomaly of the Kell blood group system in which red blood cells, white blood cells, or both react poorly with Kell antisera. The affected cells lack Kx, the product of the XK gene, which appears to be a membrane precursor of the Kell antigens. The XK gene encodes a novel 444–amino acid integral membrane transporter. As expected, Kx is defective in McLeod patients. Male hemizygotes who lack Kx have variable acanthocytosis (8% to 85%) and mild, compensated hemolysis. Because of the red blood cell mosaicism predicted by the Lyon hypothesis of X chromosome inactivation, female heterozygote carriers can have occasional acanthocytes on the peripheral blood film. Lyonized women with more severe symptoms have been described. Because of the susceptibility to alloimmunization, it is important to diagnose affected patients because if they are transfused, they can develop antibodies compatible only with McLeod red cells.

The McLeod syndrome has been reported in association with chronic granulomatous disease of childhood, retinitis pigmentosa, and Duchenne muscular dystrophy. This association is caused by the close proximity of the genetic loci for these disorders in the p21 region of the X chromosome (Xp21), suggesting the occurrence of various manifestations because of contiguous gene syndromes. This

may explain the occasional findings of either echinocytes or stomatocytes in Duchenne dystrophy, or a choreiform disorder in some subjects with the McLeod phenotype.

The Kell antigen consists of two protein components: a 37-kDa protein that carries the Kx antigen, a precursor molecule necessary for the Kell antigen expression, and a 93-kDa protein that carries the Kell blood group antigen. Red blood cells with the McLeod phenotype have no detectable Kx antigen, and they have a marked deficiency of the 93-kDa protein that carries the Kell antigen. McLeod red blood cells should be distinguished from Kell null (K_0) red blood cells, which have a normal shape. In K_0 cells, only the Kell antigen carrying the 93-kDa glycoprotein is absent, whereas these cells have twice the amount of the Kx antigen. As in the other acanthocytic disorders, the surface projections of acanthocytes may be related to asymmetry of the surface area of the two lipid bilayer hemileaflets, as indicated by correction of the acanthocytosis by agents that expand the inner lipid layer, as well as the finding of an increased rate of exchange of phosphatidylcholine (localized preferentially in the outer lipid hemileaflet) with an exogenous source.

Acanthocytosis in Other Conditions

Acanthocytes have also been noted in malnourished patients, including those with anorexia nervosa and cystic fibrosis. In these patients, red blood cell shape normalizes after restoration of the nutritional status. Likewise, a small number of cells with long spicules resembling acanthocytes are found in patients with hypothyroidism, after splenectomy, and with myelodysplasia.

Differentiation of Acanthocytes From Other Spiculated Red Blood Cells

Echinocytes (Burr Cells)

In contrast to acanthocytes, echinocytes, also called burr cells, have rather uniform surface projections. Although early echinocytic forms have a regularly scalloped cell contour, advanced forms of echinocytes have a spheroidal shape and the surface projections appear as short, narrow spikes (see Fig. 43-8). Although the finding of echinocytes on a peripheral blood film is often an artifact related to blood storage, contact with glass, or an elevated pH, several hemolytic anemias have been reported in association with echinocytosis on peripheral blood films. These conditions include mild hemolytic anemia in long-distance runners and in patients with hypomagnesemia and hypophosphatemia (presumably because of decreased intracellular ATP stores), uremia because of an unknown plasma factor, and pyruvate kinase deficiency.

Inspection of wet blood preparations (but not dried blood films) reveals echinocytosis in most patients with liver disease. In contrast to spur cells in patients with severe liver disease, these echinocytes have a normal cholesterol content, and the molecular abnormality may be related to the binding of abnormal echinocytogenic high-density lipoproteins to the red blood cell surface.

The mechanisms of echinocytosis in these diverse disorders are likely to be heterogeneous, as suggested by findings that many diverse factors, such as exposure of red blood cells to certain drugs, calcium loading, or ATP depletion, can induce the transformation of discocytes to echinocytes in vitro. However, in vitro studies of the discocyte-echinocyte-stomatocyte equilibrium have suggested a possible common denominator. As discussed earlier, the lipid bilayer of normal red blood cells is asymmetric in lipid composition: The outer half of the lipid bilayer is relatively enriched in sphingomyelin and phosphatidylcholine, whereas the inner half is preferentially enriched in the negatively charged phosphatidylserine and phosphatidylethanolamine. Agents that preferentially bind to one or another class of these phospholipids dramatically influence red blood cell shape. Consequently agents that preferentially accumulate in the outer half of the red blood cell lipid bilayer, expanding this lipid bilayer, produce an echinocytic shape, presumably by creating an asymmetry between the two surface areas of the two halves of the lipid bilayer. Conversely, agents that asymmetrically expand the inner half of the lipid bilayer, such as chlorpromazine, lead to stomatocytic shape transformation. In the case of echinocytes produced by ATP depletion or calcium loading, the altered phospholipid distribution between the two bilayer hemileaflets may be a consequence of calcium-induced phospholipid scrambling or a decrease in the activity of aminophospholipid translocase, an ATP-dependent enzyme that actively translocates aminophospholipids from the outer leaflet to the inner hemileaflet.

Keratocytes, Bizarre Poikilocytes, and Schistocytes

Mechanical trauma of circulating red blood cells has occasionally produced bizarre shapes resembling acanthocytes, such as cells with horny projections (keratocytes). Some acanthocyte-like cells are also seen in splenectomized HE and HS subjects. Similar shape changes are seen in heated red blood cells, in which spectrin has been damaged by thermal denaturation, suggesting that these cells are bizarre poikilocytes rather than true acanthocytes.

RED BLOOD CELL MEMBRANE DISORDERS MANIFESTED BY TARGET CELL FORMATION

The common feature of target cells is an increase in the ratio of the cell surface area to cell volume. In microcytic red blood cells of patients with various forms of thalassemia and hemoglobinopathies, the increased surface to volume ratio, and consequently the target cell shape, reflect at least in part the relative abundance of cell surface area. In liver disease and other disorders discussed subsequently, the target cell formation reflects an absolute expansion of the cell surface area because of a net accumulation of membrane phospholipids and cholesterol.

Liver Disease

The presence of target cells in association with either normal or slightly increased cell volume is characteristically found in patients with obstructive jaundice, including various forms of liver disease associated with intrahepatic cholestasis. These target cells have a normal survival in the peripheral circulation and do not typically account for the anemias often encountered in patients with liver disease.

In these patients, target cell formation is a consequence of a net uptake of both free cholesterol and phospholipids into the red blood cell membrane from the plasma because of abnormalities in the cholesterol/phospholipid/protein ratios of low-density lipoproteins. Target cells have a decreased osmotic fragility, because the excess of membrane surface area leads to an increase in the critical hemolytic volume.

Lecithin-Cholesterol Acyltransferase Deficiency

The lecithin-cholesterol acyltransferase (LCAT) enzyme catalyzes the transfer of fatty acids from phosphatidylcholine to cholesterol. It circulates in plasma as a complex with components of high-density lipoproteins. LCAT deficiency is a rare autosomal dominant disorder manifested by hyperlipidemia, premature atherosclerosis, corneal opacities, chronic nephritis, proteinuria, mild anemia, and the presence of target cells on the blood film. The anemia is caused by mild hemolysis together with a diminished compensatory erythropoiesis. As in obstructive jaundice, the target cells in LCAT deficiency have a marked increase in both cholesterol and phospholipids. In addition, the membrane phosphatidylcholine is increased at the expense of sphingomyelin and phosphatidylethanolamine. Bone marrow

aspiration and biopsy reveal the presence of sea-blue histiocytes. Analysis of plasma lipoproteins reveals multiple abnormalities secondary to the underlying enzyme deficiency. Inherited LCAT deficiency should be distinguished from an acquired deficiency of this enzyme, which is found in patients with severe liver disease.

Stomatocytosis and Related Disorders

Stomatocytes were first described in a girl with dominantly inherited hemolytic anemia. On blood films, her red blood cells contained a wide transverse slit or stoma (Fig. 43-10). In a three-dimensional view, these cells have a shape of a cup or a bowl. The slit-like appearance is an artifact that results from folding of the cells during blood smear preparation.

Stomatocytes are seen in a variety of acquired and inherited disorders. The latter are often associated with abnormalities in red blood cell cation permeability that lead to changes in red blood cell volume, which can be either increased (hence the designation hydrocytosis or overhydrated stomatocytosis) or decreased (desiccytosis [dessicate] or xerocytosis), or in some cases near normal.

There is no unifying theory to explain this morphologic abnormality. In vitro, stomatocytes can be produced by drugs that preferentially intercalate into the inner half of the asymmetric lipid bilayer, expanding its surface area relative to that of the outer half of the bilayer.

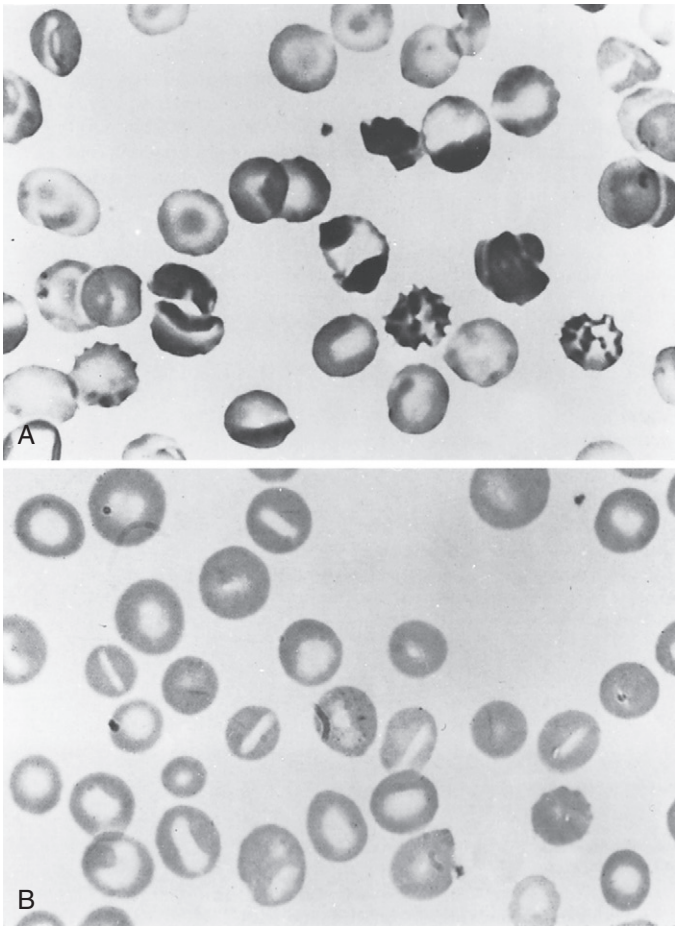

Figure 43-10 PERIPHERAL BLOOD SMEAR OF A PATIENT WITH HEREDITARY XEROCYTOSIS (DESICCYTOSIS) **(A)** AND STOMATOCYTOSIS (HYDROCYTOSIS) **(B)**. *(From Lande WM, Mentzer WC: Haemolytic anaemia associated with increased cation permeability.* Clin Haematol *14:89, 1985.)*

Hereditary Stomatocytosis-Hydrocytosis

Hereditary hydrocytosis designates a heterogeneous group of hereditary hemolytic anemias that are transmitted in an autosomal dominant manner. The disorder is characterized by a moderate to severe hemolytic anemia with 10% to 30% stomatocytes (see Fig. 43-10), an elevated MCV, and a reduced MCHC. Osmotic fragility of red blood cells is markedly increased, as some of the swollen red blood cells approach their critical hemolytic volume. For unexplained reasons, red blood cell membrane lipids and consequently membrane surface area are also increased, but this increase in surface area is insufficient to correct the osmotic fragility of the red blood cells. Red blood cell deformability is decreased.

The principal cellular lesion involves a marked increase in intracellular sodium and water content with a mild decrease in intracellular potassium as a result of a marked sodium influx into the red blood cells. Despite a marked compensatory increase in active transport of sodium (Na) and potassium by the Na^+/K^+-ATPase (which normally maintains the low sodium and high potassium concentrations in the cells) and an ensuing increase in glycolysis, the pump hyperactivity is unable to compensate for the vastly increased sodium leak. Stomatin (also known as band 7.2b), an integral membrane protein, is decreased or absent from the erythrocyte membranes of most affected patients. This deficiency appears to be a maturational loss in the bone marrow and in the circulation, perhaps because of a defect in cellular trafficking. Stomatin gene mutations have not been found in unrelated stomatocytosis patients deficient in this protein.

In some patients with hereditary hydrocytosis, missense mutations in RhAG, I61R or F65S have been found. In oocytes these mutations induce a monovalent cation leak, possibly opening the pore of an ammonium transporter. Additional studies suggest that the F65S mutation exhibits a gain-of-function phenotype with increased cation conductance/permeability.

Splenectomy can improve, but not fully correct, the hemolysis. In some patients, splenectomy can be deleterious or even contraindicated (see later), perhaps because of altered endothelial cell adherence and membrane phospholipid asymmetry.

Hereditary Xerocytosis and the Intermediate Syndromes

Hereditary xerocytosis or desiccytosis describes an autosomal dominant hemolytic anemia characterized by red blood cell dehydration and decreased osmotic fragility. Affected individuals have characteristically moderate to severe hemolysis with an increased MCHC, reflecting cellular dehydration. Hydrops fetalis with fetal anemia or fetal ascites has been reported in a number of xerocytosis kindreds. Frequently the MCV is mildly increased. In Coulter-type electronic counters, the conversion of pulse height (from the resistance of a cell passing through an electric field) to a cellular volume is dependent on cell shape. Xerocytes do not deform to the same degree as normal cells, which causes the MCV to be approximately 10% too high. The peripheral blood film (see Fig. 43-10) does not always reveal stomatocytes (which are more prominent on wet films), but frequently target cells, dessicytosis (dessicate), and spiculated cells are seen. In some of the cells, hemoglobin is concentrated ("puddled") in discrete areas on the cell periphery.

The mechanism of cellular dehydration is unclear and complex, involving a net potassium loss from the cells that is not accompanied by a proportional gain of sodium. Consequently the net intracellular cation content and cell water are decreased. In some reports a decrease in red blood cell 2,3-DPG has also been noted. The gene for xerocytosis has been mapped to 16q23-q24. A clinical syndrome of xerocytosis, perinatal ascites, and pseudohyperkalemia has been described. Genetic studies of patients with this constellation of disorders and with isolated pseudohyperkalemia also show linkage to this region.

Some of the reported cases of hereditary stomatocytosis share features of both hereditary stomatocytosis and xerocytosis categorized as "intermediate" syndromes. These patients characteristically have

both stomatocytes and some target cells on the peripheral blood smear. Osmotic fragility is either normal or slightly increased. Sodium and potassium permeability is somewhat increased, but the intracellular cation concentration and the red blood cell volume are either normal or slightly reduced. These cells were reported to have subnormal glutathione content. In some patients, red blood cells undergo in vitro hemolysis at 5° C, hence the designation *cryohydrocytosis*. A similar susceptibility to cold-induced cation permeability in which potassium and water loss predominates and xerocytes instead of hydrocytes are present, has also been described.

A study of stomatocytosis, spherocytosis, and spherostomatocytosis patients whose erythrocytes demonstrated significant cation leaks at 0° C and in some cases, band 3–deficient membranes, revealed a series of missense mutations located in an intramembrane domain of band 3. In vitro studies suggest that these mutations convert band 3 from an anion exchanger to a nonselective cation leak channel.

Several investigators have also reported a dominantly inherited hemolytic anemia with stomatocytosis, occasional target cells, spherocytes, and a decreased osmotic fragility in which the main red blood cell membrane abnormality involved a nearly 50% increase in phosphatidylcholine and a corresponding decrease in phosphatidylethanolamine. Because abnormalities in membrane phospholipid composition have not been systematically investigated, it is uncertain whether the disorder represents a distinct disease entity.

The results of splenectomy in this group of disorders are variable. In some patients the hemolytic anemia is improved, although often not fully corrected, by splenectomy, whereas in others the severity of the hemolysis is unchanged. Splenectomy should be carefully considered in patients with hereditary stomatocytosis. Several patients with stomatocytosis (both hydrocytosis and xerocytosis) have developed hypercoagulability after splenectomy, leading to catastrophic thrombotic episodes or chronic pulmonary hypertension. Fortunately, the majority of persons with hereditary stomatocytosis are able to maintain an adequate hemoglobin level, so that splenectomy is not required.

Rh Deficiency Syndrome

Rh deficiency syndrome designates rare individuals who have either absent (Rh_{null}) or markedly reduced (Rh_{mod}) Rh antigen expression, mild to moderate hemolytic anemia associated with the presence of stomatocytes, and occasional spherocytes on the peripheral blood film. Hemolytic anemia is improved by splenectomy.

The Rh antigens are present in approximately 20,000 to 30,000 copies per cell and reside on minor transmembrane proteins with an electrophoretic mobility of 28 to 33-kDa on SDS-PAGE. The Rh gene locus encodes two closely linked genes, one encoding the D polypeptide and the other encoding the CcEe proteins, the antigenic expression of which is a consequence of alternate splicing of their pre-mRNA.

Rh proteins are part of a multiprotein complex that includes two Rh proteins and two Rh-associated glycoproteins (RhAG). Other proteins that associate with this complex include CD47, LW, glycophorin B, and protein 4.2. The Rh-RhAG complex interacts with ankyrin to link the membrane skeleton to the lipid bilayer. The Rh proteins share sequence homology to the Mep/Amt family of ammonium transporters in lower organisms and may participate in ammonium transport.

Rh_{null} erythrocytes have no Rh antigen and have reduced or absent LW, Fy5, Ss, U, and Duclos antigens. Rh, RhAG, LW, glycophorin B, CD47, and protein 4.2 are also reduced or absent. Rh_{null} erythrocytes have increased osmotic fragility, reflecting a marked reduction in membrane surface area. These cells are also dehydrated, as indicated by decreased cell cation and water content and increased cell density. The potassium transport and the Na^+/K^+ pump activity are increased, possibly because of reticulocytosis. Phospholipid asymmetry is also altered.

Although the clinical syndromes are the same, the genetic basis of the Rh deficiency syndrome is heterogeneous, and at least two groups have been defined. The amorph type is caused by defects involving the RH30 locus encoding the RhD and RhE polypeptides. The regulatory type of Rh_{null} and Rh_{mod} phenotypes results from suppressor or modifier mutations at the RH50 locus. When one chain of the Rh-RhAG complex is absent, the complex either is not transported to or is assembled at the membrane.

Familial Deficiency of High-Density Lipoproteins

Familial deficiency or absence of high-density lipoproteins (Tangier disease) because of mutations in ABCA1, a protein involved in cellular export of cholesterol, leads to accumulation of cholesterol esters in many tissues. Clinical manifestations include large orange tonsils, hepatosplenomegaly, lymphadenopathy, cloudy corneas, and peripheral neuropathy. Reported hematologic manifestations include a moderately severe hemolytic anemia with stomatocytosis and thrombocytopenia. Erythrocyte membrane lipid analyses reveal a low free cholesterol content, leading to a decreased cholesterol/phospholipid ratio and a relative increase in phosphatidylcholine at the expense of sphingomyelin.

Sitosterolemia

Sitosterolemia or phytosterolemia is a recessive disorder associated with elevated plasma levels of plant sterols. Affected patients exhibit xanthomatosis and early-onset premature cardiovascular disease. Reported hematologic manifestations include hemolytic anemia with stomatocytosis and macrothrombocytopenia. Mutations in the transporters ABCG5 or ABCG8 lead to gastrointestinal hyperabsorption and decreased biliary elimination of plant sterols as well as altered cholesterol metabolism. Plant sterols are not synthesized endogenously in humans but are passively absorbed in the intestine. ABCG5 and ABCG8 actively pump plant sterols out of the intestinal cells back into the intestine and out of liver cells into bile ducts. It has been hypothesized that the stomatocytic phenotype is caused by intercalation of plant sterols into the inner leaflet of the lipid bilayer.

Acquired Stomatocytosis

Stomatocytes have been noted in diverse acquired conditions, including neoplasms, cardiovascular and hepatobiliary disease, alcoholism, and therapy with drugs, some of which are known to be stomatocytogenic in vitro. In some of these conditions, the percentage of stomatocytes on the peripheral blood smear can approach 100%. However, the clinical significance of this observation is unclear because stomatocytes are absent in most patients with the conditions listed. Furthermore, some stomatocytes can be found in normal individuals (3% to 5%). The most consistent association is that of stomatocytosis and heavy alcohol consumption.

RED CELL MEMBRANE VARIANTS AND INFECTIOUS DISEASE

Viral, bacterial, and parasitic infection can all cause anemia. Multiple mechanisms leading to hemolysis have been described. As mentioned earlier in this chapter, parvovirus B19 selectively infects erythroblasts through interaction with globoside, which encodes the P blood group antigen and temporarily shuts down erythropoiesis. Although this infection is tolerated well by healthy subjects, it can lead to severe, at times life-threatening, aplastic crises in patients with anemias because of premature erythrocyte destruction. As one might predict, parvovirus cannot invade erythroblasts of the rare P-negative individuals.

Most infections cause hemolytic anemias triggered by several distinct, and at times overlapping, mechanisms. *Plasmodium, Babesia,* and *Bartonella* species directly attack the membrane and lyse the red

cells. Some bacteria, such as *Clostridium perfringens,* elaborate hemolytic toxins or phospholipases that damage the membrane. Other infectious agents trigger occasional production of autoantibodies against red cell membrane components, which in turn leads to autoimmune hemolytic anemia. Finally, many sepsis syndromes are associated with anemia because of disseminated intravascular coagulation.

Malaria and the Erythrocyte Membrane

The red cell membrane defects described earlier in this chapter cause mild to severe hemolytic anemias. At the same time, many red cell membrane alterations have developed as a defense against microorganisms and parasites invading and lysing red cells. This is especially true for malarial parasites. Although four different species of the malaria parasite *Plasmodium,* including *P. falciparum, P. ovale, P. vivax,* and *P. malariae,* infect humans, almost all of the 1.5 to 2 million annual deaths caused by malaria are attributable to *P. falciparum*.

Because malaria coexisted with humans over the course of human evolution, it comes as no surprise that multiple erythroid genotypes were selected that confer some level of resistance to infection or mitigate disease severity. The ensuing heritable phenotypes include, among others, resistance to red cell adhesion and/or invasion, slower intraerythrocytic growth, decreased or increased adhesion of infected red cells to vascular endothelium, and increased phagocytosis of parasitized red cells.

Malaria and other infections causing hemolytic anemias are described in more detail in Chapter 160, which also discuss hemoglobinopathies and red cell enzyme variants that reduce invasion and/or retard parasite growth. Consequently we focus here on the heritable erythrocyte membrane alterations that developed as a defense against malaria.

Erythrocyte Preference

Two parasites, *P. vivax* and *P. ovale,* selectively infect reticulocytes, whereas *P. malariae* infects older erythrocytes. In contrast, *P. falciparum* infects red cells of all ages. This fact and the tendency of *P. falciparum*–infected erythrocytes to sequester in circulation explain the markedly higher severity of *P. falciparum* malaria.

Attachment and Invasion

Duffy Antigen

The *P. vivax* merozoite is completely dependent on attachment to the Duffy blood group antigen (also known as the *Duffy antigen receptor for chemokines [DARC]*) for erythrocyte invasion, and consequently it cannot invade Duffy-negative red blood cells. It has been hypothesized that this is why the Duffy-negative phenotype is common in large areas of Africa. The Duffy-negative phenotype is caused by mutation in a GATA1 motif in the Duffy antigen gene promoter, preventing its expression in erythroid cells, leaving its expression in other tissues intact. Elucidation of this mutation explained a longstanding conundrum of transfusion medicine: why individuals with the Duffy-negative phenotype never develop antibodies against the Duffy antigen.

Glycophorins

All major erythrocyte glycophorins, A, B, and C/D, are involved in attachment of *P. falciparum* to the red blood cell membrane. Consequently invasion of *P. falciparum* into red cells from subjects lacking glycophorin A (En(a–)), glycophorin B (S-s-U–), or glycophorins C and D (Gerbich negative, Ge–) is diminished. As noted earlier, the Gerbich-negative phenotype is associated with mild, asymptomatic ovalocytosis.

Protein 4.1R and Spectrin

Deficiency of protein 4.1R or self-association defects of spectrin are associated with elliptocytosis of varying severity. Both phenotypes appear to reduce the burden of red blood cell invasion.

Band 3 and Southeast Asian Ovalocytosis

Conflicting explanations of the basis of the protective phenotype of Southeast Asian ovalocytosis (described earlier) from malaria have been described. Initial reports suggested that SAO erythrocytes were resistant to malarial invasion. These results were repeatedly questioned until recent studies demonstrated SAO cells to be resistant to invasion by the more virulent *P. falciparum* strains. This may explain the apparent contradiction with the reports of comparable parasitemias in SAO carriers and subjects with a normal red cell phenotype from Papua New Guinea.

The protection from cerebral malaria afforded by SAO erythrocytes is likely because of reduced cytoadherence of SAO red cells to the cerebral vasculature. Under conditions of flow, *P. falciparum*-infected ovalocytes adhere more strongly than normal infected red cells to the endothelial receptor CD36. Because this receptor is not expressed in the brain, this raises a possibility that ovalocytosis protects from cerebral malaria by diminishing the number of parasitized red cells available for adhesion to the cerebral vasculature via alternative receptors. Moreover, ovalocytes appeared resistant to invasion by parasite strains that tend to bind to intracellular adhesion molecule I (ICAM1), the likely receptor for cytoadherence in the brain, but the exact mechanism is not yet known.

Knops Blood Group System

Severe malaria, particularly cerebral malaria, has been associated with the formation of rosettes, clumps of cells formed by the adhesion of malaria-infected erythrocytes to complement receptor 1 (CR1) on uninfected erythrocytes. Identification of the Knops blood group antigens on CR1, followed by observations that frequencies of various Knops antigens varied significantly in whites and individuals of African ancestry, led to the hypothesis that some Knops group antigens might be protective from rosetting and severe malaria. Case control studies with genotyping and/or flow cytometry have yielded conflicting results, but several have linked low-expression CR1 alleles with malaria resistance. Further studies have shown that the expression of CR1 and other complement proteins increases with age. Together these data suggest that genetic and age-related differences in complement protein expression contribute to the variability observed in individuals with severe malaria.

Although these erythrocyte membrane polymorphisms offer fascinating insight into natural defenses against one of the most serious diseases affecting humans, the mechanism of resistance to malaria has not been fully elucidated for any of them. Malaria has clearly had a profound impact on the genetic makeup of populations living in endemic areas and provided us with multiple clues about the host-parasite relationship. Better understanding of these natural defenses might eventually be converted into effective therapeutic interventions.

CHAPTER 44

AUTOIMMUNE HEMOLYTIC ANEMIA

Ulrich Jäger and Klaus Lechner

Autoimmune hemolytic anemia (AIHA) is caused by autoimmune-mediated destruction of red blood cells (RBCs) by autoantibodies with various properties and target specificities. Exact laboratory diagnosis is often difficult; therefore, experienced diagnostic reference centers play an important role. The disease can be primary (idiopathic) or caused by an underlying condition (secondary), including autoimmune diseases, infections, drugs, or neoplasms. The clinical course of the disease as well as treatment decisions are influenced by the type of antibody involved. Success in treatment and the evaluation of therapies have lagged behind the achievements in laboratory diagnosis but will hopefully improve with the introduction of new effective drugs. Currently, almost all treatments in AIHA are based on experience and opinion but not on evidence. There are no established guidelines. Thus, management of the disease requires general hematologic skills and critical evaluation of treatment recommendations.

HISTORY

The history of diagnostic and therapeutic progress in AIHA has been described by Dacie,[1] one of the great pioneers in this field. Milestones were the discovery of the first RBC autoantibody (Donath-Landsteiner antibody) in 1904, the introduction of the Coombs test in 1945, the establishment of splenectomy as effective treatment of AIHA in the 1950s, and the finding that rituximab is an effective treatment in the past decade. The diagnosis and treatment of patients with AIHA were recently reviewed by several authors.[2-8]

EPIDEMIOLOGY

The incidence of primary AIHA is 0.8% per year. Secondary AIHA has at least the same frequency. Because only a low proportion of patients have spontaneous or treatment-induced long-term remissions and the death rate is low, the prevalence of AIHA is relatively high and has been estimated as 17 in 100.00 (in Denmark). The incidence of AIHA in children and teenagers is 0.2 to 1.0 per million per year.[9] There is some evidence of a familial clustering of AIHA in children, but no hereditary genetic background has been identified. Warm antibodies (WAIHAs) are found in 87% and cold antibodies (CAIHAs) in 13% of patients with AIHA.

Primary AIHA and Evans syndrome are slightly more prevalent in women and in children.[10] In secondary AIHA, the female-to-male ratio is very high in systemic lupus erythematosus, but low in chronic lymphocytic leukemia (CLL)–associated AIHA. The incidence of chronic cold agglutinin disease (CAD) is estimated to be one per million per year with a female prevalence. Geographical differences have been suggested with a higher incidence of CAD in Northern climates.

PATHOBIOLOGY

Hemolysis is initiated when an autoantibody binds to the RBC membranes and recruits complement. Destruction of the RBC can occur directly in the circulation (intravascular hemolysis) or by removal of the cell by macrophages in spleen, liver, or both (extravascular hemolysis) (Fig. 44-1). Several immunoglobulin subclasses can fix complement: immunoglobulin (Ig) G, IgA, and IgM. Macrophages recognize opsonized erythrocytes via receptors specific for the Fc fragment of IgG and for C3d. RBCs coated with IgG or complement alone are destroyed in spleen and liver, IgG-coated cells in the spleen, and IgM-coated cells in the liver. This has major implications for treatment, particularly for the effect of steroids and splenectomy.

Warm Antibody Hemolytic Anemia

About 70% to 80% of cases of AIHA are caused by warm antibodies. The RBC antibodies in WAIHA are mostly polyclonal IgG (IgG_{1-4}), which have a low capacity to activate the complement system (Table 44-1). The direct antiglobulin test (DAT) in WAIHA is positive either with IgG (37%) or IgG + C3d (43%). Rarely, the DAT is only positive with C3d (when the amount of IgG on the RBCs is very small). Patients with IgG antibodies may have also IgA antibodies, but IgA antibodies without IgG antibodies are a very rare cause of WAIHA. Warm antibodies are often directed against Rh antigens but also against other blood group antigens (non–Rh-related autoantibodies) such as band 3 protein or glycophorin A. The antibodies fix complement and bind tightly to the RBCs at 37° C. Therefore, there is only a small amount of antibody detectable in the serum. The antibody coated RBCs are removed from the circulation by splenic (to a lesser degree also by hepatic) macrophages via $F_{c\gamma}$RIII receptors. IgG_3 and IgG_1 have the highest affinity for the Fc receptors of macrophages. Erythrocytes that are only partially phagocytosed by the macrophages become spherocytes, which are removed in the splenic cords because of their rigid structure. Destruction of RBCs may also be caused by other mechanism such as antibody-dependent cellular cytotoxicity.[11]

Immunoglobulin M warm antibodies are a very rare cause of AIHA. This type of AIHA can be suspected if a RBC autoagglutination occurs at room temperature. The DAT result is positive with C3d alone (65%) or with IgG (24%). Using sensitive methods, IgM on the RBCs can be detected in 71%.[12] Non-Hodgkin lymphoma (NHL) is the underlying disease in some of these cases. This AIHA is severe, often fatal and refractory to steroids and splenectomy.

Cold Antibody Hemolytic Anemia

Cold antibodies in primary or secondary CAIHA are usually monoclonal IgM. The IgM has two binding sites for C1q and fixes complement easily. The targets are polysaccharides (I, I^T, i or Pr antigens). The "i" antigen is a nonbranched polysaccharide in the cord blood, and the "I" antigen is a similar but branched molecule expressed in the RBCs of adults. The cold antibodies bind to the RBCs at low temperatures and cause their lysis at temperatures above 22° C. The DAT is typically positive with C3d alone. When cold antibodies are present at high titers, they may activate the complement system directly and produce a membrane attack complex (MAC) and intravascular hemolysis with hemoglobinuria. Usually the complement-coated RBCs are sequestered by liver macrophages.

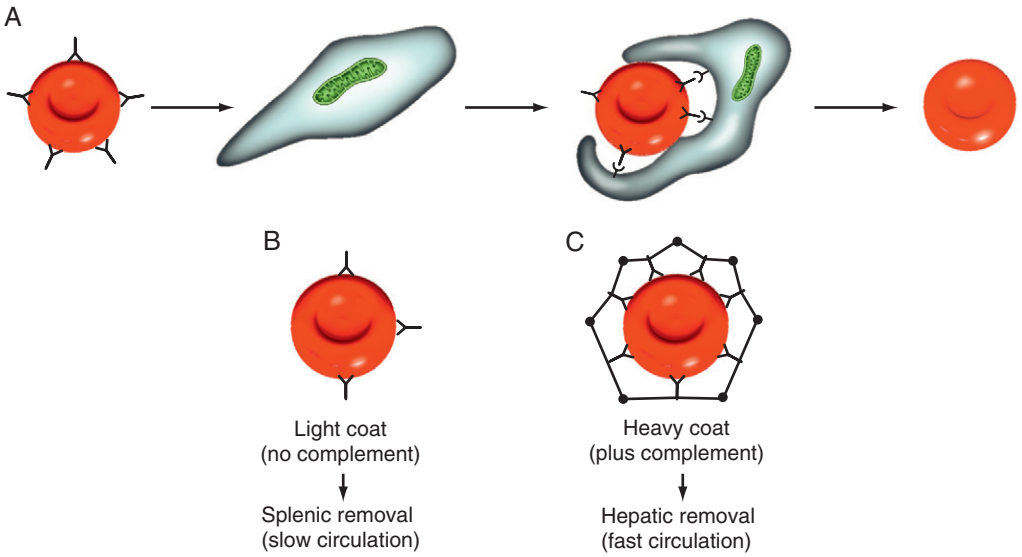

Figure 44-1 MECHANISM OF EXTRAVASCULAR HEMOLYSIS IN AUTOIMMUNE HEMOLYTIC ANEMIA. **A,** Macrophage encounters an IgG-coated erythrocyte and binds to it via its Fc receptors. Thus entrapped, the red blood cell (RBC) loses bits of its membrane as a result of digestion by the macrophage's ectoenzymes. The discoid erythrocyte transforms into a sphere. **B,** RBC lightly coated with IgG (and therefore incapable of activating the complement cascade) is preferentially removed in the sluggish circulation of the spleen. **C,** RBC with a heavy coat of IgG; thus, C3b *(black circles)* can be removed both by the spleen and the liver. *(From Cunnigham MJ, Silberstein LE: Autoimmune Hemolytic Anemia. In Hoffman R, Benz EJ Jr, Shattil SJ, et al, eds:* Hematology: Basic principles and practice, *ed 4, 2005, Philadelphia, Elsevier.)*

Table 44-1 Properties and Specificities of Red Blood Cell Autoantibodies

	Immunoglobulin (Subclass)	Type of Antibody	Clonality	Specificity	Hemolysis	Site of Removal of Red Blood Cells
WAIHA	$IgG_{(1-4)}$, IgA	Incomplete	Mostly polyclonal	Rh- and non–Rh- antigens	Extravascular	Spleen (liver)
CAIHA	IgM	Complete	Mostly clonal	Anti-i, -I^T, -I, -Pr	Intravascular	Liver
Donath-Landsteiner antibody	IgG	—	Polyclonal	P antigen	Intravascular	—

CAIHA, Cold autoimmune hemolytic anemia; *Ig,* immunoglobulin; *WAIHA,* warm autoimmune hemolytic anemia.

Paroxysmal cold hemoglobinuria (PCH) is caused by the Donath-Landsteiner antibody. This is a rare, usually polyclonal IgG cold antibody to P antigen (glycosphingolipid globoside), which binds to the RBCs at 4° C. The cells are lysed at higher temperatures. The DAT is positive with C3d, and the diagnosis is made by the Donath-Landsteiner test. In this test, normal RBCs and patient and normal serum are incubated at 4° C. Agglutination occurs after warming to 37° C. The prominent clinical feature of PCH is a brisk, immediate but sometimes also delayed hemoglobinuria after cold exposure even in patients with low antibody titers. In the past, it has been associated with secondary or tertiary syphilis. Now, two types can be distinguished clinically[13]: (1) an acute, severe form (often associated with hemoglobinuria) but self-limiting AIHA after (respiratory) infections in children and (2) a rare chronic AIHA in nonsyphilitic persons with various underlying conditions, including NHL. Patients with chronic PCH respond poorly to steroids and splenectomy.

ETIOLOGY AND PATHOPHYSIOLOGY

Our knowledge about the etiology of AIHA is still limited. Factors that may play a role are antigen mimicry; immune deficiency; and to a lesser extent, probably genetic factors. AIHA, similar to other autoimmune diseases, is a consequence of the loss of immunologic (self-) tolerance against antigens expressed on the erythrocyte surface. Production of RBC antibodies is a result of the interaction of T and B cells as well as regulatory factors (e.g., T regulatory cells, cytokines).[14] Disturbances of the Th1/2 T-cell subset balance as well as the occurrence of clonal regulatory T cells specific for a RBC autoantigen have been described. This may be linked to the fact that AIHA does not only occur in immunocompetent individuals but frequently occurs in patients with acquired T-cell defects such as HIV infection or immunosuppressive therapy, particularly after organ transplantation. Polymorphisms or altered expression of negative regulators of T-cell responses such as CTLA-4 (cytotoxic T lymphocyte antigen 4) or interleukin-10 (IL-10) may also play a role. Mouse models (New Zealand black mice) have revealed an association of genetic loci with antierythrocyte antibody production or cold agglutinin escape tolerance after *Mycoplasma* infection.

Various target antigens have been described, with Rhesus polypeptides, glycophorin, and erythrocyte band 3 being the most prominent in WAIHA. Cold reactive antibodies frequently target the I or i blood group–specific antigens. Events linked to the development of secondary AIHA by induction of cross-tolerance (molecular mimicry) are infections (*Mycoplasma pneumoniae* [I antigen target], parvovirus, herpes viruses), neoplastic diseases (paraneoplasia), and drugs by various mechanisms. There are important differences in the pathogenesis of WAIHA and CAIHA. The pathogenesis of primary WAIHA is largely unknown. Secondary WAIHA is a complication of several congenital or acquired immune deficiencies. Both moderate (for example in CLL) and severe (HIV, posttransplant, congenital severe T-cell deficiencies) T-cell and humoral immune deficiency predispose to WAIHA, but no correlation between the type and severity of immune deficiency and the risk of AIHA has been established.

One phenomenon that is poorly understood is the lack of a clear relationship between the presence of RBC antibodies and anemia. In many instances, there is no anemia despite a strongly positive DAT or high titers of cold antibodies. There is also only a poor correlation between antibodies titers and severity of anemia. Another unexplained finding in secondary AIHA is the occurrence of both warm and cold antibodies in the some condition for example in lymphomas or infections.

Antibodies in primary AIHA are frequently polyreactive and polyclonal (no clonal B cells detected by polymerase chain reaction [PCR]). Antibodies in CAD are mostly produced by PCR-detectable oligo- or monoclonal B-cell populations. The nature of these antibodies has been extensively studied in CAD. However, in only a few cases, it has been established that the RBC antibody is clonal. In most reports, clonality of RBC antibodies was assumed if the patient had a paraproteinemia.

B-cell neoplasms expressing IgMκ antibodies directed against RBC antigens have few somatic mutations, which seem to be fairly restricted to certain immunoglobulin heavy and light chain families (VH4-34, VκIV).[15] Moreover, a VH4-34 CLL confounding subclone was shown to arise from a preexisting CAD-producing B-cell population. The restricted clonality of CAD producing B cells is further corroborated by the detection of recurrent chromosomal aberrations (trisomy 3).[16] CLL cells may also drive AIHA by presenting the autoantigen (e.g., erythrocyte protein band 3) to T cells.

Four Important Questions for the Diagnosis and Management of Autoimmune Hemolytic Anemia

It is of utmost importance to differentiate between various types of AIHA. A stepwise approach helps in making the right decisions:

Question 1: Hemolytic anemia? The basic features of hemolytic anemia are reticulocytosis, low haptoglobin levels, elevated indirect bilirubin, and elevated LDH.

Question 2: Autoimmune hemolytic anemia? A direct DAT is initially performed with a polyspecific antibody to detect IgG or complement C3d bound to RBCs. If the DAT result is positive, the diagnosis of AIHA is established.

Question 3: Warm or Cold Autoimmune Hemolytic Anemia? The DAT is further elaborated with monospecific antibodies to IgG and complement (C3d). If the DAT result is positive with IgG alone or with IgG + C3d, the AIHA is most probably caused by a warm antibody (WAIHA). If the DAT is positive with C3d only, the AIHA is most probably caused by a cold antibody (CAIHA).

Question 4: Primary or secondary AIHA? More than half of AIHAs are secondary to underlying diseases. Secondary AIHA should be suspected in patients with additional findings or who are refractory to initial steroid treatment. In this case, the underlying disease has to be diagnosed (e.g., by serologic tests, CT scan, or bone marrow biopsy).

SYMPTOMS, CLINICAL FINDINGS, AND RISKS

The symptoms of AIHA depend on the type of antibody, the mode of onset, and the severity of anemia. In patients with WAIHA, the onset is mostly gradual or subacute, and the symptoms (i.e., tiredness, reduction of physical activity, and shortness of breath in elderly patients) are attributable only to anemia. However, patients with postinfectious, drug-induced AIHA or patients with Donath-Landsteiner or Pr antibodies often present with acute severe symptoms such as malaise, fever, jaundice, abdominal pain, shortness of breath, and hemoglobulinuria. The course in such patients may be fulminant and even fatal. Patients with chronic cold antibody AIHA (CAD) often have an indolent course. Symptoms suggestive for CAIHA are cold sensitivity, cold-dependent acrocyanosis, acral numbness, and rarely livedo reticularis or organ ischemia. Anemia worsens after cold exposure or conditions associated with an acute phase reaction.

During clinical examination, a subicterus may be seen. Lymphadenopathy, palpable splenomegaly, or any organomegaly is rare in patients with primary AIHA. Its presence suggests secondary AIHA.

Patients with WAIHA are at an increased risk of venous thromboembolism, particularly when the AIHA is associated with a lupus anticoagulant (LA).[17] Older patients with AIHA are at an increased risk of cardiovascular complications, which may also be partly caused by the treatment.

LABORATORY DIAGNOSIS OF AUTOIMMUNE HEMOLYTIC ANEMIA

Autoimmune hemolytic anemia is essentially a laboratory diagnosis. The diagnostic pathway of AIHA should proceed in a stepwise fashion answering the following questions:

Step 1: Hemolytic Anemia?

The first step is to establish the diagnosis of hemolytic anemia (see box on Four Important Questions for the Diagnosis and Management of Autoimmune Hemolytic Anemia). This diagnosis is established by the presence of the following pentad of findings: normocytic or macrocytic anemia (male hemoglobin < 13.0-14.0 g/dL; female <12.0 g/dL), reticulocytosis (corrected reticulocyte count >2% or absolute reticulocyte count >100.000-120.000/μL), low haptoglobin, elevated lactate dehydrogenase (LDH), and elevated unconjugated (indirect) bilirubin. Haptoglobin is an α2-globuline that binds hemoglobin. This hemoglobin–haptoglobin complex is degraded in the liver. Hemopexin is another plasma protein with a very high binding affinity to hemoglobin. It scavenges heme released from RBCs and protects the organisms from the adverse effects of circulating hemoglobin. The determination of hemopexin is not essential for the diagnosis of AIHA. Indirect bilirubin is usually not more than 5 mg/dL except in associated liver disease (Epstein-Barr (EBV)–associated AIHA). Additional findings are increased urobilinogen in the urine and spherocytes in the blood smear. Leukoerythroblastosis occurs only in peracute AIHA, but microangiopathic hemolytic anemia should always be suspected in such cases. Bone marrow examination is usually not necessary except in patients in whom secondary AIHA, in particular lymphoma, is suspected. RBC survival is shortened, but its measurement with radioisotopes has no diagnostic value, not even for the prediction for the efficacy of splenectomy.

Among methodologic diagnostic problems, reticulocyte counting is the biggest because in many laboratories, low-precision microscopic counts are still performed. Automatic flow cytometric methods are more precise, reliable, and convenient. With flow cytometry, the number of highly fluorescent reticulocytes (which are increased in AIHA but are low in hereditary spherocytosis) can also be measured. Falsely very high mean corpuscular volume and mean corpuscular hemoglobin concentration occur in some cases of CAIHA because RBC counts are falsely low because of agglutination of RBC at room temperature. If a CAIHA is suspected, blood samples should be sent to the laboratory in warmed containers.

All of the findings of the pentad are not always present. Reticulocytosis is often (in ≈25%) not present at the onset of AIHA. This is mostly because of a delayed initial bone marrow response of erythropoiesis. After 1 week, most of these patients have reticulocytosis. In other patients (particularly in secondary cases), absence of reticulocytosis may be attributable to impairment of erythropoiesis caused by bone marrow infiltration or blunted erythropoiesis caused by an acute phase reaction. If the reticulocyte count is very low, pure RBC aplasia (PRCA), either immune mediated or induced by a parvovirus (or HHV6) infection, should be suspected. Haptoglobin may be falsely normal or even increased, particularly in patients with malignant or

immune diseases, because haptoglobin is an acute phase protein. Haptoglobin may be falsely low in patients with a haplotype H_0H_0 and in patients with severe liver disease. Both increased bilirubin and elevated LDH have a limited sensitivity and specificity for AIHA.

Step 2: Autoimmune Hemolytic Anemia?

The next step is to find out whether the hemolytic anemia is an AIHA. This is best done by the DAT (Fig. 44-2). In this test, washed RBCs of the patient (obtained from an EDTA [ethylenediaminetetraacetic acid] blood sample) are incubated in a tube with a polyspecific antibody to IgG and complement (C3d). If the RBCs agglutinate, the test result is positive. In many laboratories, the tube test has been replaced by the tube gel test, which is easier to perform, more reliable, and probably more sensitive. In the indirect antiglobulin test (IAT), patient plasma or serum is incubated with test RBCs, and (after washing) RBC-bound IgG is detected with the DAT. IAT is usually not required for the diagnosis of AIHA except when a drug-dependent antibody is suspected. For the differentiation of drug-dependent antibodies and autoantibodies, an acid eluate of the patient's RBCs should be made and tested in the IAT. If the IAT result is positive, the patient has autoantibodies. The severity of AIHA does not correlate with the strength of the DAT but rather with the immune globulin subclass of the antibody (IgG_1 or IgG_3). The result of the DAT is not a reliable marker of treatment success because patients with a complete hematologic remission may remain DAT positive, and DAT positivity or negativity has only limited value to predict the duration of hematologic remission.

Falsely Negative and Positive Direct Antiglobulin Test Results without Hemolysis or Anemia

If the conventional DAT test result is negative, hemolytic anemia is defined as DAT negative. However, AIHA cannot be definitely excluded because about 5% (2%-11%) of AIHA patients are DAT negative. If AIHA is suspected for clinical grounds despite a negative DAT result, more sensitive quantitative tests are required to determine the amount of IgG on the RBCs. The threshold of positivity of the conventional DAT is 100 to 200 IgG molecules per RBCs, but in some AIHA patients, the RBC IgG is less than this amount. In about one-third of DAT-negative cases, one of the more sensitive test results (e.g., immunoradiometric tests) will be positive. However, the relationship between the amount of RBC IgG and hemolysis is not clearcut, and there is no "hemolysis threshold."[18] The reasons for these discrepancies between the in vitro and in vivo activity of RBC antibodies are largely unknown. Differences in macrophage activity may be one possible explanation. A search for antibodies in the RBC eluate in which antibodies are more concentrated is also useful. IgA antibodies are rare and sometimes not included in the analysis. Finally, there is the possibility of low-affinity antibodies. Such antibodies are washed out when the washes are made with 37° C saline. A high rate of DAT-negative AIHA has been observed in AIHA induced by nucleoside analogues but also in other secondary AIHA.

The DAT result is positive in one in three to 10,000 normal persons and 10% of hospital patients without anemia or signs of hemolysis.

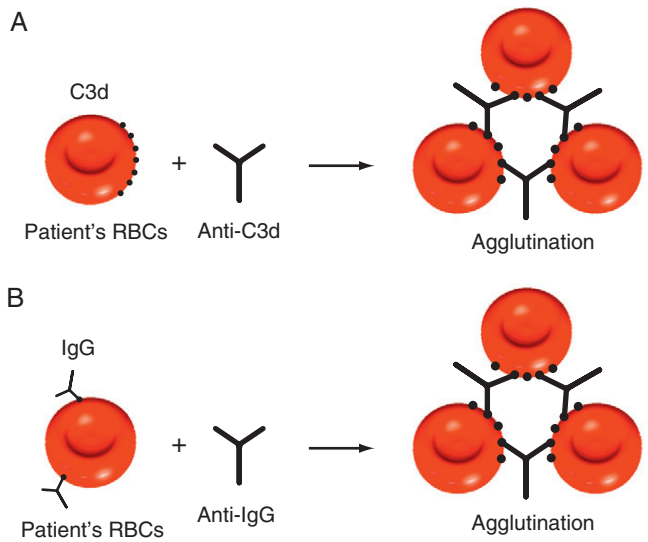

Figure 44-2 DIRECT ANTIGLOBULIN TEST (DAT) FOR DETECTION OF **(A)** ERYTHROCYTE-BOUND C3D OR **(B)** IGG. Hemagglutination occurs when anti-C3d or anti-IgG can create a lattice structure by bridging sensitized red blood cells (RBCs). *(From Cunnigham MJ, Silberstein LE: Autoimmune hemolytic anemia. In Hoffman R, Benz EJ Jr, Shattil SJ, et al, eds:* Hematology: Basic principles and practice*, ed 4, 2005, Philadelphia, Elsevier.)*

Step 3: Warm or Cold Autoimmune Hemolytic Anemia?

In a further step, the DAT is done with monospecific antibodies to IgG and complement (C3d) to find out whether a warm or cold antibody is the cause of hemolysis. If the DAT result is positive with IgG alone or with IgG plus C3d, the AIHA is most probably a WAIHA. If the DAT result is positive with only C3d, the AIHA is most probably a CAIHA. The differentiation between WAIHA and CAIHA is extremely important for the choice of treatment.

There are some special diagnostic problems in CAIHA. If cold antibodies are suspected, it must be taken care that the blood that is sent to the laboratory is kept at 37° C to get reliable results. Patients with only RBC C3d may (rarely) have WAIHA when the amount of RBC IgG is very small. In patients with C3d positivity, the cold agglutinin titer should be determined. If it is greater than 1:512, the diagnosis of a CAD is established. There is no threshold titer that separates normal from abnormal. If the titer is less than 1:512 the thermal amplitude of the antibody must be determined. If the thermal amplitude is above 22° C, the diagnosis is CAD. Mixed-type AIHA is probably rare. The criteria are a positive IgG DAT result and a positive eluate (WAIHA) result plus a C3d-positive DAT result and the presence of cold antibodies with a thermal amplitude of greater than 30° C (CAIHA). Many published cases of mixed-type antibodies do not fulfill these criteria.[19]

Step 4: Primary or Secondary Autoimmune Hemolytic Anemia?

In the last diagnostic step, it must be determined whether the AIHA is primary or a complication of an underlying disease (secondary). The decision regarding which diagnostic procedures should be used for this purpose depends mainly on the type of AIHA (WAIHA or CAIHA) and should include history, physical examination, laboratory tests, and imaging procedures if indicated. In children and younger patients with WAIHA, evidence for an infection should be sought. A list of all recent medication should be made. A history of weight loss, fever, or poor general condition and arthritis points to a malignancy or immune disease as the underlying condition. Palpable lymphadenopathy and splenomegaly do not belong to the clinical picture of primary WAIHA. In this case, lymphoma (particularly splenic marginal zone lymphoma [SMZL]) should be suspected. Laboratory tests should include acute phase proteins, LDH, quantitative determination of immune globulins, and other tests guided by the clinical history. A bone marrow examination is not obligatory except when lymphoma is suspected. Abdominal ultrasonography is reasonable in all cases to exclude splenomegaly, the remote (but important) possibility of an ovarian teratoma (in women), lymphadenopathy, or solitary extranodal lymphomas. Some experts recommend computed tomography (CT) of the abdomen or thorax in all cases, but there is concern

of radiation exposure. An activated partial thromboplastin time (aPTT) with a lupus-sensitive reagent may reveal a LA. Fluorescence activated cell sorting (FACS) or PCR for the detection of monoclonal lymphocytes may be done, but the clinical usefulness of such tests to guide treatment decisions is uncertain.

In CAIHA, a history of a febrile illness should prompt a thoracic radiography, and if results are positive, a serologic test for mycoplasma pneumoniae is required. The quantitative determination of serum immunoglobulins and a search for a clonal immune globulin by immune fixation are important. If immune fixation findings are positive, a search for lymphoma is necessary, which may include bone marrow biopsy even when there is no lymphadenopathy.

Other tests, including blood glucose, Hba_{1c}, renal and hepatic function tests, HIV serology, hepatitis B antigen, and exclusion of latent tuberculosis are necessary to avoid complications of steroids (in WAIHA) or rituximab (in CAIHA and WAIHA).

IMMUNOLOGIC PHENOMENA ASSOCIATED WITH AUTOIMMUNE HEMOLYTIC ANEMIA

Evans syndrome is the combination of WAIHA with autoimmune thrombocytopenia (ITP), a typical but rare association. Platelet antibodies are usually directed against glycoprotein IIB/IIIA. Neutropenia occurs in 25% of patients. There is no sex predilection; about half of the cases are secondary. Evans syndrome is relatively more common in patients with systemic lupus erythematosus (SLE), antiphospholipid antibodies (APAs), and autoimmune lymphoproliferative syndrome (ALPS).[20] A search for an ALPS is mandatory in younger patients with Evans syndrome. In roughly 50% of the cases, AIHA and ITP occur simultaneously; in 25%, the disease starts with ITP; and in 16%, the disease starts with AIHA. There may be an interval of several years between the onset of AIHA and ITP.[10]

WAIHA, CAIHA, or a positive DAT result without anemia may be associated with PRCA. PRCA may be either immune mediated such as in T-cell neoplasms (particularly T-cell large granulocytic leukemia) or may be caused by an infection with parvovirus. Patients with parvovirus-associated AIHA often present with PRCA.

Autoimmune hemolytic anemia is definitely associated with APAs and LA. In one single centre prospective study, LA was found in 30% predominantly idiopathic AIHA. AIHA (4%) and Evans syndrome (10%) are frequent in patients with APA. It is well established that patients with AIHA have a significantly (2.8- to3.8-fold) elevated risk of venous thromboembolism.[17] It is likely but not proven that patients with AIHA associated with LA are at a higher risk.

In lymphomas, some cases of AIHA are associated with C1-esterase inhibitor deficiency and mixed cryoglobulinemia.

SECONDARY AUTOIMMUNE HEMOLYTIC ANEMIA

About half of cases of AIHA (or probably even more) are secondary. The main causes are immune diseases and malignancies. Other underlying conditions are infections, drugs, transplantation, and congenital defects.

Temporal Relationship of Secondary Autoimmune Hemolytic Anemia to the Underlying Condition

The temporal relationship of AIHA to an underlying condition is complex. AIHA antedates the diagnosis of malignancy in many cases—in NHL, sometimes for years. In population-based studies, clonal B cells have been detected in some patients with seemingly idiopathic AIHA. In most instances, AIHA occurs concurrently with the malignancy. In some other cases, AIHA occurred only at the recurrence and rarely in complete remission after successful treatment. In CLL, AIHA occurs in a late phase of the disease. The patients have poor prognostic factors and often have been treated with various agents.

In immune diseases, particularly SLE, AIHA is a complication of the early phase of the disease. Infection-related AIHA occurs shortly after the onset of symptoms except in HIV infection, in which AIHA is a complication in the late advanced stage of the disease.

Serologic Type of Autoimmune Hemolytic Anemia in Secondary Autoimmune Hemolytic Anemia

It is an interesting phenomenon that in underlying diseases associated with AIHA, all serologic types of AIHA may occur, but usually one serologic type (WAIHA, CAIHA, or Donath-Landsteiner (DL) antibody) prevails. The only exception is ovarian teratoma, which is only associated with WAIHA.

Autoimmune Hemolytic Anemia in Immune Diseases

Autoimmune Hemolytic Anemia in Systemic Lupus Erythematosus and Primary Antiphospholipid Syndrome

The prevalence of AIHA in patients with SLE is 7.5% (average of seven studies; range, 5.2%-12.5%). AIHA may occur at any time during the course of SLE, but two-thirds of cases of AIHA occur at diagnosis or soon thereafter. Almost half of the patients are already taking steroids. Most patients are women and have WAIHA. Evans syndrome is common. Compared with SLE patients without AIHA, those with AIHA are younger; have a higher prevalence of thrombocytopenia, APAs, renal disease, serositis, and central nervous system involvement; and have a higher risk of venous thrombosis.[21]

The prevalence of AIHA in primary antiphospholipid syndrome (PAPS) is about 10%. AIHA precedes PAPS in 25% of cases, but in others occurred after a median time of 4.4 years after the diagnosis of PAPS. Patients with PAPS and AIHA have an increased risk for the development of SLE.[22]

Autoimmune Hemolytic Anemia in Inflammatory Bowel Disease

In the only larger study the prevalence of AIHA in ulcerative colitis was 1.7%. The mean time from diagnosis of colitis to AIHA was 17 months. Three-quarters of these patients had a total colitis. AIHA may also be associated with Crohn disease, but the prevalence is lower than in ulcerative colitis.

Autoimmune Hemolytic Anemia in Other Immune Diseases

A few or single cases of an association of WAIHA with Sjögren syndrome, dermatomyositis, biliary cirrhosis, Graves disease, Churg Strauss syndrome, crescentic glomerulonephritis, polymyalgia rheumatica, scleroderma, or autoimmune pancreatitis and of CAIHA with rheumatoid arthritis have been reported. A high prevalence of AIHA was found in small children with giant cell hepatitis.

Autoimmune Hemolytic Anemia in Transplanted Patients

Autoimmune hemolytic anemia is a rare but important and dangerous complication of allogeneic hematopoietic stem cell transplantation (HSCT). Beside AIHA, causes of hemolytic anemia in transplanted patients may be lymphocyte passenger syndrome and ABO incompatibility. AIHA may be caused by severe immune suppression by drugs to prevent rejection or graft-versus-host-disease (GVHD), viral infections, EBV lymphoproliferative disorder (LPD), or the recurrence of an immune disorder after transplantation (biliary cirrhosis).

The highest rate of AIHA occurred in small children after unrelated cord HSCT for inborn metabolic defects (44%) and in children with severe combined immune deficiency after haploidentical HSCT with T cell–depleted stem cell grafts.

In adults, the incidence of AIHA ranges from 3.0% to 4.4% after allogeneic HSCT.[23] The median time from HSCT to AIHA is 4 to 10 months. Most patients have warm antibodies. Risk factors for AIHA are unrelated donor, T-cell depletion, and extensive GVHD. In most cases, AIHA occurred in patients in complete remission of the underlying disease, but in one study, AIHA was associated with a relapse of chronic myeloid leukemia in the majority of patients.

After transplantation of solid organs, the highest risk of AIHA was in patients with pancreatic transplantation. A number of patients with AIHA or CAIHA were observed after liver transplantation but only a small number after cardiac, lung, intestinal, and renal transplantation. The most likely cause of AIHA in these patients is severe drug-induced immunosuppression.

Autoimmune Hemolytic Anemia in Pregnancy and After Blood Transfusion

Very few cases of AIHA and Evans syndrome occurred during pregnancy, all with warm antibodies. In these patients, there seems to be a higher risk for preeclampsia. AIHA responds well to steroids and resolves in most cases after delivery. In two cases, the newborns had mild hemolysis.

Development of RBC autoantibodies is common in multitransfused patients and is associated with presence of alloantibodies. However, anemia is rare.

Autoimmune Hemolytic Anemia in Malignancies

Autoimmune Hemolytic Anemia in Lymphoproliferative Disorders

Autoimmune hemolytic anemia is a typical, relatively common immune-mediated paraneoplastic syndrome in LPD. It occurs in almost all histologic subtypes of NHL, but there is no correlation between the frequency of lymphoma and the risk of AIHA. AIHA is relatively most common in SMZL and angioimmunoblastic T-cell lymphoma (Table 44-2). In most LPD WAIHA is predominant. Most warm antibodies, particularly in CLL, seem to be polyclonal. The proportion of patients with WAIHA is highest in CLL and Hodgkin disease; in other malignancies, the ratio of WAIHA to CAIHA is two to one. In lymphoplasmacytic lymphoma (LPL), almost all antibodies are clonal cold antibodies.

Table 44-2 Secondary Autoimmune Hemolytic Anemia in Malignancies

Malignancy	Prevalence	WAIHA	CAIHA
MGUS	Very low	None	All
All NHL	0.23-2.6%		
CLL	4.3%-9%	90%	10%
SMZL	10%	2/3	1/3
LPL	3%-5%	None	Most
Angioimmunoblastic T-cell lymphoma	13%	One-third	Two-thirds
Hodgkin disease	0.19%-1.7%	All	None
Ovarian teratoma	Very low	All	None
Solid tumors	Very low	Two-thirds	One-third

CLL, Chronic lymphocytic leukemia; *LPL,* lymphoplasmacytic lymphoma; *MGUS,* monoclonal gammopathy with unknown significance; *NHL,* non-Hodgkin lymphoma; *SMZL,* splenic marginal zone lymphoma.

Autoimmune Hemolytic Anemia As a Risk Factor for Lymphoproliferative Disorder

In various population-based studies, AIHA emerged as a risk factor for subsequent development of diffuse large B-cell lymphoma, LPL, CLL, monoclonal gammopathy with unknown significance (MGUS), and multiple myeloma. Data regarding the type of AIHA and a possible influence of treatment were not available in these studies. It is uncertain whether autoimmune disorder per se is the causal factor or whether these patients had a clinically silent clonal disorder at the time of AIHA.

Autoimmune Hemolytic Anemia in Chronic Lymphocytic Leukemia

The prevalence of AIHA is highest in CLL, ranging from 4.3 to 9%. The prevalence is highest in poor-risk patients (Binet stage B or C, increased ZAP70 expression, unmutated IgVH status, and CD38 positivity) and patients who had already been treated. However, AIHA may also occur in very early stages of CLL, including B-cell monoclonal lymphocytosis. In a large group of nontreated CLL patients, the prevalence of positive DAT result (with or without anemia) was 14%.[24] Most CLL patients with AIHA are men. The vast majority of patients have (presumably) polyclonal warm antibodies, but in all studies, there is small number of cases with CAIHA (specificity anti-I), often with IgM paraproteinemia.

Autoimmune Hemolytic Anemia in Monoclonal Gammopathy With Unknown Significance and Lymphoplasmacytic Lymphoma

The clinical picture of primary chronic CAD suggests the presence of an "idiopathic" CAIHA, but in fact, most of these patients have a clonal disease with either only clonal IgM (IgM-MGUS) or LPL with IgM paraproteinemia and bone marrow infiltration (or Waldenström macroglobulinemia). Traditionally, the latter category would be classified as secondary AIHA. More than 90% of patients with "CAD" have a monoclonal IgMκ; 7% had IgG or IgA monoclonal immune globulin with λ chains. The course of CAD is usually indolent. Fewer than half of patients require transfusions, and the risk for progression to highly malignant lymphomas is small.

Autoimmune Hemolytic Anemia in Other Lymphoproliferative Diseases and Myeloma

The prevalence of AIHA is low in NHL, ranging from 0.23% to 2.6%. AIHA has been described in all histologic subtypes of NHL. Based on the prevalence of NHL, the association with AIHA is highest with SMZL, LPL, angioimmunoblastic T-cell lymphoma, and γ heavy chain disease. The antibody may be either a warm (two-thirds) or a cold (one-third) antibody. In NHL, there seems to be a relatively frequent association of AIHA with LA, C1-esterase deficiency, or essential cryoglobulinemia.

A number of predominantly WAIHAs have been described in IgG and IgA myelomas.

Autoimmune Hemolytic Anemia in Myeloid Disorders

Generally, AIHA is rare in patients with myeloid malignancies. A number of cases have been reported in myelodysplastic syndromes, particularly chronic myelomonocytic leukemia. Very few cases were described in acute myelogenous and lymphoblastic leukemia, myelofibrosis, and polycythemia.

Autoimmune Hemolytic Anemia in Solid Tumors

A special, rare, but highly interesting cause of WAIHA is ovarian dermoid cyst. These patients respond very poorly to drug therapies, but the AIHA resolves completely, and the DAT result becomes

negative a few weeks after ovariectomy. The same behavior has been described in microcystic adenoma of the pancreas and dermoid cyst of the mesentery associated with AIHA.

Autoimmune hemolytic anemia is rarely but definitely associated with solid tumors. It is a very rare complication of lung, renal cell, and ovarian cancer. In some cases of renal cell cancer, AIHA resolved after curative surgery.

Infection-Related Autoimmune Hemolytic Anemia

In immune-competent patients, AIHA may occur after viral, bacterial, or parasitic infections (Table 44-3). Virus-associated AIHA occurs mostly in newborns and children; bacterial AIHA occurs more often in adults. The onset of AIHA is often shortly after signs of infection but sometimes after a latency time up to weeks. After some specific infections, patients may develop preferentially a warm or a cold antibody (sometimes with specific targets such as I, i, P, or Pr antigen), but in almost all instances beside the dominant antibody (cold or warm), there are a few cases of another antibody (see Table 44-3). Of particular interest is varicella-zoster virus– and rubella-associated CAIHA because the cold antibody is mostly directed to the Pr antigen and the AIHA is clinically severe. In *Mycoplasma*-associated AIHA, the antibody target is almost always "I". After *Mycoplasma* infection, the DAT result is positive in 50% to 60% of cases, but anemia is rare. In some specific infections, the antibody was a DL antibody, but in a large study, most DL antibodies were found after unspecific respiratory infections.[13] In many cases, the course of AIHA is short, uncomplicated, und self-limited, but some cases with a severe, even fatal, course, particularly in patients with Pr antibodies and in *Mycoplasma*-associated AIHA, have been reported. In AIHA associated with bacterial infections or in leishmaniasis, treatment of the infection seemed to be beneficial.

Table 44-3 Autoimmune Hemolytic Anemia After Infections

	Infection	WAIHA	CAIHA (Specificities)
Respiratory tract infections (unspecified)	–	–	+ (DL)/PCH
Viral infections (specific)	EBV	+/–	+ (anti-i)
	CMV	+	+/– (anti-i)
	Parvovirus (B19)	+ (often with PRCA)	+/– (DL)
	Varicella	+/–	+ (anti-Pr, anti-I, anti-DL)
	Rubella	–	+ (anti-Pr1) Monotypic IgM
	HIV	+	+ (anti-I, anti-i, anti-Pr)
Bacterial infections (specific)	Mycoplasma	+/–	+ (anti-I, anti-Pr)
	Brucellosis	+/–	+ (anti-I)
	Haemophilus influenzae		+ (DL)
Parasitic infections (specific)	Visceral leishmaniosis	+	–

–, not reported; +, predominant type of autoimmune hemolytic anemia; +/–, single or few cases reported; *CMV*, cytomegalovirus; *DL*, Donath-Landsteiner antibody; *EBV*, Epstein-Barr virus; *PCH*, paroxysmal cold hemoglobinuria; *PRCA*, pure red blood cell aplasia.

Autoimmune hemolytic anemia has been described in a few cases of acute hepatitis A, B, C, or E and in a number of cases of untreated chronic hepatitis C. However, in a large study, an increased prevalence of AIHA has only been found in interferon (INF)-treated hepatitis C patients.[25]

Anecdotal reports have described patients in whom WAIHA was associated with measles, *Chlamydia pneumoniae*, or miliary tuberculosis and CAIHA with adenovirus, measles, leptospiral pneumonia, *Escherichia coli* infection (all anti-I), pneumococcal pneumonia (anti-Pr), *Haemophilus influenzae*) (DL), or *Bartonella henselae* (DAT negative).

Some cases of AIHA have been described after vaccination against hepatitis B, influenza (MF59 adjuvanted), diphtheria–tetanus–pertussis, or rubella. Such associations could not be confirmed in systematic studies.

Drug-Induced Autoimmune Hemolytic Anemia

Historically, methyldopa, an antihypertensive drug, was the first known drug to induce AIHA. The prevalence of methyldopa induced AIHA is 1% with 10 to 20% DAT-positive patients without anemia, indicating that DAT positivity is not always followed by overt disease. Currently, INF-α and purine nucleoside analogues are the most common causes of drug-induced AIHA (Table 44-4). The diagnosis of drug-induced AIHA in a patient with AIHA after drug exposure can only be made if the *indirect* DAT result is positive and the RBC eluate contains a RBC antibody. Such tests have not been performed in all patients in whom drug-induced AIHA was claimed.

The temporal relationship between drug exposure and AIHA is complex. In some instances, AIHA may occur after long-term exposure to a drug (INF or targeted antibodies). In AIHA caused by purine analogues, AIHA occurs typically after a few cycles of therapy of CLL and is probably dose related (lower incidence and severity at reduced doses of fludarabine). Chlorambucil is said to induce AIHA, particularly after the end of treatment. This has not been found in all studies.

Interferon-induced AIHA has been described in various diseases (particularly hepatitis C and malignant diseases). It is caused by warm antibodies, occurs usually after long exposure to the drug, and disappears spontaneously after cessation of the drug within weeks. AIHA induced by purine analogues (fludarabine, cladribine) occurs mostly during or immediately after the end of drug treatment, but the onset is delayed in some cases. The antibodies are warm or mixed antibodies. This complication occurs predominantly in patients with CLL but seems to be very rare in lymphoma patients treated with these drugs. The incidence of AIHA in patients with CLL after fludarabine or cladribine monotherapy ranges from 2% to 11%. When fludarabine is combined with cyclophosphamide (and rituximab), AIHA is less frequent and probably less severe, but this may be attributable to the lower fludarabine dose in these protocols. Patients with a positive DAT result before treatment have a higher risk of purine analogue–induced AIHA. With steroids alone, about half of the patients achieve a lasting complete remission. So far no cases of AIHA have been reported after treatment of CLL with bendamustine.

An interesting and as yet unexplained phenomenon is the fact that some patients with CLL-associated AIHA may achieve remissions after fludarabine or cladribine treatment. However, it is general practice to avoid purine analogues in patients with AIHA.

Other drugs that have been associated with WAIHA (in single case reports) were INF-ß, the monoclonal anti-CD 11 antibody efalizumab, and lenalidomide.

A peculiar type of CAIHA has been described in some patients with paroxysmal nocturnal hemoglobinuria who had been treated with the anti C5 antibody ecuzulimab. These patients had an incomplete response to ecuzulimab. The RBCs of these patients accumulate C3d on their surfaces.

Table 44-4 Drug-Induced Autoimmune Hemolytic Anemia

Drug	Risk Factors	AIHA Onset	Type of AIHA	Response to Treatment	Diseases Treated
Methyldopa	Not known	Delayed	WAIHA	Resolution after withdrawal	Hypertension
INF-α	Pretherapeutic positive DAT	Delayed (8-11 mo)	WAIHA	Resolution spontaneous or after steroids	Hepatitis C Hematologic malignancies
Efazulimab	Not known	Many months	WAIHA	Resolution after withdrawal	Arthritis (rare)
Etanercept	Not known	Delayed	CAIHA	Resolution after rituximab	Rheumatoid arthritis (rare)
Fludarabine Cladribine Pentostatin	CLL Pretherapeutic positive DAT result	Early (median, 3-4 cycle) or delayed	WAIHA Mixed AIHA	Half of AIHA resolve after steroids	CLL Lymphomas* AML*
Bendamustin	CLL	No or only very low risk of AIHA			CLL Lymphomas
Chlorambucil	CLL	Delayed onset	WAIHA		CLL
Eculizumab	Patients with incomplete response	After treatment	CAIHA		PNH
Lenalidomide		During treatment	WAIHA	Resolution after withdrawal	One case treated for lymphoma

*No or very low risk.

Autoimmune Hemolytic Anemia in Immune Deficiency States

Autoimmune hemolytic anemia is one of the classical complications of common variable immune deficiency (CVID). The prevalence of AIHA was 4% to 5.5% in large studies. AIHA preceded the diagnosis of CVID in more than half of the cases (median time from diagnosis of AIHA to CVID, 5.5 years). Evan syndrome is common.

Autoimmune hemolytic anemia (often combined with thrombocytopenia) occurs in 23% to 51% of patients with ALPS. The diagnosis of ALPS is made by the demonstration of a high number of circulating TCRαβ$^+$ double-negative (CD4$^-$ CD8$^-$) T lymphocytes. The basic defect of ALPS is a disturbance of apoptosis.[20]

Autoimmune hemolytic anemia is also common in deficiency of purine nucleoside phosphorylase (a T-cell deficiency with almost normal B cells). At least 15% of patients with Wiskott-Aldrich syndrome have AIHA. AIHA occurs before the age of 5 years and is associated with high serum IgM levels. These patients are candidates for allogeneic stem cell transplantation.

DIFFERENTIAL DIAGNOSIS

In patients with DAT-positive hemolytic anemia, the distinction from drug-dependent immune hemolytic anemia is important. In recipients of ABO- or D-incompatible allografts, anti-RBC antibodies are probably produced by immunocompetent memory B cells from the donor. This so-called passenger lymphocyte syndrome (PLS) is frequent in heart and lung transplantation (≤68%). A difficult problem is differential diagnosis of DAT-negative AIHA or Evans syndrome. In younger patients with isolated hemolytic anemia with or without symptoms, hereditary diseases such as hereditary spherocytosis, sickle cell anemia, and thalassemia must be considered. Family history and RBC morphology are most helpful in these cases. In patients with drug-induced hemolytic anemia, nonimmune hemolysis caused by glucose-6-phosphate-dehydrogenase deficiency should be considered. Babesiosis or other infections may cause nonimmune hemolytic anemia. In severely ill patients with hemolytic anemia and thrombocytopenia, idiopathic or cancer-related thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, or disseminated intravascular coagulation should prompt a search for schistocytes in the blood smear.

Paroxysmal nocturnal hemoglobinuria is diagnosed by a deficiency of glycosylphosphatidylinositol (GPI)-anchor proteins on the cell surface caused by a mutation of the *PIG-A* gene. Type II mixed cryoglobulinemia is a condition caused by a monoclonal IgM autoantibody with anti-IgG activity with rheumatoid factor properties frequently associated with hepatitis C. The clinical picture is characterized by a systemic vasculitis syndrome but not by anemia.

TREATMENT

For man years, drugs and procedures routinely used in the treatment of AIHA were not subjected to studies that today are regarded as the gold standard for approval and recommendation. No randomized studies have ever been performed, and even the phase II studies were usually not prospective, small, and often with a heterogeneous population of patients and with a short observation time. Thus, the treatment recommendation in this chapter should be viewed critically.[8]

Goals of Treatment

As in all diseases, the goal of treatment of AIHA is the achievement of a complete clinical and laboratory sustained remission without any residual signs of the disease. Such results can be obtained not only in primary AIHA but also in a substantial number of secondary cases when the underlying disease disappears spontaneously (infection), when the causative drug is withdrawn, or after (curative) treatment (surgery or chemoimmunotherapy) of an underlying malignancy). In most patients with primary WAIHA, the expectations for success must be tempered. Therefore, a practical goal is the achievement of a good clinical response with freedom from symptoms in the absence of side effects of treatment. Remission of AIHA after treatment is often defined by laboratory values, but there is no consensus on the definition of complete (CR) or partial (PR) remission regarding hemoglobin concentration. Formally, one could define CR as absence of transfusion requirement, a normal hemoglobin value (according

to the age and sex of the patient), and absence of signs of hemolysis (normal reticulocyte counts, haptoglobin, and LDH; negative DAT result). Such CR is sometimes seen in secondary AIHA. In primary AIHA, CR is often defined as hemoglobin above 11.0 g/dL without sign of hemolysis, but the DAT result may remain positive. A minimal requirement for PR is the absence of transfusion requirement and a satisfactory clinical condition (usually hemoglobin >9 g/dL). Thus, in AIHA, the treatment goals must be defined individually and tailored to the patient's needs.

Blood Transfusions

Blood transfusions may be necessary for emergency treatment of AIHA. The problem is to find well-matched RBC concentrates. In critical cases, transfusions should not be avoided or delayed because of uncertainty in matching (see box on Transfusion Therapy in Selected Patients With Severe Autoimmune Hemolytic Anemia). The decision is made on an individual basis depending on the speed of development and severity of anemia, the type and cause of hemolytic anemia (the highest acute death rates were observed in patients with fludarabine associated AIHA, IgM WAIHA, and DL antibodies), and the age and clinical condition of the patient. Because the antibody in WAIHA is directed against blood group antigens, no truly matched blood transfusions are possible, but RBCs can be safely given if alloantibodies are excluded.[3] However, some precautions have to be taken. In patients without a history of previous transfusions or pregnancy, the risk of alloantibodies is low, allowing for transfusion of only ABO- and RhD-matched RBCs. In all other patients, extended phenotyping with respect to Rh subgroups (C, c, E, e), Kell, Kidd, and S/s using monoclonal IgM antibodies should be performed for selection of compatible RBC concentrates. Warm autoadsorption or allogeneic adsorption procedures for detection of alloantibodies may be used in exceptional cases. In patients with CAIHA, transfused blood must be prewarmed using commercial warming coils. In all instances, an important precaution is a biological in vivo compatibility test, which includes rapid infusion of 20 mL of blood; 20 minutes observation; and, if there is no reaction, further transfusion at usual speed.

Treatment of Primary Warm Antibody Hemolytic Anemia

First-Line Treatment with Steroids

Newly diagnosed severe WAIHA should be treated immediately with glucocorticoids (steroids) (Fig. 44-3 and Table 44-5; see also box on Initial Steroid Therapy). Therapy starts with an initial dose of 1 mg/kg/day of prednisone orally or an equivalent dose of methylprednisone intravenously. It is recommended to continue with this dose until a hematocrit of greater than 30% or a hemoglobin level of greater than 10 g/dL is achieved. Complete or partial remission is obtained in approximately 80% of patients. Failure to achieve this goal after 3 weeks should result in a switch to second-line therapy. In responding patients, prednisone dose is gradually reduced to 20 to 30 mg/day within a few weeks. Subsequently, the dose is tapered slowly by 2.5 mg to 5 mg/day per month guided by hemoglobin and reticulocyte counts. If the patient is still in remission after 3 to 4 months at a dose of 5 mg/day, withdrawal of steroids can be attempted. The exact rate of patients remaining in CR after the end of steroid therapy is not known but is estimated to be around 20%. Most responders require maintenance steroids to keep the hemoglobin above 9 to 10g/dl\L. About 40% to 50% of patients need 15 mg/day or less prednisone (regarded as the highest tolerable dose for long-term treatment). However, 15% to 20% need higher maintenance prednisone doses.

Great concerns are osteoporosis, osteonecrosis, and bone fracture, particularly of the lumbar spine. About 30% to 50% of patients on long-term steroid treatment experience fractures. The highest loss of bone density occurs early, even at smaller steroid doses, and the risk of fracture increases by 75% during the first months of treatment.

Thus, patients on steroid therapy should receive bisphosphonates, vitamin D, and calcium from the beginning. Folic acid is also recommended. Steroid-induced diabetes is a major risk factor for treatment-related deaths from infections. Although heparin treatment is not recommended for all patients, the possibility of pulmonary embolism must be considered, particularly in patients with AIHA and LA or recurrent AIHA after splenectomy. Previous studies have also found a beneficial effect of standard heparin on AIHA.

Second-Line Treatment

Second-line treatment is considered in patients (1) refractory to initial steroids as defined earlier, (2) in need of a maintenance dose of more than 15 mg/day of prednisone (absolute indications) or (3) who need between 15 mg/day and 0.1 mg/kg/day (relative indication) (Fig. 44-4). Patients with prednisone requirement of 0.1 mg/kg/day or less are potential candidates for long-term low-dose prednisone. Patients refractory to steroid treatment should be reevaluated for underlying diseases or warm IgM antibodies.

Currently, there are two major second-line options for primary WAIHA with proven short- (and long-) term efficacy these ae splenectomy (preferentially laparoscopic) and therapy with the

Transfusion Therapy in Selected Patients With Severe Autoimmune Hemolytic Anemia

Immediate blood transfusion should not be withheld from patients with severe anemia. Small amounts of RBCs may be lifesaving in patients with acute cardiac or cerebral dysfunction caused by anemia. However, precautions have to be taken to avoid transfusion reactions. This requires close cooperation between clinicians and the blood bank. The exclusion of alloantibodies is most important. Patients with a low risk for severe reactions caused by an alloantibody are those without a history of previous transfusions or pregnancy. In high-risk patients, extended RBC phenotyping should be performed for selection of compatible RBC concentrates. In all instances, a biologic in vivo compatibility test has to be performed at the beginning of the transfusion.

Initial Steroid Therapy

Steroid therapy is initiated with oral prednisone (or intravenous methylprednisone) at a dose of 1 mg/kg/day. It is important to keep this dose up until a stable response (hemoglobin >10 g/dL or hematocrit >30%) is achieved. When response is achieved, the prednisone dose should be reduced to 20 to 30 mg/day within a few weeks. The dose is then tapered slowly by 2.5 mg to 5 mg/day per month guided by hemoglobin and reticulocyte counts. If the patient is still in remission after 3 to 4 months at a dose of 5 mg/day, withdrawal of steroids can be attempted. Most responders require maintenance steroids to maintain hemoglobin of greater than 9 to 10 g/dL. Second-line treatment is indicated if the AIHA does not respond within 3 weeks of initial treatment or if high steroid doses are needed for maintenance.

Therapeutic management should include blood glucose monitoring, prophylaxis against osteoporosis (commence early), supplementation with folic acid, and heparin treatment in selected cases.

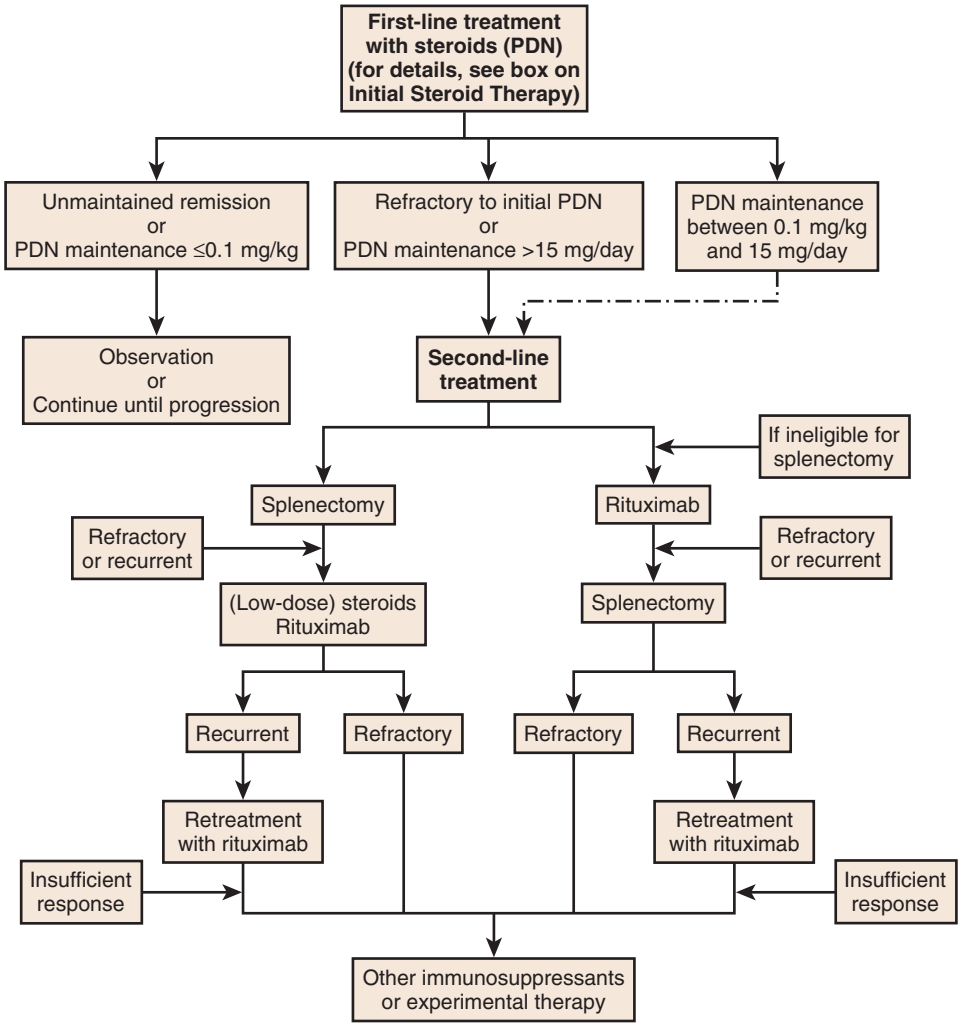

Figure 44-3 PROPOSED ALGORITHM FOR THERAPY OF WARM AUTOIMMUNE HEMOLYTIC ANEMIA. *PDN,* Prednisone. *(Modified from Lechner K, Jäger U: How I treat autoimmune haemolytic anemias in adults.* Blood *116:1831, 2010.)*

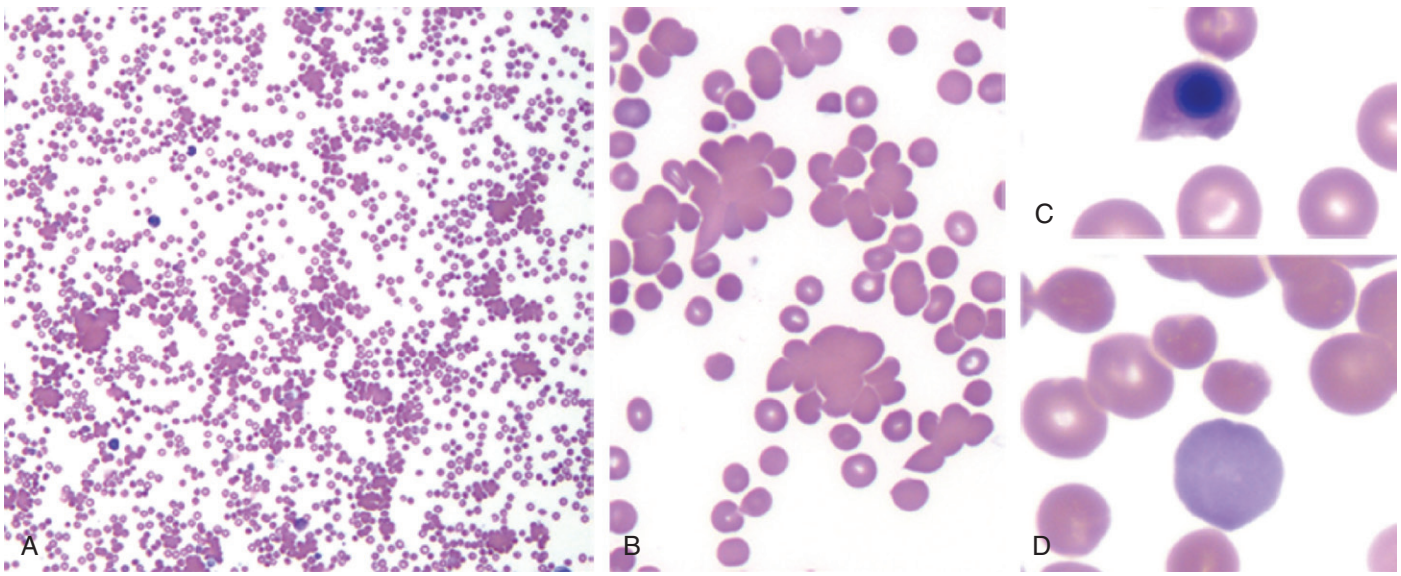

Figure 44-4 PERIPHERAL SMEAR IN COLD AGGLUTININ DISEASE. Low-power scan shows uneven distribution of red blood cells (RBCs) **(A),** which at slightly higher power **(B)** shows the RBCs to be clumped together or agglutinated. This must be distinguished from rouleaux formation. High-power scan shows nucleated RBCs **(C),** polychromatophilia, and microspherocytes **(D).**

Table 44-5 Treatment Options for Primary and Secondary Warm Autoimmune Hemolytic Anemia and Cold Autoimmune Hemolytic Anemia

Disease or Condition	First Line	Second Line	Beyond Second Line	Last Resort
Primary AIHA	Steroids	Splenectomy Rituximab	Azathioprine, MMF, cyclosporine, cyclophosphamide	High-dose cyclophos-phamide, alemtuzumab
B- and T-cell NHL	Steroids	Chemotherapy +/– rituximab (splenectomy in SMZL)		
Hodgkin's lymphoma	Steroids	Chemotherapy		
Solid tumors	Steroids Surgery			
Ovarian dermoid cyst	Ovariectomy			
SLE	Steroids	Azathioprine	MMF	Rituximab Autologous SCT
Ulcerative colitis	Steroids	Azathioprine		Total colectomy
CVID	Steroids + IgG replacement			
ALPD	Steroids	MMF	Sirolimus	
Wiskott Aldrich syndrome	Steroids	Allogeneic SCT		
Allogeneic SCT	Steroids	Rituximab*	Splenectomy T-cells infusion	
Organ transplantation	Reduction of immune suppression, steroids			
Drug induced	Withdrawal	Steroids		
Primary CAD	Protection from cold exposure	Rituximab Chlorambucil	Fludarabine + rituximab	Ecuzulimab,† bortezomid†
PCH	Supportive treatment (postinfectious)	Rituximab* (chronic)		

AIHA, Autoimmune hemolytic anemia; *ALPD,* autoimmune lymphoproliferative disorders; *CAD,* cold agglutinin disease; *CVID,* common variable immune deficiency; *IgG,* immunoglobulin G; *MMF,* mycophenolate mofetil; *NHL,* non-Hodgkin lymphoma; *PCH,* paroxysmal cold hemoglobinuria; *SCT,* stem cell transplantation; *SLE,* systemic lupus erythematosus; *SMZL,* splenic marginal zone lymphoma.
*Early second-line treatment because of known poor response to steroids.
†Off-label use in single cases.

monoclonal anti-CD20 antibody rituximab. From the scientific point of view on the basis of published data, no definite preference for one these treatments is possible because of the insufficient quality of data. For both treatments, there have been no randomized studies comparing these two options, no prospective phase II studies of the individual treatments, and not even high-quality retrospective studies with unselected consecutive patients with uniform diagnosis and pretreatment. The decision for the preferred treatment in a specific patient has to be made on an individual basis based on judgment of the treating physician, the validity of available data on short- and long-term efficacy, the assumed individual risk of adverse events, and the preference of the patient (Table 44-6).

Splenectomy

For splenectomy, there are more, but older data on the short- term efficacy, few data on long-term efficacy, and good recent data on long-term adverse events. CR or PR is achieved in two-thirds of patients (38%-82%), depending on the percentage of secondary cases. In addition, there is good evidence that a substantial number of patients will remain in remission without need of medical intervention for years. In the initial series by Chertkow and Dacie,[26] only two of 28 patients were in remission for more than 5 years, but six patients remained in a stable PR for up to 7 years. In 52 splenectomized patients (percentage of primary AIHA unknown), Coon[27] found that 63% had a hematocrit of 30% or greater without steroids after a mean follow-up of 33 months and 21% had a hematocrit of 30% or greater with a prednisone requirement of 15 mg/day or less after a mean follow up of 73 months. In a study by Allgood and Chaplin,[28] 44% of patients were in CR after more than 1 year after splenectomy.

Splenectomy can safely be performed laparoscopically in almost all patients with primary AIHA with normal-sized spleens. Withdrawal of steroids after splenectomy should be done slowly (as described for primary treatment) to prevent hemolytic crises in case of recurrence. The mortality rate of laparoscopic splenectomy was 0.5% in a large national study. The main short-term risks of splenectomy (in general) are infections, pulmonary embolism, and splenic-portal thrombosis (rare in patients with normal-sized spleen), but these risks have not studied specifically in primary WAIHA.

There is a lifelong increased risk of infections and of venous thrombosis and a very small risk of pulmonary hypertension. The most serious, often fatal, but rare infectious complication is overwhelming pneumococcal septicemia). The risk of infections is highest shortly after splenectomy and decreases after 1 year. In a Scandinavian population-based study, the adjusted relative risk of major infections (requiring hospital contact) in a matched indication comparison 1 year after splenectomy for ITP (with a probably similar risk as AIHA) was 1.4. Although fatal postsplenectomy infections seem to be less common in recent years, it is mandatory to take all measures to reduce this risk. There is good but not definite evidence that preoperative vaccination reduces the risk of severe infections. Vaccination for pneumococci, meningococci, and

Table 44-6 Second-Line Treatment Options After Steroids

Treatment	Dosing and Application	Side Effects	Precautions
Splenectomy (acute)	Preferentially laparoscopic	Infections, thrombosis	Postoperative thromboprophylaxis
Splenectomy (long term)	—	Infections Venous thrombosis	Vaccination, patient information
Rituximab	375 mg/m^2 on days 1,8, 15, and 22 IV	Infusional reactions Infections	Premedication with antihistamines (and steroids)
Danazol	200-400/day PO	Hepatotoxicity	None
Cyclophosphamide	PO or IV Dose adjusted to neutrophil count	Neutropenia Mutagenesis	Neutrophil count monitoring, bladder protection after high doses
Azathioprine	2.0-3.mg/kg/day PO Dose adjusted to neutrophil count	Neutropenia	Neutrophil count monitoring; avoid interaction with other drugs (e.g., allopurinol)
Mycophenolate mofetil	1-2 × 1 g/d PO	Gastrointestinal	
Cyclosporine	PO Dose adjusted to blood levels of CyA Target level, 200-400 ng/mL	Nephrotoxicity Gum hyperplasia	Monitoring of CyA levels and creatinine
Alemtuzumab	SC (variable doses)	Neutropenia	Anti-infectious prophylaxis

CyA, Cyclosporine A; *IV,* intravenous; *PO,* oral; *SC,* subcutaneous.

Haemophilus influenzae should be done before splenectomy. Pneumococcal vaccination should be repeated regularly. Long-term antibiotic prophylaxis is probably not required in adults, but patients should be informed about this risk and should take immediately antibiotics in case unexplained fever. Risk in children maybe reduced by subtotal splenectomy. The long-term risk of venous thrombosis is moderate. Information for patients about short- and long-term risks is required and may be one of the reasons for the fact that surgical treatment is underused. However, splenectomy is the only therapy so far which may provide freedom from treatment in a substantial number of patients for more than 2 years and possibly cure in about 20%.

Rituximab

Rituximab is currently the best available drug option for second-line treatment. Given at a standard induction dose of 375 mg/m^2 intravenously on days 1, 8, 15, and 22, it induces an overall response rate of 82% with a range 17% to 100%. Half of the remissions were reported to be CR. The rituximab schedule and dose are empirically derived from lymphoma treatment, and it is not known whether other schedules including maintenance are equal or better. There are limited data on short-term and almost no data on long-term efficacy and no data on long-term adverse effects. With regard to short-term efficacy, there seems to be no much difference between rituximab and splenectomy. However, in all rituximab studies, the patient population was heterogeneous and included primary and secondary cases, recurrences after splenectomy, and sometimes multiply pretreated patients with WAIHA or CAIHA. In only one study, almost all patients (10 of 11) had steroid-refractory primary WAIHA, but four patients received additional therapies.[29] Eight patients achieved CR and three PR, but six patients had still moderate signs of hemolysis and therefore did not formally fulfill the criteria for a complete remission. Thus, the true response rates for steroid-refractory WAIHA are still unclear. The efficacy and toxicity of rituximab monotherapy was tested in several additional retrospective studies in a mixed population of refractory primary or secondary AIHA. Response usually occurs within 3 weeks. Patients taking steroids before initiation of rituximab should continue on steroids until response to the CD20 antibody. In the D'Arena et al study,[28] at a mean follow-up of 604 days, all patients were still in CR or PR. The longest remission duration was 2884 days. Because of the small patient number, data on long-term efficacy of rituximab should be regarded with caution. Predictors of long-term response are achievement of a CR, conversion to a negative DAT result, and previous splenectomy. Retreatment with rituximab is feasible and may be necessary after 1 to 3 years. Rituximab has been given to children without apparent safety problems.

The caveats of rituximab therapy are that the drug is not licensed for the indication and that infectious complications are rare but sometimes life threatening, particularly with repeat or maintenance treatment. There is a small long-term risk of progressive multifocal leukodystrophy. Nevertheless, rituximab is the preferred option for patients who are not eligible for splenectomy. If one explains the benefits and risks of the two second-line treatments to a patient, he or she usually favors rituximab because it is a noninvasive outpatient treatment, and splenectomy remains still an option in case of failure.

Treatment of Patients with Refractory or Recurrent Disease After Splenectomy or Rituximab

In patients failing splenectomy, an accessory spleen should be excluded. Patients who are refractory to splenectomy or with recurrence after splenectomy can be retreated with steroids, assuming that the disease has become more responsive. This may work well in patients with previous requirement of lower steroid doses (<15 mg/day of prednisone). The other option is to initiate treatment with rituximab immediately.

Patients who are refractory to rituximab should undergo splenectomy, if eligible. There are no data on the influence of initial remission duration on the efficacy of retreatment. In patients relapsing late (>1 year) after rituximab, retreatment with the antibody maybe a good option.

A potentially interesting drug for second-line treatment (which has also been used as first-line treatment along with steroids) is danazol, an attenuated androgen (see Table 44-6).[14] It has established efficacy in C1 esterase deficiency, and efficacy has been claimed in several immune diseases, including WAIHA. Initial very promising results (overall response rate [ORR] 60%-70%) in AIHA could not be confirmed in subsequent studies, but it may worthwhile to do further studies because the toxicity seems to be relatively low with the exception of a potentially increased risk for hepatocellular carcinoma.

The advantage of high-dose immunoglobulins is low toxicity. Remission rates are low, and routine use in patients with AIHA is not recommended in a recent guideline.

Treatment Options Beyond Second-Line Therapy in Primary Warm Autoimmune Hemolytic Anemia

Given the nature of the disease, the use of immunosuppressive treatment of all kinds seems logical. Response rates of up to 60% have been reported, but data are frequently based on low patient numbers or anecdotal reports. Cyclophosphamide was very effective in two studies. Other published data of treatment with azathioprine or cyclophosphamide are less favorable with only about one-third of patients having any response. Evaluation is even more complicated by the fact that patients frequently received concomitant treatment with steroids. Dosing of azathioprine is difficult because of the narrow therapeutic window, hypersensitivity because of genetic defects, and interaction with other drugs. Cyclophosphamide may have long-term mutagenic effects. Other immunosuppressive drugs such as cyclosporine or mycophenolate mofetil (MMF) have shown high response rates in very small series.

Repeated cycles of high-dose cyclophosphamide (50 mg/kg/day for 4 days) remain an option in selected, highly refractory patients. In a pilot study, six of nine patients received a CR with a median duration of 15 months or more. Alemtuzumab has also been effective at a dose of 10 mg/day for 10 days. Promising results were recently published for a combination of low-dose rituximab (100 mg on days 1, 8, 15, and 22) with alemtuzumab (10 mg on days 1-3). The results of autologous stem cell transplantation were disappointing, but allogeneic transplantation may be used as treatment of last resort in patients with Evans syndrome.

In general, second-line treatment should be selected taking into account severity of AIHA, age, comorbidity, and patient preference. Because of the low curative potential of all treatment options, patient safety remains the major concern.

Treatment of Secondary Warm Autoimmune Hemolytic Anemia

In secondary AIHA, the treatment goal depends on the type and severity of the underlying disease. The treatment goal may vary from palliative treatment of AIHA to cure by eradication of the underlying disease. Preferred treatment options are listed in Table 44-6.

Warm Autoimmune Hemolytic Anemia Associated With Systemic Lupus Erythematosus

Steroids used similar as in primary WAIHA induce high response rates. Maintenance treatment with azathioprine, cyclophosphamide, or both may be required. Rituximab is effective against WAIHA and SLE but may be associated with a higher risk of progressive multifocal leukoencephalopathy in this setting.

Warm Autoimmune Hemolytic Anemia Associated With Chronic Lymphocytic Leukemia

In previously untreated CLL with isolated DAT-positive anemia but no other treatment indication, treatment with prednisone as in primary WAIHA is the first choice. In case of refractoriness or relapse, rituximab monotherapy is moderately effective but produces response rates of more than 80% in combination with cyclophosphamide and dexamethasone. Cyclosporine also has good activity. In refractory AIHA or in AIHA with advanced or progressive CLL, treatment of the underlying disease with a rituximab-containing regimen according to International Workshop on Chronic Lymphocytic Leukemia guidelines is recommended.[30] In elderly or comorbid patients with active CLL, chlorambucil with prednisone with or without rituximab is a good choice. In general, fludarabine-containing regimens should be used with caution in the presence of a positive DAT result or overt AIHA. In this case, bendamustine with (or without) rituximab is a good alternative. Alemtuzumab has proven activity against CLL and AIHA and is a good second-line option, particularly in patients with associated pure RBC aplasia.

Warm Autoimmune Hemolytic Anemia in Other Non-Hodgkin Lymphomas

AIHA in NHLs does not respond well to steroids in general and splenectomy is only effective in splenic marginal zone lymphomas. Sustained responses in most other lymphoma subtypes have been obtained with lymphoma-specific treatment with or without rituximab.

Drug-Related Warm Autoimmune Hemolytic Anemia

Cessation of the drug may be effective in many cases, and further use of the drug should be avoided. Fludarabine-induced AIHA may be life threatening but responds to steroid therapy.

Treatment of Warm Autoimmune Hemolytic Anemia in Congenital and Acquired Immune Deficiency States and Special Serologic Types

The treatment of WAIHA in patients with CVID is very similar to that of those with primary WAHA. Additional regular prophylactic treatment with IgG concentrates reduces the risk of recurrence. Splenectomy is effective, but the risk of serious infections is high.

In ALPS, treatment should be started with steroids and then switched to MMF, but sirolimus has the highest efficacy improving not only AIHA but also lymphadenopathy. AIHA associated with IgM hypergammaglobulinemia in Wiskott-Aldrich syndrome is an indication for allogeneic stem cell transplantation.

Patients with AIHA after allogeneic stem cell transplantation respond poorly to steroids but often do respond to rituximab. An early switch to rituximab may be reasonable in these patients. AIHA in drug-related severely immunesuppressed patients after transplantation of solid organs responds best to reduction of immune suppression. Patients with IgM WAIHA respond poorly to steroids. These patients are candidates for early rituximab treatment. The same is true for chronic AIHA caused by DL antibodies.

Treatment of Cold Autoimmune Hemolytic Anemia

Primary Chronic Cold Agglutinin Disease

Primary CAD is defined as a CAIHA in patients with IgM MGUS or in lymphoma without overt clinical signs but with bone marrow infiltration. All patients should be advised to avoid cold exposure. Drug treatment is required in only half of the patients. Treatment is initiated in symptomatic patients or when hemoglobin levels drop below 9 to 10 g/dL. Because IgM-coated RBCs are mainly destroyed in the liver, CAIHA does not respond to splenectomy and poorly to steroids. The most effective and best evaluated treatment is rituximab in a standard lymphoma dose. Two studies have provided similar results. In a prospective phase II study, 20 of 27 patients responded, but most responses ($n = 19$) were partial. The median response duration was 11 months, but most patients responded to retreatment with rituximab. A combination of rituximab and oral fludarabine induced higher overall response rates (76%) with a longer duration (median, 66 months).[31] Remarkable responses have recently been obtained with the terminal complement inhibitor ecuzulimab and the proteasome inhibitor bortezomib in

single rituximab-refractory patients. Preparation of patients with high-titer cold antibodies for surgery by cryofiltration may be required in rare instances.

Secondary Cold Autoimmune Hemolytic Anemia

In CAIHA associated with lymphomas or solid tumors, treatment of the underlying disease by chemo(immuno)therapy or curative resection results in good responses. Cases of infection related CAIHA usually resolve spontaneously, but antibiotic therapy may accelerate the process.

FUTURE DIRECTIONS

Future research should mainly be directed toward generation of better treatment options. The generation of international guidelines is still hampered by the lack of evidence from randomized trials. Every effort should be made to initiate valid comparisons of major treatment options such as steroids, splenectomy, and rituximab, potentially through registries or randomized trials.

Novel therapeutic options may be provided by next-generation anti-CD20 antibodies or antibodies against other targets such as complement factors. Insights into the way T cells drive and control the immune reaction could lead to novels immunotherapeutic approaches. Synthetic peptides modulating Th1 responses via regulatory T cells may be developed into therapeutic tools. Another option would be to target structures on macrophages responsible for RBC destruction (e.g., the CD47–SIRP-α interaction). There is hope that novel targeted therapies will replace splenectomy and even steroid treatment of patients with AIHA.

CHAPTER 45

EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIAS

Elizabeth A. Price and Stanley S. Schrier

By definition, extrinsic causes of hemolysis are abnormalities in the environment in which the red blood cells (RBCs), usually normal themselves, circulate. These abnormalities can be acute or chronic in nature. They can arise from congenital lesions but usually result from acquired lesions. Inherited anomalies of glucose-6-phosphate dehydrogenase (G6PD) deficiency, which reduces the RBCs' ability to deal with oxidative insults, can leave RBCs more vulnerable to environmental insults. Determination of hemolysis with various levels of compensation as the cause of an anemia is accomplished using the approaches described in Chapter 32. Signs of extrinsic hemolysis with minimal or no anemia can be valuable clues to diseases of other organ systems. Among the most important forms of extrinsic hemolytic anemia are those caused by immune mechanisms; these are discussed in Chapter 44.

Clinical and morphologic findings suggest the many misfortunes that can befall RBCs in their travels. They can be trapped in an abnormal bone marrow stroma network, sheared by jets in an abnormal heart, cut and fragmented by fibrin strands stretched across damaged areas in the microvasculature, or attacked by parasites. They can undergo stasis and perhaps metabolic depletion in giant hemangiomas or in an enlarged spleen. An abnormally functioning liver or kidney can cause a buildup of substances in plasma that alter RBC shape and metabolism. Drugs can cause oxidation or other metabolic damage. Oxidant injury provokes degradation of hemoglobin with the formation of hemichromes (see Drug-Induced Oxidative Hemolysis later). Degraded hemoglobin and hemichromes bind avidly to the cytoplasmic tail of the major transmembrane protein band 3 (see Chapter 43) and cause clustering of band 3 oligomers. Immunoglobulins and complement then bind to the external membrane face over clusters of band 3, promoting immune destruction. Other membrane proteins may be subject to oxidative attack. Toxins, venoms, heat, and mechanical trauma can directly destroy the membrane. These agents may cause an alteration in the asymmetry of the phospholipid bilayer, causing phosphatidylserine to move from the inner leaflet of the membrane bilayer to the outer leaflet, where it can be recognized by macrophages.

In general, only the most devastating damage leads to direct intravascular destruction. Usually, the initial insult leads to an eventual change in the external portion of the RBC membrane, which causes macrophages to retard, hold, remove, or otherwise modify RBCs. Infection or inflammation can activate these macrophages. Some RBC changes are accompanied by a decrease in RBC deformability, which retards flow and thereby facilitates the action of macrophages on the affected RBC. All of these changes lead to extravascular hemolysis.

FRAGMENTATION HEMOLYSIS: MICROANGIOPATHY

Clinical Manifestations

Patients present with various degrees of hemolytic anemia and compensation, with evidence of RBC fragmentation on smear (Fig. 45-1; see box on Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias). RBC removal is generally extravascular, with minimal or moderately decreased levels of haptoglobin. If RBC damage is sufficiently severe, signs of intravascular hemolysis may be present. Because of the underlying pathology, some of these syndromes show evidence of platelet removal, leading to thrombocytopenia. Occasionally, the underlying cause produces activation and depletion of procoagulant factors with consequent activation of the fibrinolytic system, consistent with disseminated intravascular coagulation (DIC) (see box on Causes of Red Blood Cell Fragmentation Hemolysis).

Pathophysiology

Fragmentation hemolysis occurs when mechanical forces disrupt the physical integrity of the RBC membrane. In vitro shear stresses in excess of 3000 dynes/cm^2 cause RBC fragmentation. In vivo studies in patients with mitral prosthetic regurgitation and hemolysis show high peak shear stresses of 4500 dynes/cm^2, very rapid acceleration or deceleration, or both.

Research suggests alternative mechanisms of producing microangiopathic hemolysis that involve platelets and small vessel thrombi. The platelet-rich, fibrin-poor microvascular thrombi found in many patients with thrombotic thrombocytopenic purpura (TTP) now are thought to be caused by abnormally decreased ADAMTS-13 activity.[1] This metalloprotease is responsible for converting the highly thrombogenic ultra large multimers of von Willebrand factor made by platelets and endothelial cells into the smaller forms normally found in circulation. Mutations in or antibodies against ADAMTS-13 result in unusually large multimers of von Willebrand factor attached to endothelial cell surfaces, where platelets may excessively aggregate, leading to formation of microvascular thrombi even in the absence of endothelial damage. In the case of disseminated cancer, the cause of microangiopathy may be microvascular tumor emboli.

Whatever the mechanism of mechanical trauma, the RBC membrane is viscoelastic and has self-sealing properties (see Chapter 43) so that little hemoglobin leaks out as the cell is being cut. However, prolonged distortion of the membrane produces a plastic change; therefore, the smaller RBC fragments usually do not become microspheres or microdisks but continue to display evidence of the shearing

Differential Diagnosis of Extrinsic Nonimmune Hemolytic Anemias

There is no simple approach to the differential diagnosis of hemolysis caused by extrinsic nonimmune hemolytic anemia. The physician must pay close attention to the clinical finding. Useful clues come from a determination of whether RBC breakdown is predominantly extravascular or intravascular, but most important in the analysis is the observation of RBC morphology, which can focus the differential diagnosis. Unhelpful terms such as *aniso* and *poik* should be discarded. RBCs are spherocytic, stomatocytic, fragmented, echinocytic, acanthocytic, spurred, or bite cells or can be mixtures of these types.

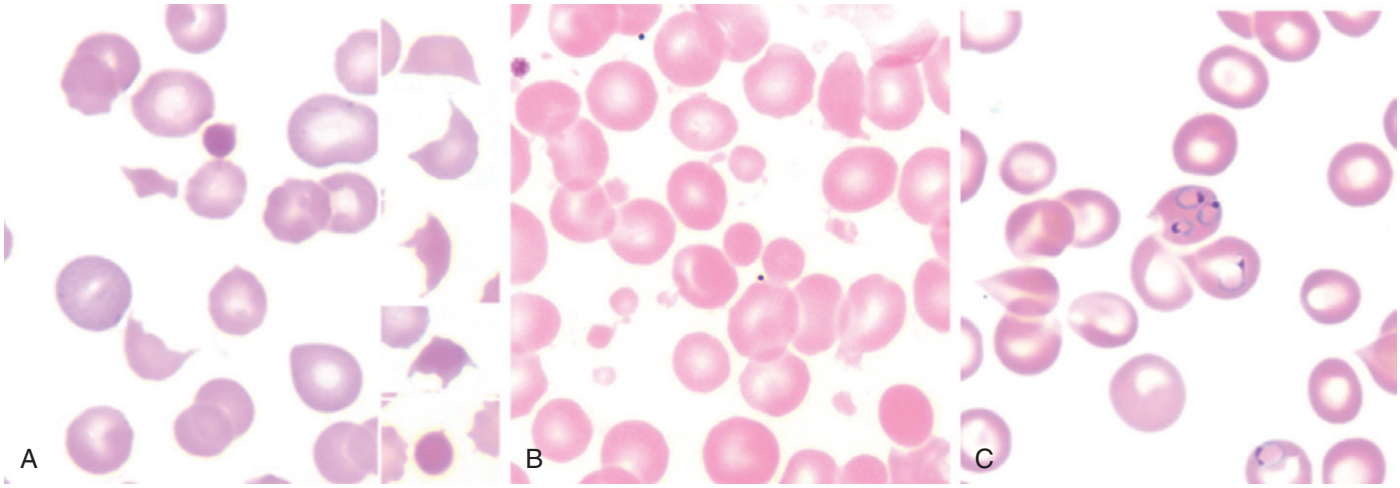

Figure 45-1 PERIPHERAL BLOOD SMEARS FROM EXAMPLES OF EXTRINSIC NONIMMUNE HEMOLYTIC ANEMIA. **A**, Microangiopathic hemolytic anemia. Note the schistocytes, fragmented cells, spherocyte, and polychromasia. More examples of damaged red blood cells (RBCs), including classic "helmet cell" *(top),* are seen to the immediate *right insert*. **B**, Thermal injury from a burn. Thermally damaged RBCs form numerous microspherocytes and tiny RBC fragments. **C**, Malaria infestation. RBCs containing *Plasmodium falciparum* malaria. Note the high rate of infestation, the presence of only ringed forms, and the multiply infested RBC *(center)*.

Causes of Red Blood Cell Fragmentation Hemolysis

- Damaged microvasculature
- Thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS)
- Associated with pregnancy: preeclampsia or eclampsia; hemolysis plus elevated liver enzymes plus low platelets (HELLP syndrome)
- Associated with malignancy, with or without mitomycin C treatment
- Vasculitis: polyarteritis, Wegener granulomatosis, acute glomerulonephritis, or *Rickettsia*-like infections
- Systemic lupus erythematosus
- Abnormalities of renal vasculature: malignant hypertension, acute glomerulonephritis, scleroderma, or allograft rejection with or without cyclosporine treatment
- Disseminated intravascular coagulation
- Malignant hypertension
- Catastrophic antiphospholipid antibody syndrome
- Atrioventricular malformations
- Kasabach-Merritt syndrome
- Hemangioendotheliomas
- Atrioventricular shunts for congenital and acquired conditions (e.g., stents, coils, transjugular intrahepatic portosystemic shunt, Levine shunts)
- Cardiac abnormalities
 - Replaced valve, prosthesis, graft, or patch
 - Aortic stenosis or regurgitant jets (e.g., in ruptured sinus of Valsalva)
- Drugs: cyclosporine, mitomycin, ticlopidine, clopidogrel, tacrolimus, or cocaine
- Systemic infection: bacterial endocarditis, brucellosis, cytomegalovirus, HIV, ehrlichiosis, Rocky Mountain spotted fever

event or distortion in the form of typical irregular shapes. These irregular shapes and the rigidity that they reflect subsequently interfere with the ability of RBCs to fold, elongate, and deform sufficiently to pass through 3-μm capillaries and even smaller slits in the walls of the sinusoids of the reticuloendothelial system. This sequence leads to their destruction.

Differential Diagnosis

Generally, the differential diagnosis of fragmentation hemolysis can be deduced from the clinical findings. The presence of a prosthetic heart valve or a regurgitant jet that fragments or accelerates (i.e., Waring blender syndrome) can be readily discerned. The clinical picture of thrombotic thrombocytopenic purpura–hemolytic uremic syndrome (TTP–HUS) is generally dramatic and acute (see Chapter 136). Atrioventricular malformations may be associated with DIC and platelet removal; the diagnosis requires a high index of suspicion and imaging studies. The presence of preeclampsia in a pregnant woman with microangiopathic hemolysis usually is obvious, but the HELLP (hemolysis, elevated liver enzymes, and low platelet count) syndrome is a serious complication of pregnancy that can occur without other signs of preeclampsia or hypertension. This syndrome can produce hepatic rupture, visual failure, DIC, seizures, and congestive heart failure and requires treatment by prompt delivery of the fetus. Cancer can be an underlying cause of microangiopathy. Vessels supplying malignant tumors are thought to be structurally abnormal. They exhibit the same sort of fibrin stranding that produces fragmentation hemolysis in DIC and TTP–HUS.

Continued use of invasive diagnostic and therapeutic procedures with insertion of foreign bodies into the circulation has been complicated by microangiopathic hemolysis. A transjugular intrahepatic portosystemic shunt can cause the syndrome in approximately 10% of patients. The hemolysis usually disappears after 12 to 15 weeks. Similarly, use of coil embolization to seal off a patent ductus arteriosus may also cause significant hemolytic anemia. Vasculitis has also been implicated as a cause.

Multiple drugs are associated with microangiopathic hemolysis, most commonly quinine.[2] Cyclosporine, tacrolimus, and mitomycin C have been implicated as causing an HUS picture that typically develops within weeks to months of exposure. Total body irradiation and bone marrow transplantation also are associated with microangiopathic hemolysis. Both chemotherapeutic agents and targeted cancer agents, including immunotoxins, monoclonal antibodies, and tyrosine kinase inhibitors, are associated with thrombotic microangiopathy.[3] The thienopyridines ticlodipine and clopidogrel are both capable of producing a significant thrombotic microangiopathy that differs somewhat in presentation. Ticlodipine-associated TTP typically occurs between 2 and 12 weeks after initiation of therapy and presents with severe thrombocytopenia, microangiopathic hemolytic anemia, highly elevated lactate dehydrogenase, and normal renal function and is associated with severe deficiency of plasma ADAMTS13 activity.[4] In contrast, clopidogrel-associated TTP usually

presents within 2 weeks of drug initiation and is associated with mild thrombocytopenia, microangiopathic hemolytic anemia, mildly elevated lactate dehydrogenase (LDH) levels, marked renal insufficiency, and near-normal levels of ADAMTS13 activity. Other reported exposures associated with microangiopathic hemolytic anemia include the use of cocaine and the herb echinacea, The mechanisms of drug-induced thrombotic microangiopathy are not well understood but include immune-mediated causes (as in the case of quinine) and direct toxicity to the endothelium.[5]

Thrombotic microagniopathic hemolytic anemia can also be the presenting feature of severe, systemic infection, including viral (cytomegalovirus [CMV], HIV), fungal, and bacterial infections.[6] Whether infection "triggers" the development of TTP or instead the presentation remains debatable.

In one large series, 10 of 351 (2.8%) patients diagnosed with TTP were subsequently diagnosed with disseminated malignancy.[7] Symptoms suggesting an underlying malignancy include dyspnea, cough, atypical pain, and poor response to plasma exchange. The diagnosis was made by bone marrow biopsy in six of the 10 patients, and all patients died shortly after the diagnosis of malignancy was made.

Therapy

Management is primarily directed toward the underlying disease or event. Compensation of RBC production should be optimized by replacing iron or folic acid if the patient is deficient in these nutrients. Occasionally, removal or repair of a damaged native or prosthetic heart valve is necessary when the hemolysis produces a disabling transfusion requirement. Treatment of TTP with plasma exchange has been found to be superior to plasma infusions, with fresh-frozen plasma and cryo-free plasma appearing to have equal efficacy. Thrombotic microangiopathy associated with cyclosporine often is reversible with cessation of cyclosporine.

OTHER FORMS OF MECHANICAL DAMAGE TO RED BLOOD CELLS

Heat Denaturation

Normal RBCs undergo budding and fragmentation when exposed to a temperature of 49°C (120°F) in vitro (Fig. 45-1, *B*). In some of the hereditary hemolytic anemias, this process occurs at temperatures as low as 46°C (115°F) (see Chapter 43). Under some clinical circumstances, temperatures sufficient to cause heat denaturation of RBCs have been generated. Occasionally, cell warmers used with transfusions in cold agglutinin disease have malfunctioned and cooked the RBCs about to be transfused. In one case, a patient's mother warmed the RBCs with a hot water bottle, reasoning that such cells would cause less vein irritation to her child. Such transfusion was followed by evidence of intravascular and extravascular hemolysis, and the peripheral smear showed RBC budding and fragmentation (Fig. 45-2). Presumably, similar events can lead to hemolysis in patients who have sustained very extensive burns. In patients with heat stroke, the temperature usually is below 42°C (108°F), a temperature at which little RBC denaturation occurs.

Mechanical Trauma

The classic example of RBC damage caused by mechanical trauma is march hemoglobinuria, which occurs in soldiers after a long march, in joggers after running on a hard road, or in karate or conga drumming enthusiasts after practice. Anemia is rare, and reticulocytosis is uncommon. Evidence of typical intravascular RBC destruction is present and is thought to be caused by direct trauma to RBCs in the vessels of the feet or hands. Switching jogging paths or wearing better footwear often relieves the problem. Some cases show evidence of an underlying RBC membrane abnormality. Strenuous exercise may induce oxidant stress, as evidenced by increased levels of malonyldialdehyde, a marker of lipid peroxidation, in marathon runners after a race. Occasionally, malfunction of the cell savers used during abdominal or thoracic surgery mechanically injures RBCs.

Cardiopulmonary Bypass

Postperfusion syndrome occurs in some patients after cardiopulmonary bypass. The syndrome includes acute intravascular hemolysis and leukopenia as part of a febrile, inflammatory clinical picture. Affected patients may develop pulmonary distress and even adult or acute respiratory distress syndrome. Visible hemoglobinemia occurs, with rising plasma hemoglobin levels, and is associated with an increase in lysed RBC ghosts seen in the whole blood and plasma. These ghosts are coated with the complement complex C5bC9 (see Chapter 22). Presumably, the complement pathway is activated as the blood passes through the oxygenator. The reason why complement activation results in lytic attack on RBCs (and granulocytes) is unknown. Free hemoglobin released into the plasma secondary to intravascular hemolysis may contribute to acute kidney injury after cardiopulmonary bypass.[8] Treatment involves knowledge of the process and requisite support until the situation corrects itself.

Osmotic Attack

Abrupt changes in osmolality can cause hemolysis. Freshwater drowning may be associated with so much water in the lungs that the RBCs swell as they undergo an in vivo osmotic fragility test in the pulmonary vasculature. Conversely, saltwater drowning can cause profound dehydration of RBCs, producing a situation analogous to xerocytosis (see Chapter 43). Rarely, acute hemolysis occurs from mistaken infusion of or exposure to concentrated hypertonic solutions such as those used in hemodialysis. To manage such an event, the physician must recognize its cause, appreciate the shrunken RBCs on a peripheral smear, and restore isotonicity as quickly as possible. In these cases, use of a hemodialysis device, if available, may be helpful.

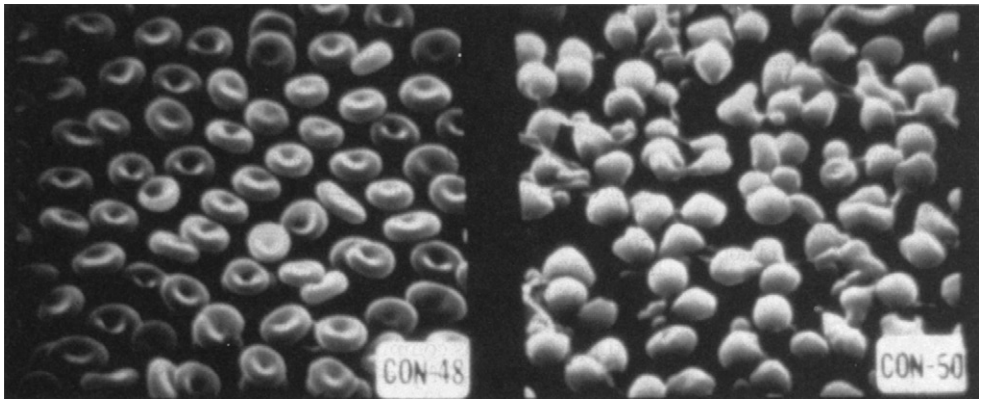

Figure 45-2 MORPHOLOGIC CHANGES ARE PRODUCED BY HEATING NORMAL RED BLOOD CELLS AT THE INDICATED TEMPERATURES. Budding begins abruptly at 50°C (122°F) and eventually leads to spherocytosis.

Hypersplenism

In all organs of the monocyte–macrophage system (i.e., reticuloendothelial system), blood cells leaving the arterial bed are generally unloaded into channels such that the RBCs must pass through the wall of the sinus to reenter the circulation. The sinusoidal wall has slits 2 to 3 μm long and usually is endothelialized on one side and has a macrophagic lining on the other side. The normal human adult RBC is a discocyte with a surface area 40% larger than a sphere of that volume (see Chapter 31). This excess surface area allows an RBC with a diameter of approximately 8 μm to twist, elongate, and deform sufficiently to squeeze through these 2- to 3-μm slits. The excess surface area, occasionally referred to as the ratio of surface area to volume (SA:V), is critical and normally is approximately 1.4. Any condition that reduces SA:V reduces the ability of RBCs to traverse these sinusoidal slits because plump spheres cannot deform sufficiently.

Factors that interfere with interaction of the cytosol and the membrane also impair the ability of the RBC to deform. Oxidant attack may produce Heinz bodies that come to lie adjacent to the membrane. They interfere with the smooth movement of the membrane over the cytosol, a process called *tank treading*. Such cells are selectively blocked from leaving the splenic cords and entering the sinuses. Inflammation or infection may enhance the ability of splenic macrophages to attack and ingest RBCs. Although not strictly a mechanism of hypersplenism, Kupffer cell erythrophagocytosis is a prominent finding in patients undergoing graft-versus-host hemolysis seen after liver transplantation.

The spleen is more complicated than other reticuloendothelial organs in that the afferent arterioles pass through lymphoid nodules (i.e., white pulp) and then terminate in the cords of Billroth (i.e., red pulp), into which blood cells are discharged. In the slow flow of the cords of Billroth, blood cells are selectively attacked by macrophages and are in direct contact with several classes of lymphocytes. The blood cells then must pass through the cordal walls before they can approach the sinus wall, which they must pass through to reenter the circulation. The spleen provides a double filter, and the blood cells must be remarkably deformable to pass through it. This slow passage permits highly selective action by macrophages, which have receptors that can detect several sorts of alterations in these blood cells. These receptors include the Fc receptor for the appropriate portion of the immunoglobulin molecule, receptors for complement components such as C3b, and perhaps receptors that detect alterations in the outer portion of the phospholipid bilayer or in the externally oriented glycopeptides. The macrophage then holds, retards, modifies (i.e., pitting function), or removes (i.e., culling function) the blood cells identified. Normally, the pitting function of the spleen allows it to remove Howell-Jolly bodies and normally occurring endocytic vacuoles (called *pocks* because of their appearance on phase interference or Nomarski microscopy). The normal culling function of the spleen is exemplified by its removal of senescent RBCS.

All the activities of the spleen presumably are markedly accentuated in a large spleen, and if the increased activity is sufficiently extensive, hypersplenism ensues. The size of the spleen, not the portal pressure, is important in determining the degree of RBC sequestration. Other factors that may play a role are the state of activation of the splenic macrophages and the size of the small slits between the splenic cords and sinuses. The macrophages and slits seem to be under a degree of control, as evidenced by variations in splenic removal of RBCs in patients with malaria.

The clinical picture of hypersplenic hemolysis is dominated by the specific cause of the splenomegaly. Although the causes of splenomegaly are legion, there are several general mechanisms (Table 45-1). Usually some degree of anemia is seen, with evidence of a compensatory increase in RBC production. Because stasis and trapping in the spleen are associated with macrophagic attack and remodeling of the RBC surface, the reduction in SA:V leads to spherocytosis. If the RBCs undergo a prolonged period of distortion when traversing the cordal–sinus barrier, tailed RBCs will be present as the RBC membranes undergo a plastic change (see Chapter 43). Because the enlarged spleen can trap and remove platelets and white blood cells, variable thrombocytopenia and leukopenia may occur. The bone marrow may show normal to increased cellularity with erythroid hyperplasia.

Table 45-1 Causes of Splenomegaly

Cause	Example
Neoplasia	Lymphoma, hairy cell leukemia
Infection	Bacterial endocarditis, malaria, schistosomiasis, tuberculosis
Portal bed obstruction	Alcoholic cirrhosis, splenic vein thrombosis
Collagen vascular disease	Systemic lupus erythematosus, malignant phase of rheumatoid arthritis
Chronic inflammatory disease	Rheumatoid arthritis
Chronic hereditary or acquired hemolytic anemia	Severe β-thalassemia, autoimmune hemolytic anemia
Lipoidosis	Gaucher disease
Amyloidosis	AL and AA types
Tropical splenomegaly syndrome	Hyperreactive malarial splenomegaly syndrome

Management depends on the cause of splenic enlargement. The anemia or pancytopenia usually is not profound; however, splenectomy may be contemplated if the anemia is severe. In most situations, recognition of the possibility of hypersplenism is most important in guiding the approach to diagnosis of an unexplained anemia. Massive splenomegaly frequently is associated with expansion of the plasma compartment, and measurement of hemoglobin, hematocrit, or RBC levels may give a falsely low value of the RBC mass present. In that circumstance, the true RBC mass can be determined by ^{51}Cr assay.

A good example of massive splenomegaly causing plasma volume expansion is tropical splenomegaly syndrome, also known as *hyperreactive malarial splenomegaly syndrome*. Diagnostic criteria include massive splenomegaly more than 10 cm below the costal margin with no other cause identified; immunity to malaria; elevated serum immunoglobulin M (IgM) levels; and clinical response to treatment with antimalarial drugs such as chloroquine, proguanil, or pyrimethamine and folic acid. The pathophysiology of the splenomegaly seems to be poorly controlled B-lymphocytic production of antibodies, and IgM stimulation may be a response to malarial antigens or an unidentified mitogen. Malarial parasites are almost never found. The apparent anemia is in large part caused by plasma volume expansion, although RBC survival is reported to be slightly attenuated. Antimalarial therapy for several months reduces spleen size, so splenectomy is unnecessary.

Infection

Infection can cause hemolytic anemia via several pathophysiologic mechanisms (Table 45-2).

Parasite Infections

The classic example of direct parasitization is infection by *Plasmodium falciparum* (Fig. 45-1, *C*), *Plasmodium vivax,* or *Plasmodium malariae*. Infection with malaria, primarily *P. falciparum,* is a major health problem in the developing world, causing an estimated 300 to 500 million infections and 1 to 3 million deaths annually.[9] The burden of disease rests most heavily on young children and pregnant women. *Falciparum* malaria can cause a life-threatening anemia, with severe anemia defined as hemoglobin less than 5 g/dL associated with parasitemia and a normocytic blood film.[9] Malaria is primarily a

Table 45-2 Mechanisms by Which Infection Can Cause Hemolysis

Mechanism	Example
Direct parasitization of red cells	Malaria, babesiosis
Immune mechanisms	Cold agglutinin hemolysis after infectious mononucleosis or mycoplasmal pneumonia (see Chapter 44)
Induction of hypersplenism	Malaria, schistosomiasis
Altered red cell surface topology	*Haemophilus influenzae* infection
Release of toxins and enzymes	Clostridial infection causing thrombotic thrombocytopenic purpura–hemolytic uremic syndrome, *Escherichia coli* 0197, human immunodeficiency virus infection

disease of the tropical developing world but is still seen in the United States and its territories, primarily as an import from outside the United States.[10] Of the 1298 cases reported in the United States in 2008, 117 (9%) were classified as severe, two of which were fatal. In each of the malarias, sporozoites injected by the mosquito in its saliva make their way to liver cells. After 1 to 2 weeks, they become merozoites, which burst out of the liver cells and into the bloodstream. Then, in a remarkable process, the parasite, by means of its apical end and related organelles called rhoptries, attaches to a specific receptor on the RBC surface. For *P. vivax,* the Duffy blood group antigen appears to be involved.

Plasmodium falciparum binds to sialic acid residues on the RBC surface that are on glycophorin A. After specific attachment, a convulsive movement occurs during which the RBC engulfs the parasite by a process resembling receptor-mediated endocytosis. Upon invasion of the RBC, the malarial parasite starts digesting the hemoglobin, depositing the undigested heme in the form of hemozoin. Knobs appear on the RBC surface, and the RBC becomes a sphere. Many proteins of parasitic origin are inserted into the RBC membrane, and some appear to cluster underneath these knobs. A parasite protein called mature-parasite-infected erythrocyte surface antigen (MESA) binds to membrane protein 4.1, and another parasite protein called ring-infected erythrocyte surface antigen (RESA) binds to β spectrin. Both spectrin and protein 4.1 are integral components of the membrane skeleton, and the consequence of the binding of malarial proteins is RBC membrane stabilization. Thus stabilized, the parasitized RBC can continue to survive while the parasite continues to digest its contents.[11]

The parasite recruits the RBC's metabolic machinery, degrades and ingests hemoglobin, and grows, eventually bursting out of the RBC, and the cycle begins again. The RBCs are lysed intravascularly as a consequence of direct parasitic destruction, extravascularly as a consequence of changes in the splenic microvasculature and in the activation state of the monocyte–macrophage system. Treatment consists of the use of appropriate antimalarials and the support of erythropoiesis, including the use of RBC transfusion or exchange (or both) when indicated.

The anemia of malarial infections also involves mechanisms distinct from lysis of parasitized RBCs. Erythropoiesis is suppressed, leading to suppression of erythroid precursors and inadequate reticulocytosis during acute infection.[12] This inadequate hematopoietic response may be exacerbated by underlying iron deficiency, hemoglobinopathies, or concomitant infection (e.g., HIV), all potential contributors to the severity of anemia. In addition, loss of uninfected erythrocytes plays a major role in the development of anemia, with an eight- to 10-fold greater loss of unparasitized RBCs compared with parasitized cells. Uninfected RBCs have reduced deformability, and the degree of reduced deformability correlates with the severity of infection. Poorly deformable RBCs likely are cleared by the spleen. Evidence of in vivo removal of immature malarial forms prompts the question of whether "uninfected" cells that are lost represent previously infected cells that nevertheless remain abnormal. Insertion of a merozoite rhoptry protein, ring surface protein 2, on RBCs in which infection was aborted has been implicated in the clearance of unparasitized erythrocytes and erythroid progenitors. In addition, uninfected RBCs demonstrate increased binding of immunoglobulins that probably are nonspecific immune complexes. Acute malarial infection, particularly with *P. falciparum*, also leads to alteration in splenic function that incites premature destruction of uninfected RBCs.[13]

The lifespan of transfused RBCs is likewise decreased. ^{51}Cr-labeled normal RBCs infused into patients infected with malaria demonstrate a shorter lifespan than in normal control participants; this effect may persist after clearance of the parasitemia. Alternatively, parasites can be removed from RBCs along with RBC membrane by the process of pitting, producing parasite-free spherocytes. This mechanism potentially explains the observed disparity between anemia and parasitemia.

Other infections that have somewhat similar pathophysiologies include Carrión disease (i.e., bartonellosis), in which a bite from the sandfly injects *Bartonella bacilliformis,* which attaches to the RBC surface of up to 80% of erythrocytes and causes lysis, leading to the massive hemolysis that characterizes acute infection. It appears that invasion of RBCs partly depends on the flagella of *Bartonella* spp. Incubation with antiflagellin antiserum reduces invasion of RBCs. The bacteria also secrete deformin, a factor that leads to deep pitting on the surface of RBCs, presumably providing a portal of entry into the erythrocyte. There also may be a role for splenic clearance of infected cells, and prior splenectomy appeared to protect a patient from hemolysis during acute infection.

Babesia organisms also directly invade RBCs, producing fever and hemolytic anemia. The parasite is transmitted by ticks and transfusions of infected blood products[14] and can be transmitted vertically. Most tickborne cases occur on the West Coast, particularly in Washington and California, and in the northern portion of the Midwest; cases occurring on the East Coast are concentrated in Massachusetts and Nantucket Island. However, transfusion-associated cases have been reported throughout the United States.[14] In one report of transfusion-associated babesiosis, the median interval from transfusion to onset of clinical manifestations was 37 days. The organisms can be seen invading RBCs on smear examination, somewhat like *P. falciparum* malaria, but these organisms produce no pigment. The highest risk of death from babesiosis occurs in individuals who are older than 50 years or are immunocompromised because of acquired immunodeficiency syndrome (AIDS), drugs, transplantation, or asplenism. Sporadic reports indicate that acquired chronic toxoplasmosis occasionally is associated with hemolytic anemia.

Alteration of the Red Blood Cell Surface by Bacterial Products

Infection can produce hemolysis by altering the RBC surface. An example is the hemolysis caused by *Haemophilus influenzae* type b. Severely affected patients, particularly those with meningitis, have developed hemolytic anemias requiring RBC transfusions. The capsular polysaccharide of the bacterium, composed of polyribosyl ribitol phosphate (PRP), is released during infection and binds to the RBC surface. Infected patients develop antibodies to PRP. When the balance between PRP-coated RBCs and anti-PRP antibodies is correct, an immune-type hemolysis occurs and requires complement. RBC destruction is thought to be both intravascular and extravascular.

Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells

The most dramatic example of hemolysis caused by bacterial action is clostridial infection, during which the organism releases enzymes that acutely degrade the phospholipids of the membrane bilayer and

the structural membrane proteins. The resulting spherocytes are extremely sensitive to osmotic lysis. The setting can be any infection, but our experience is limited to acute cholecystitis, surgery of the biliary tree, and infections surrounding an obstetric event, including criminal or self-induced abortion or other infection of the gravid uterus. Patients may also have an underlying gastrointestinal, genitourinary, neuroendocrine, or hematologic malignancy.[15] The signs of infections may be obvious, but fever may be unimpressive. Signs of collapse appear acutely, and the clue is profound intravascular hemolysis, with a spherocytic anemia developing with shocking suddenness. The blood smear characteristically has numerous spherocytes with little evidence of microangiopathy, may be tinged red because of marked hemoglobinemia, and may have ghost cells. A clue to the severity of the process may be the inability of the laboratory to perform chemical determinations or to type and cross-match the blood because the sample is hemolyzed. With even the slightest suspicion of hemolysis caused by bacterial action, the physician immediately starts full doses of penicillin and clindamycin; evaluates the patient for DIC (see Chapter 141); and prepares to support the patient for shock, DIC, acute renal failure, and hemolytic anemia. Whether hysterectomy is lifesaving in the case of septic abortion is unclear.

Hemolysis Caused by Less Well Understood Infections

HIV infection can cause Coombs-positive autoimmune hemolytic anemia, a TTP-like syndrome, and microangiopathic hemolysis. Primary HIV infections manifested as an acute hemolytic crisis in a patient with G6PD deficiency.[16] CMV infection has been reported to cause severe Coombs-negative hemolytic anemia in immunocompetent adults.[17] Case reports of autoimmune hemolytic anemia and HUS associated with CMV infection have emerged. The hemolytic anemia in visceral leishmaniasis may be caused in part by generation of oxidative metabolic products. Severe microangiopathic hemolytic anemia has been described in cases of cutaneous anthrax.

Hemolysis Associated with Liver Disease

Hemolysis in liver disease by itself usually is not of overwhelming clinical importance, but it may contribute to the severity of anemia when coupled with defects in RBC production and the type of gastrointestinal blood loss that occurs in several forms of liver disease. Hemolysis in patients with liver disease has several causes. The spleen may be enlarged as a consequence of portal hypertension and produce a hypersplenic picture, a phenomenon seen commonly in hepatic cirrhosis.

The literature on RBC shape change in liver disease is considerable. The target cell in cirrhosis has an increased SA:V that appears to be a consequence of increased cholesterol and phospholipid content of the membrane bilayer. The cholesterol increase usually is proportionately greater, resulting in an increased cholesterol-to-phospholipid ratio. This increase in lipid probably accounts for the increased RBC surface area, such that more membrane than usual is present in relation to cellular contents. These RBCs probably circulate as bell-shaped RBCs called *codocytes*. However, on dried blood films, they assume the appearance of target cells. Target cells do not have a shortened survival. The RBCs of patients with liver disease frequently are echinocytes when wet preparations are examined, but these echinocytes are not easily apparent on dried blood smears. The echinocytes seem to be produced by a material in the patient's plasma that causes normal RBCs to become echinocytic; this material is an abnormal echinocytogenic high-density lipoprotein. Echinocytes do not necessarily have a shortened survival. Some forms of echinocytic RBCs are normally deformable when studied in the ektacytometer or rheoscope.

A brisk, clinically important hemolysis can occur in some patients with severe liver disease. The peripheral smear in these individuals usually shows acanthocytes (i.e., distorted RBCs). Extreme forms are called *spur cells,* which probably are acanthocytes additionally remodeled by an enlarged spleen (see box on Reduction of Dangerous Methemoglobin Levels) and are considerably enriched in cholesterol. They are rapidly removed in the spleen, which usually is enlarged.

Reduction of Dangerous Methemoglobin Levels

Levels of methemoglobin in excess of 20% to 30% can be dangerous, but they can be easily treated with methylene blue (1-2 mg/kg) infused intravenously over 5 minutes as 0.1 to 0.2 mL/kg of a 1% solution. In the presence of a functioning, intact NADPH–methemoglobin reductase system, methylene blue is reduced to leukomethylene blue, which reduces methemoglobin to hemoglobin.

Increased RBC membrane proteolytic activity may be a partial explanation for the differences between acanthocytosis and spur cells, and additional pathophysiologic mechanisms may be involved. Although the adult RBC cannot synthesize phospholipids de novo, it can identify and remove peroxidized fatty acid chains that interfere with normal membrane lipid fluidity. When the fatty acid is removed, a lytic lysoderivative remains; therefore, the missing fatty acid chain must be replaced. A store of acyl groups in the form of acylcarnitine exists in RBC membranes. When needed, the fatty acid (i.e., acyl group) is transferred to acyl-coenzyme A and then inserted into the potentially lytic lysophospholipid by the enzyme lysophosphocholine acyltransferase. Lysophosphocholine acyltransferase is inhibited in spur RBCs, and the same inhibition can be produced by heavily loading RBCs with cholesterol in vitro.

In a case of almost fatal oxidative hemolysis, hydrogen peroxide was injected directly into the Hickman catheter of a patient with AIDS because some persons infected with HIV had circulated a pamphlet suggesting that hydrogen peroxide could be used therapeutically to control HIV infection. We now are seeing AIDS patients with dapsone-induced methemoglobinemia and hemolytic anemia (see Chapter 42). Methemoglobinemia, if severe, is treated as described in the preceding paragraph and in Chapter 42.

In spur cell anemia, the RBCs have an abnormal membrane SA:V ratio, their membrane fluidity is impaired, and they are unable to remove and repair peroxidatively damaged fatty acids. Occasionally, spur cell hemolytic anemia is severe enough to necessitate consideration of splenectomy. Operative morbidity in such cases is considerable because the underlying liver disease usually produces problems with thrombocytopenia and leukopenia as well as with procoagulants and intolerance to anesthesia. Spur cell anemia is typically associated with alcoholic cirrhosis, but can also be seen in patients with nonalcoholic cirrhosis. The anemia tends to be severe and portends a poor prognosis. Transfusions are of limited efficacy because the membrane abnormalities are acquired by transfused RBCs.[18] In one case, spur cell anemia occurred in a pediatric patient after orthotopic liver transplantation and resolved after retransplantation.[19]

Acute alcoholism can be associated with hypophosphatemia, defined as levels less than 0.2 mg/dL. Such hypophosphatemia presumably interferes with RBC intermediary metabolism (see Chapters 31 and 42), and RBC adenosine triphosphate (ATP) levels fall. Very low ATP levels are associated with RBC rigidity, which leads to fragmentation, loss of surface area, and spheroidicity. The RBCs then are further trapped in the spleen. This hypophosphatemia syndrome can also cause neuromuscular disorders, including weakness, paresthesias, tremors, and seizures. It should be treated aggressively with orally and intravenously administered phosphate supplements. Hypophosphatemia also occurs in patients with cirrhosis, patients receiving total parenteral nutrition whose phosphate intake is not carefully monitored, and patients taking large amounts of phosphate-binding antacids.

Stomatocytosis can occur in severe liver disease and is thought to be a sign of acute alcoholic intoxication. The change in RBC shape

can also be seen in acute pancreatitis. The stomatocyte is a cell well on its way to becoming a spherocyte. The reduction in SA:V leads to trapping in the microvasculature of the spleen and other organs of the monocyte–macrophage system, producing various degrees of hemolysis.

Renal Disease

The anemia in renal disease is multifactorial. A major component is impaired RBC production, which can be well controlled with erythropoietin. Renal disease also impairs platelet function, which may lead to occult blood loss. However, hemolysis also can occur and is multifactorial. Disease of the small renal arterioles can produce fragmentation hemolysis of the sort seen in TTP–HUS, preeclampsia, and malignant hypertension (see the box on Causes of Red Blood Cell Fragmentation Hemolysis). Otherwise, whether uremia produces significant shortening of RBC survival is not clear. Patients with chronic renal failure who are undergoing hemodialysis may be particularly susceptible to oxidative damage to their RBCs. RBC glutathione (GSH) is reduced in some patients, and the activity of the enzymes G6PD and glutathione peroxidase is relatively low. The ability of these RBCs to deal with generation of peroxides probably is impaired.

Venoms, Bites, Stings, and Toxins

The best-known example of toxin-caused hemolysis is discussed in the earlier section on Bacterial Products Causing Hemolysis by Direct Damage to Red Blood Cells.

Insect, Spider, and Snake Bites

Hemolysis occurs after bee and wasp stings, snake bites, and spider bites. Isolated cases of acute intravascular hemolysis after bee and wasp stings have been reported. Two kinds of dangerous spiders live in the United States: the southern black widow and the brown recluse spider. Both sexes of the black widow produce the venom, but only the female has fangs capable of penetrating human skin. Black widow spider bites produce generalized muscle pain and muscular rigidity. Hemolysis is not common. Brown recluse spider bites cause a considerable local reaction, called the *volcano lesion*. DIC and hemolysis may occur after a lag of 24 to 48 hours. Envenomation results in cleavage of RBC glycophorins, presumably making the RBCs more susceptible.[20] Corticosteroids may be beneficial. The hemolysis appears to be self-limiting, but RBC transfusion support may be needed.

In some parts of the world, cobra bites can cause intravascular hemolysis because the venom contains phospholipases. In the United States, the two classes of venomous snakes are pit vipers (e.g., rattlesnakes, cottonmouths, moccasins, and copperheads) and coral snakes. Pit viper venom affects hemostasis and may produce DIC with bleeding but rarely hemolysis. Coral snake venom produces severe neurologic impairment. Therapy consists of support and use of the appropriate antivenin and prophylactic antimicrobials and tetanus injections.

Drugs and Chemicals Exclusive of Those Producing Oxidative Hemolysis

Potassium Chlorate

Potassium chlorate ingestion is listed as a cause of hemolysis, but this compound is no longer available in hospital pharmacies and has no currently recognized medical use. Arsine gas (AsH3) is generated in industrial plants that engage in lead plating, galvanizing, etching, and soldering. Inhalation of a toxic amount produces a severe intravascular hemolysis of unknown pathogenesis and may require urgent RBC and plasma exchange.

Copper

The idea that copper can produce human hemolytic disease is best supported by observations of episodes of severe hemolysis and acute liver failure in patients with Wilson disease. The patient usually is a child, adolescent, or young adult for whom the diagnosis of Wilson disease has not yet been made. The initial clinical presentation usually is dominated by Coombs-negative hemolytic anemia accompanied by weakness and dark urine. Associated findings include coagulopathy, a rapid progression to renal failure, relatively modest rises in serum aminotransferases, and a low alkaline phosphatase level. In addition to the presence of a brisk reticulocytosis, the typical findings of intravascular hemolysis may be present, including elevated LDH, low haptoglobin, and markedly elevated bilirubin levels.[21] Review of the peripheral smear may not reveal any specific morphologic findings, although both stomatocytosis and blister cells consistent with oxidant injury have been described. In one reported patient with concomitant transfusion-dependent hemoglobin E/β thalassemia, the acute hemolysis led to a severe unexpected drop in the post-transfusion hemoglobin level.[22] Because of the hereditary deficiency in the copper-binding protein ceruloplasmin, urine and serum non–ceruloplasmin-bound copper levels in patients with hemolysis are very high.

Free copper can interfere with glucose metabolism by hexokinase inhibition and alternatively can generate oxidative hemolysis, perhaps by acting as a Fenton reagent. It is important to establish the diagnosis promptly. When this condition is suspected, the practitioner should look for Kayser-Fleischer rings on physical examination and measure serum and urine copper and ceruloplasmin levels. Treatment with penicillamine[23] or trientine plus zinc reduces the serum copper level and stops the hemolysis. In the case of acute liver failure, the treatment is urgent liver transplantation. Plasmapheresis and hemofiltration may be beneficial in reducing the copper level and can serve as a bridge to transplant. In some cases, plasmapheresis in combination with chelation therapy or the use of a fractionated plasma separation and adsorption dialysis system may avert the need for transplant in impending acute liver failure. Other forms of copper poisoning may cause hemolysis in patients who do not have underlying Wilson disease. The amount of copper ingested would have to exceed the copper-binding capacity of normal ceruloplasmin levels.

Lead

There are at least two general forms of lead intoxication. One type is chronic, slow cumulative poisoning (i.e., saturnism). An example is occupational exposure. Symptoms are predominantly neurologic and nephrologic, with variable degrees of anemia, which may be caused by a production defect combined with hemolysis. Relatively acute poisoning occurs when lead inadvertently finds its way into a food source or is consumed as part of an exotic medication. Subacute lead poisoning leads to central nervous system symptoms, hepatitis, nephrotoxicity, hypertension, and abdominal colic along with seizures and severe hemolytic anemia. Physical examination may reveal a lead line on the gums. Peripheral smear shows extensive coarse basophilic stippling and reticulocytosis; however, RBC morphology is not otherwise characteristic. Some researchers state that intravascular destruction occurs, but no proof has been provided. Bilirubin levels are not significantly elevated.

The diagnosis of lead-related hemolysis can be made from the history and findings on physical examination, which include a lead line on the gingiva and coarse basophilic stippling on RBCs, which reflects the pathologic aggregation of ribosomes. The diagnosis is confirmed by measuring blood and urine lead levels. The level of acuity determines the therapy.

The cause of the anemia is complex. Lead interferes with several steps in heme synthesis, particularly those involving heme synthetase and δ-aminolevulinic acid dehydratase (see Chapter 36). The inhibition of heme synthetase probably accounts for the elevation in free erythrocyte protoporphyrin, which provides a useful corroborative diagnostic test for lead toxicity. Inhibition of heme synthesis also probably accounts for the elevated urinary levels of δ-aminolevulinic acid and coproporphyrin. Lead poisoning mimics the basophilic stippling and accumulation of pyrimidines seen in hereditary deficiency of the enzyme pyrimidine 5′-nucleotidase, probably because lead attacks the enzyme (see Chapter 42).

Ribavirin

Current treatment of chronic hepatitis C virus (HCV) infection consists of combination therapy with pegylated interferon (INF) and ribavirin, a nucleoside analogue. Ribavirin's activity against HCV includes inhibition of inosine monophosphate dehydrogenase, a key step in de novo guanine synthesis. Treatment with ribavirin may produce a dose-dependent hemolytic anemia, which typically is reversible 1 to 2 months after discontinuing treatment.[24] The hemoglobin drops by an average of 2 to 3 g/dL and may fall below 11 g/dL in one third or more of patients. The anemia may necessitate a dose reduction of ribavirin or may be treated with recombinant erythropoietin at 40,000 units weekly. A decrease in the total cumulative dose of ribavirin may be associated with decreased sustained virologic response, which would suggest that dose reduction secondary to anemia would have an adverse impact on treatment efficacy. However, in one retrospective study, a drop in hemoglobin of greater than 3 g/dL was instead associated with improved sustained viralogic response rate compared with those with a drop in hemoglobin 3 g/dL or less,[25] suggesting conversely that the degree of hemolytic anemia may serve as a biomarker of efficacy. Ribavirin is transported into the erythrocytes and accumulates as ribavirin monophosphates, diphosphates, and triphosphates.[24] The steady-state concentration of ribavirin in erythrocytes is approximately 100-fold higher than that of plasma, and higher erythrocyte ribavirin levels correlate with worsened anemia during therapy. Accumulation of phosphates leads to a decrease in ATP levels compared with control erythrocytes. Because ATP is required to generate the glucose-6-phosphate needed for glycolysis and the hexose monophosphate shunt, reduced levels of ATP may lead to oxidative damage, as evidenced by increased aggregates of band 3, which bind anti–band 3 immunoglobulin G (IgG) and complement. The ribavirin prodrug viramidine induces less anemia than ribavirin, although efficacy was decreased when used at fixed-doses compared with a ribavirin-containing regimen. Fellay et al[26] have detected two polymorphisms in the inosine triphosphatase (ITPA) gene, which encodes a protein that hydrolyses inosine triphosphate, and were protective against severe anemia in patients treated with HCV. These two polymorphisms were associated with reduced ITPA activity and accumulation of inosine triphosphate in red blood cells. The mechanism of this protective effect is not yet fully understood. The anemia in patients treated with ribavirin may be exacerbated by concomitant treatment with pegylated INF, which suppresses hematopoiesis, and may also be associated with autoimmune hemolytic anemia. Anemia may also be exacerbated when ribavirin and INF are used in combination with the protease inhibitor,[27] a regimen which is efficacious in the treatment of genotype 1 disease.

DRUG-INDUCED OXIDATIVE HEMOLYSIS

General Concepts

The potential for normal RBCs to undergo auto-oxidative destruction is great because the cell is loaded with 20-mM hemoglobin, most of which is bonded to oxygen at the iron(II) atom in heme. The bond that allows the reversible association and dissociation of oxygen from the heme moiety of hemoglobin involves partial transfer of an electron from iron(II) to oxygen. That oxygen then has an extra electron, which makes it a superoxide radical. Ordinarily, when oxygen leaves hemoglobin, it returns the electron. If it does not, a highly reactive superoxide ion is released, leaving behind it an iron(III) moiety called *methemoglobin*.

$$\text{Hb Fe}^{2+}\text{O}_2 \rightarrow \text{Hb Fe}^{3+} + \text{O}_2^{-1}$$

Methemoglobin cannot reversibly bind oxygen. Methemoglobin in itself is not harmful to RBCs, but if the oxidative assault persists, methemoglobin is converted to hemichromes, which are variably denatured hemoglobin intermediates in which the distal histidine unit binds to the oxidized heme. This step is associated with conversion from a high to a low spin state, as measured by electron spin resonance. Continued oxidation leads to irreversibility of hemichrome oxidation, precipitation, and eventually formation of Heinz bodies. Hemichromes and Heinz bodies can destroy membrane function directly or by causing oxidation of membrane proteins and lipids.[28] Approximately 3% of hemoglobin is converted to methemoglobin each day, but the finding that only 1% of hemoglobin normally is in the form of methemoglobin indicates that a mechanism preventing oxidation in RBCs is in effect. These mechanisms are limited because RBCs lack the ability to either efficiently generate ATP or synthesize enzymes. The primary means for preventing or addressing oxidant injury are the generation of the reduced form of nicotinamide adenine dinucleotide (NADH) via the Embden-Meyerhof glycolytic pathway and the generation of nicotinamide adenine dinucleotide phosphate (NADPH) via the hexose monophosphate shunt. NADH is used to reduce methemoglobin by cytochrome b5 reductase, and NADPH is used to reduce glutathione and for catalase activity. Defects in this defense system against oxidation lead to an enhanced tendency to oxidative hemolysis. Examples are G6PD deficiency states. G6PD catalyzes the initial rate-limiting step in the hexose monophosphate shunt. Deficiencies lead to a reduced ability to generate NADPH in response to oxidant stress. Any agent or event that interferes with the smooth offloading of oxygen enhances the generation of O_2^{-1} and methemoglobin, as indicated in the equation. If the reducing power of the RBC is inadequate, hemichromes and Heinz bodies are generated. Many agents appear to cause oxidative hemolysis by interfering with the smooth functioning of the heme cleft.

Pathophysiology

After the oxidative attack has been initiated, the sequence proceeds along a recognizable track. The oxidative attack is directed at hemoglobin and the RBC membrane. However, these structures are not clearly separable because the precipitated hemichrome and Heinz bodies come to lie against the cytosolic face of the membrane. Methemoglobin may be detectably elevated, with levels as high as 50% to 60% of total hemoglobin. The hemichromes, by themselves or with their iron portions acting as a Fenton reagent, mediate the generation of hydroxyl free radicals, which add their effect to that of superoxide and hydrogen peroxide. Lipid peroxidation may take place, leading to membrane blebbing and cell lysis as well as loss of asymmetry of the phospholipid membrane bilayer. Movement of phosphatidylserine and phosphatidylethanolamine to the outer bilayer of the membrane results in increased recognition by macrophages in the reticuloendothelial system. Membrane proteins may be cross-linked, with binding of denatured, oxidized hemoglobin to the membrane cytoskeleton, which may increase splenic macrophage recognition. In addition, the RBCs are rigid and susceptible to trapping in sinusoidal structures, whether or not they have Heinz bodies lying against the membrane. In vitro evidence suggests that oxidized RBCs are increasingly susceptible to phagocytosis by macrophages. These features may account for extravascular destruction. The oxidative lesions can be severe enough to cause intravascular destruction as well, producing hemoglobinemia and hemoglobinuria.

Agents that Cause Oxidative Hemolysis

Therapeutic agents
- Nitrofurantoin (Furadantin)
- Sulfasalazine (Azulfidine)
- *p*-Aminosalicylic acid
- Phenazopyridine (Pyridium)
- Phenacetin
- Dapsone and other sulfones
- Primaquine

Recreational drugs
- Isobutyl nitrate
- Amyl nitrite

Miscellaneous agents
- Naphthalene mothballs
- Paraquat
- Hydrogen peroxide

The smear may show bite cells, which look as if a macrophage had taken a bite, removing a Heinz body–containing segment of membrane. RBC rigidity may result in irregularly shaped cells because these undeformable cells are unable to undergo elastic recoil after fighting their way through the sinus wall. Recurrent loss of membrane material may produce spherocytes. Severe hemolysis may produce the kind of circulating ghost or hemighost called a *blister cell* or *bite cell*. These RBCs have an empty veil of membrane on one side and puddled hemoglobin on the other. A Heinz body preparation may be positive. However, the absence of bite cells does not rule out the diagnosis.

The clinical picture is determined by the specific agent used. Screening for G6PD deficiency or a related disorder using an enzyme assay or the ascorbate cyanide test may be useful. Although any defect in the antioxidant defense mechanisms, such as G6PD deficiency, considerably increases the susceptibility to hemolysis, many agents can produce oxidant hemolysis even in persons with normal defense mechanisms (see box on Agents That Cause Oxidative Hemolysis). Paraquat ingestion has occurred inadvertently and in suicide attempts. Profound cyanosis with methemoglobinemia can occur within hours, with levels of 120% or higher. The condition may be succeeded by hemolysis, with Heinz bodies seen in appropriate preparations of RBCs.

Toxic ingestion or inhalation of nitrites may occur in suicide attempts from industrial exposures; via diets high in pickled or smoked foods; through intentional recreational use; or in infants from formulas prepared using well water high in nitrates, which are reduced to nitrites in the infant gut.[29] Nitrites bind to hemoglobin, producing methemoglobinemia, which may be so profound as to produce coma. If methylene blue infusion does not quickly turn the chocolate color of blood back to normal, the physician must consider the possibility that the patient is G6PD deficient and therefore unable to generate adequate amounts of NADPH (discussed earlier under Drug-Induced Oxidative Hemolysis: General Concepts). In that case, exchange transfusion may be lifesaving. Benzocaine topical anesthesia in the form of a spray or cream can cause severe methemoglobinemia, with cyanosis and dyspnea requiring methylene blue treatment.

Pyridium (phenazopyridine) can cause oxidative hemolysis even in the absence of renal disease. This agent is commonly used for treatment of bladder irritation. The *Physician's Desk Reference* recommends maximum therapy of 2 days. However, patients not uncommonly are given a prescription for 1 to 4 weeks of therapy.

It has been recognized for more than 130 years that therapy with dapsone causes oxidative hemolysis. In the past, dapsone was used primarily to treat leprosy and dermatitis herpetiformis and was not often encountered as a cause of oxidative hemolysis. Dapsone has come into more widespread use in some communities as a very effective prophylactic agent against *Pneumocystis carinii* pneumonia in patients with AIDS. The reduced levels of GSH reported in patients with AIDS may enhance dapsone toxicity. Some clinics screen potential recipients for G6PD deficiency (see Chapter 42) and, if results are negative, proceed with dapsone therapy. However, dapsone can cause oxidative attack on normal RBCs, leading sequentially to methemoglobinemia, Heinz bodies, and hemolysis, all occurring at generally accepted standard doses. Dapsone is metabolized to a hydroxylamine derivative that is directly toxic to RBCs.

Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia

Although large granular lymphocytic leukemia usually manifests as neutropenia and a rheumatoid-like picture, several patients with a severe Coombs-negative hemolytic anemia in the absence of splenomegaly have been described. Large granular lymphocytic leukemia has occurred in a splenectomized subject. The mechanism is unknown, but one report identified direct cytotoxicity against RBCs by the large granular lymphocytic cell lines.

There have been no formal studies on therapy for large granular lymphocytic leukemia–related hemolysis, although immunosuppressive therapy with prednisone or methotrexate has been reported as being partially or wholly successful.

MISCELLANEOUS, POORLY CHARACTERIZED CAUSES OF EXTRINSIC HEMOLYTIC ANEMIAS

Interferon-α as a Cause of Hemolytic Anemia

Both microangiopathic and autoimmune hemolysis have been reported with INF-α use. Zuber et al[30] reported eight patients with chronic myeloid leukemia who developed thrombotic microangiopathy confirmed by renal biopsy. Seven of these patients had identifiable hemolysis, and three had thrombocytopenia. They also reviewed 13 other cases of microangiopathy associated with INF-α reported in the literature and observed that most cases occurred in the setting of prolonged therapy in chronic myeloid leukemia. Two cases of chronic hepatitis with microangiopathy were notable for having received unusually high doses of INF for this indication. Cases of autoimmune hemolysis have been reported with INF-α therapy in the setting of chronic myeloid leukemia or chronic hepatitis C.

Hemolysis With Intravenous Immunoglobulin G

Strictly speaking, hemolysis with intravenous IgG is a form of immune hemolysis. However, preparations of IgG contain anti-A and anti-B antibodies and rarely cause an alloimmune hemolytic anemia, as described in two young women undergoing treatment for idiopathic thrombocytopenic purpura. If this situation occurs and more intravenous IgG is needed, performing a minor cross-match and choosing a preparation of intravenous IgG that gives no reaction is recommended. In addition to isoantibody production, anemia has been reported with intravenous IgG because of immune complex–mediated complement activation.

For hemolytic anemia with large granular lymphocyte leukemia, see box on Hemolytic Anemia in Chronic Large Granular Lymphocytic Leukemia.

CHAPTER 46

NEUTROPHILIC LEUKOCYTOSIS, NEUTROPENIA, MONOCYTOSIS, AND MONOCYTOPENIA

Lawrence Rice and Moonjung Jung

Abnormalities of leukocyte number are commonly encountered in medical practice. The clinical significance of leukocytosis or leukopenia varies from none at all to being an early clue to a life-threatening process, whether a primary hematologic or secondary reactive process. Potential causes of leukocytosis or leukopenia are myriad. This chapter considers disorders faced by adult practitioners in hospital and outpatient clinics, where the predominant hematologic abnormality is neutrophilic leukocytosis, neutropenia, monocytosis, or monocytopenia; other chapters consider lymphocytosis, lymphopenia, eosinophilia, pancytopenia, and hematologic neoplasms.

The normal range for leukocyte count in most laboratories is from about 4500 to 11,000/mm^3. Neutrophils (and band forms) comprise the majority of circulating leukocytes (1800-7700); monocytes are about 4% of cells (mean absolute count, 300/mm^3). The physician must always think in terms of absolute counts of leukocyte subpopulations (total leukocyte count multiplied by the differential percentage). Thus, in a patient presenting with a normal white blood cell (WBC) count of 5000/mm^3 and an elevated lymphocyte percentage of 65%, the differential diagnosis to be considered is that of neutropenia, not lymphocytosis, because the absolute neutrophil count (ANC) is decreased but absolute lymphocytes are normal (only relatively increased).

When approaching a patient with abnormal leukocyte number, several factors impact heavily on the differential diagnosis and the vigor with which diagnosis and therapy should be pursued. Diagnostic considerations are vastly different when the abnormality first manifests **in the hospital versus in the outpatient clinic.** Also crucial is the **degree of the abnormality,** providing guidance to its likely cause and consequence. For example, agranulocytosis is a life-threatening disorder in which neutrophils are at or near zero, has a limited spectrum of underlying causes (drug reactions being paramount), and demands immediate interventions. **Duration** has major implications; determining the onset of changes and whether they are stable or progressive informs as to etiology and significance. Whether the abnormality is **symptomatic**—for example, whether a neutropenic or monocytopenic patient has or has had infectious complications—bears on likely etiologies and need for therapy. If there are known or suspected **comorbid conditions,** such as autoimmune or inflammatory disorders, this can crystallize the approach; occasionally, the leukocyte abnormality may be the first sign of a previously unrecognized disorder or may provide important confirmation (e.g., neutropenia in a patient with systemic lupus erythematosus [SLE]). If the leukocyte abnormality is accompanied by **additional hematologic abnormalities** (unexplained abnormalities of red blood cells [RBCs], platelets, or cell morphology), this would point away from disorders considered in this chapter and often toward a primary hematologic disease. Beyond *history and physical examination,* the peripheral blood smear is key to establish the direction of further evaluation.

NEUTROPHILIC LEUKOCYTOSIS (NEUTROPHILIA)

A high WBC count, particularly high neutrophil count, is common with any infectious or inflammatory disorder. In the emergency department, leukocytosis is often equated with significant bacterial infection or at least a sign of illness severe enough to warrant hospital admission rather than outpatient management. Leukocytosis can also be a prominent presenting feature of leukemias and myeloproliferative disorders (MPDs). The presence of increased neutrophils assures that acute leukemia is not present. When leukocytosis is extreme, it indicates chronic myeloid leukemia (CML), other MPDs, or a leukemoid reaction.

Leukemoid reaction has been defined as a reactive (nonclonal) neutrophilic leukocytosis with a WBC count above 50,000/mm^3. The clinician must differentiate this from a neoplastic proliferation.

Leukoerythroblastosis refers to the presence in the peripheral blood of immature myeloid cells (generally myelocytes) and nucleated RBCs, often with giant platelets as well. This is always abnormal. Patients with leukoerythroblastosis do not necessarily have leukocytosis, but they usually do. Most patients (two-thirds) with leukoerythroblastosis have an underlying myelophthisic process, such as primary or secondary myelofibrosis, metastatic tumor, necrosis, or granulomas in the bone marrow (BM). Therefore, BM examination is indicated when leukoerythroblastosis is unexplained. Teardrop poikilocytes and elliptocytes on blood smear would strengthen concerns for myelophthisis. In 20% of patients with leukoerythroblastosis, the cause is hemolytic anemia, and miscellaneous other causes consist mainly of those with shock (septic, hemorrhagic, cardiogenic, anaphylactic) when hypoperfusion of areas of BM disrupt the microenvironment and permit disorderly egress of precursor cells.

Left-shifted neutrophils refers to relative immaturity of circulating cells, often manifest as an increased percentage of band neutrophils. Marked left shift includes less mature precursor forms, myelocytes and metamyelocytes. Left shift is nonspecific and may occur with infection or any cause of marked neutrophilia.

Detailed directed history and physical examination are indispensible to the evaluation of neutrophilia (Table 46-1). Fever and chills suggest infection (or inflammation), mandating a search for more specific symptoms that could pinpoint the focus. Examples include a sore throat, pharyngeal erythema, and exudate in pharyngitis; productive cough and abnormal lung auscultation in pneumonia; and dysuria and flank tenderness in urinary tract infection. Medication history mainly explores glucocorticoid use. With mild chronic neutrophilia, smoking habits and obesity become considerations. Recent vigorous exercise, emotional stress, burns, shock, or trauma can increase circulating neutrophils because of catecholamine-induced demargination. A positive family history may suggest hereditary neutrophilia. Often neglected are attempts to delineate the time course of the leukocyte abnormality by seeking prior medical contacts and blood count results at the time. On the physical examination, care should be directed to lymph node palpation because this can be an important clue for infection or malignancy. Palpable splenomegaly may not only direct the evaluation toward hematologic disorders but can be a cardinal sign of a variety of infectious and inflammatory disorders.

Blood smear should always be a part of initial evaluation when there are abnormalities of blood counts. BM aspirate or biopsy morphology may be helpful when pathophysiology and diagnosis are unclear. When appropriate, essential information can be gained by sending BM for microbiologic cultures, cytogenetic or molecular, or other ancillary studies.

Table 46-1 Causes of Neutrophilia

1. Hematologic malignancy (CML, CNL, CMML)
2. Infection
3. Inflammation, physiologic stress, hemorrhage, hemolysis
4. Hereditary or congenital neutrophilias
5. Smoking
6. Drugs: colony-stimulating factors, glucocorticoids, epinephrine, lithium
7. Nonhematologic malignancy
8. Asplenia
9. Obesity
10. Recovery from neutropenia

CML, Chronic myeloid leukemia; *CMML,* chronic myelomonocytic leukemia; *CNL,* Chronic neutrophilic leukemia.

Leukemoid Reaction Versus Chronic Leukemia

A relatively common reason for hematologic consultation is for very high WBC count. CML is reviewed elsewhere in this text, as are chronic myelomonocytic leukemia (CMML) and a rarer, more difficult disorder to pinpoint, chronic neutrophilic leukemia. Marked neutrophilic leukocytosis or overt leukemoid reaction (WBC count >50,000/mm^3) can represent an overly exuberant reaction to any stimulus associated with neutrophilia. In patients with leukemoid reaction, a disproportionate number have infection with *Clostridium difficile,* an organism that elicits a vigorous neutrophil response. Leukemoid reactions are commonly associated with solid tumors, particularly lung cancers and aggressive tumors with necrotic areas. It can be important to quickly differentiate a reactive neutrophilic leukocytosis from a clonal leukemic proliferation.

The history and clinical context are usually quite different between leukemoid reaction and CML. Most patients with leukemoid reaction are encountered very ill in the hospital with obvious underlying illnesses (e.g., sepsis, organ rejection). Prior WBC counts, which are often available, demonstrate normal WBC counts until the recent onset of acute illness. This contrasts with CML, typically presenting in outpatients with hypermetabolism (weight loss, sweats, low-grade fever), symptoms referable to splenomegaly, or frequently asymptomatic. On physical examination, the spleen is palpable (occasionally massive) in the great majority of patients with CML but is unusual with leukemoid reaction (in the absence of comorbidities such as liver disease).

Laboratory findings reliably differentiate CML from leukemoid reaction. The total leukocyte count is commonly extremely high with CML (median, 100,000/mm^3), but with leukemoid reaction, counts above 100,000/mm^3 are rare and are virtually unheard of above 150,000/mm^3. Circulating myelocytes and even a few blasts are more typical of CML but can be seen in both disorders. Similarly, changes in platelet number and morphology can be seen with both but point to CML when changes are extreme. RBC changes do not reliably separate the disorders except in a few cases with prominent teardrops, which point toward MPD. More helpful is the leukocyte differential: patients with CML almost always have some degree of absolute basophilia and eosinophilia, but infection and glucocorticoid excess induce eosinopenia. (When the leukocyte count is 100,000/mm^3, realize that 2% to 3% basophils is a substantial absolute increase.)

The leukocyte alkaline phosphatase (LAP) score, which is high with leukemoid reaction and classically low with CML, has limited utility now that more sensitive and specific tests for CML have emerged. When CML is reasonably considered, testing should be done for the Philadelphia chromosome (t[9;22];bcr/abl) generally by chromosome banding or FISH. When other MPDs are judged reasonably possible, *JAK2* mutational status may be informative.

Infection

To protect against the ever-present threat to health and longevity, evolution has armed us with reactant cytokine cascades designed to increase the number of phagocytes and dispatch them to threatened locales. Neutrophilia is classically seen as a response to bacterial infection, responding to such cytokines as interleukin-6 (IL-6), tumor necrosis factor (TNF), and granulocyte colony-stimulating factor (G-CSF). Neutrophilia is also a frequent response to other infections, including fungal, parasitic, mycobacterial, and sometimes viral.

Changes in neutrophil morphology may be useful in predicting whether bacterial or other infection underlie a neutrophilic response. The authors have confirmed some published reports that prominent neutrophil vacuolization is highly specific and has moderate sensitivity for serious bacterial infection, as do prominent Dohle bodies (in the absence of a primary hematologic disorder). The authors blindly scored blood smears from 50 patients with serious bacterial infection (half bacteremic), 25 with influenza, 25 with noninfectious fever, and 25 control smears. Toxic granulation of neutrophils, touted as a sign of bacterial infection, was found useless in distinguishing infections from other febrile illnesses.

Inflammation and Stress

Acute or chronic inflammation can cause neutrophilia by mechanisms similar to infection, mediated by the proinflammatory cytokines G-CSF, granulocyte macrophage colony-stimulating factor (GM-CSF), TNF, IL-1, IL-6, IL 8, and others. Diseases such as rheumatoid arthritis (RA), vasculitis, inflammatory bowel disease, thyrotoxicosis, eclampsia, and many others are commonly accompanied by neutrophilia. Another rare but notable example is familial Mediterranean fever in which an inherited *MEFV* mutation leads to dysfunctional pyrin downregulation of neutrophil activation, leading to chronic inflammatory serositis and secondary AA amyloidosis.

Physiologic stresses, including exercise and emotional stress, lead to endogenous catecholamine and glucocorticoid release in addition to inflammatory cytokines. This causes a rapid doubling of circulating neutrophils caused by demargination and by more rapid BM egress of maturing neutrophils. Paulsen found early peaks in M-CSF, growth hormone, and cortisol after exercise followed by increases in G-CSF, IL-6, and monocyte chemoattractant protein 1. Acute hemorrhage and hemolytic anemia are other physiologic stresses. This contributes to increased steady-state neutrophil counts recorded in patients with sickle cell anemia, and the degree of elevation correlates with pain crisis frequency, other complications, and mortality; leukocyte reduction has been postulated to be one mechanism of hydroxyurea's beneficial actions. The stress of acute myocardial infarction is commonly accompanied by mild neutrophilia, and the early magnitude of rise has correlated with poor outcomes.

Hereditary and Congenital Neutrophilias

In newborns, neutrophilia and leukoerythroblastosis are among the hematologic abnormalities associated with trisomy 13, trisomy 18, and trisomy 21 (Down syndrome). A transient clonal MPD can be seen in children with Down syndrome and is usually self-limited, but it does put patients at increased risk for later acute megakaryoblastic leukemia.

Very rare hereditary neutrophilias sometimes are first appreciated in adults. In 1971, Herring reported a mother and three of her four children with lifelong neutrophilia (WBC, 14,000-164,000/mm^3; granulocytes, 9000-62,000/mm^3), unusual bleeding, thickened calvariae, and hepatosplenomegaly. They had no increase in infections. LAP score was high, BM revealed few Gaucher-like histiocytes, karyotype was normal by routine banding, but chromatid breaks and gaps were increased. In 2009, French investigators identified a mutation in the *CSF3R* gene in a kindred with hereditary chronic neutrophilia. The point mutation led to constitutive activation of the

G-CSF receptor, driving neutrophil proliferation and differentiation. One of 12 affected individuals in this kindred developed overt myelodysplastic syndrome (MDS). The frequency of this and other mutations are unknown with hereditary neutrophilias.

Smoking

Smoking has been well associated with mild neutrophilia in epidemiologic and animal studies. Perry et al found a 27% higher WBC count in smokers. Sunyer et al correlated the degree of leukocytosis and percentage of neutrophils with the number of cigarettes smoked. The effect can persist up to 5 years in those who stop smoking. A suggested mechanism was chronic inflammation because inflammatory markers, including C-reactive protein (CRP) and fibrinogen, are elevated. In a rodent model, cigarette smoke caused overexpression of hematopoietic growth factor genes IL-6, G-CSF, and GM-CSF. Thus, mild neutrophilia without other symptoms in an active smoker or recent smoker could be attributed to this practice without further evaluation.

Drugs

Systemic glucocorticoids cause neutrophilia mainly by interfering with neutrophil adhesion to the capillary wall and decreasing neutrophil turnover rate. Maximal neutrophil count occurs 4 to 6 hours after dexamethasone use in normal volunteers. G-CSF increases circulating neutrophils by increasing BM production and mobilization. Epinephrine increases proinflammatory cytokines and demargination. Suggested mechanisms for lithium-induced neutrophilia are induction of G-CSF and downregulation of CXCR4, thus facilitating egress from the BM.

Malignancy

Leukocytosis is frequently associated with solid tumors without direct BM involvement. Some malignant tumors have been reported to produce G-CSF or GM-CSF, occasionally producing leukocytosis in the range of a leukemoid reaction.

Asplenia

Whereas neutrophilia is classically observed early after splenectomy, lymphocytosis predominates in the long run. Nevertheless, chronic mild neutrophilia can also be seen in functionally asplenic individuals. Furthermore, there may be an exaggerated neutrophil response to infections or other stresses. On the blood smear, Howell-Jolly bodies are a very sensitive and specific (when numerous) sign of functional asplenia.

Obesity

Recent studies have documented chronic mild neutrophilia with obesity. Fat tissue can release inflammatory cytokines, creating a state of low-grade inflammation manifest by elevated CRP. Leptin is a key hormone elevated with obesity, and it has been found to act on $CD34^+$ cells to promote neutrophil differentiation. In an obese patient with chronic mild neutrophilia and no obvious other underlying disorder, this can be assumed to be the cause.

NEUTROPENIA (AND AGRANULOCYTOSIS)

The risk of neutropenia-related infection begins to rise at an ANC near 1000/mm^3, rising dramatically below 500/mm^3 and more so below 100/mm^3; thus, an ANC of 500 to 1000/mm^3 is considered moderate neutropenia, and below 500/mm^3 is considered severe. This corresponds to NCI criteria for adverse hematologic event reporting: grade 1 toxicity is 1500/mm^3 to lower limit of normal, grade 2 is 1000 to 1500/mm^3, grade 3 is 500 to 1000/mm^3, and grade 4 is less than 500/mm^3. Beyond the ANC, the risk for infection is greatly influenced by the nature of the underlying problem, the BM myeloid reserve, and whether other risk factors for infection are present (e.g., immunoglobulin deficiency or breaks in mucosal barriers). The course with mild and moderate neutropenia is often benign.

The history focuses on the severity and duration of neutropenia, whether infectious complications have occurred (including severe stomatitis or gingivitis), and whether prior blood counts can be obtained. A history of drug exposures and their timing is especially relevant, not only for prescribed medications but also for over-the-counter, herbal, and illicit drugs. Symptoms of systemic inflammatory illness, such as arthritis, skin rash, and photosensitivity, can bear on the etiology and significance of the low WBC count. Fevers, weight loss, and sweats could be clues to many disorders, including malignancy. Liver disorders commonly present with cytopenias, so a history of hepatitis, jaundice, hepatitis risk factors, and HIV risks should be specifically questioned. Symptoms of anemia or bleeding could be clues to more general hematologic disorders. As with most hematologic problems, physical examination should devote extra attention to lymph node areas and the spleen. Oropharynx and skin examination also take on added importance.

Peripheral blood smear review is irreplaceable to direct the workup. MDS does not characteristically present with isolated neutropenia, but this is occasionally the predominant finding in this relatively common syndrome affecting older patients. Specific blood smear findings should be sought, which could suggest MDS, such as pseudo-Pelger Huet neutrophils, hypogranularity, Dohle bodies, macrocytosis, and dimorphic RBCs with a hypochromic population. Megaloblastic processes, such as vitamin B_{12} and folic acid deficiency, similarly do not characteristically present with isolated neutropenia, but this occasionally predominates (especially in the presence of acute infection). Hypersegmentation of neutrophils is always present with megaloblastic processes, including those that are drug induced (e.g., methotrexate, hydroxyurea), and can also be seen with uremia, as an autosomal dominant benign polymorphism, and in MDS and MPD. In a neutropenic patient, one should always specifically look for large granular lymphocytes (LGLs). A modest increase could indicate a reactive T-cell natural killer (NK) cell process, and a more dramatic increase could alert to clonal T-NK or NK cell proliferations. Hairy cells, other morphologic types of circulating lymphoma cells, and blasts are obvious indicators of hematologic malignancy. Morphologic suspicions for such processes could be confirmed by flow cytometry. Reactive lymphocytes may suggest viral infection but could also be present with drug reactions and other processes.

Further laboratory testing in patients with neutropenia may often be unnecessary. Especially in mild or moderate cases, the lack of specific diagnostic tests has created some overlap and confusion among what have been called chronic idiopathic neutropenia, chronic benign neutropenia, ethnic neutropenia, and autoimmune neutropenia. Autoimmune neutropenia is a relatively common cause of both mild and more severe neutropenia, so serologic tests for antinuclear antibodies and rheumatoid factor can be informative when this is considered. Positive results may raise suspicion for a previously undiagnosed collagen vascular disorder or just be supportive of a less specific autoimmune problem. Direct antiglobulin test and antiphospholipid antibodies can be supportive when there is very high suspicion of this diagnosis. Quantitative immunoglobulin levels may reveal an underlying immunodeficiency when there is evidence of autoimmunity or when infectious complications are disproportionate. Serologic tests for some viral infections (HIV, hepatitis, Epstein-Barr virus [EBV]) may be appropriate for many. Flow cytometry finds its main utility when peripheral blood smear suggests an abnormal lymphocyte population (e.g., LGLs or hairy cells). BM examination may not be helpful or warranted with mild or even moderate isolated neutropenia or in straightforward cases of severe neutropenia (e.g., after drug exposure) but can be essential when the diagnosis is in doubt and especially if other cell lines are compromised.

Severe Congenital Neutropenias

It is beyond the scope of this chapter to review in detail the heterogeneous genetic disorders that manifest in early childhood as severe congenital neutropenia; nevertheless, consultant hematologists should have some familiarity with the problem because modern therapy has extended survival for many into adulthood, and there may be milder forms of disease that go undiagnosed until young adulthood. The more severe of these disorders present with severe stomatitis and recurrent bacterial infections in infancy. The molecular bases have been greatly elucidated in recent years. Kostmann syndrome and Schwachman-Bodin-Diamond syndrome (SBDS), both associated with mental retardation and other congenital defects, have been linked to mutations in *HAX1* and *SBDS,* respectively. Several other severe congenital neutropenic disorders and their genetic bases have been defined. In young children, the differential diagnosis often includes transient postinfectious neutropenia, alloimmune neutropenia, or hematologic malignancy. BM examination often shows a pattern of maturation arrest. The majority of affected patients are responsive to G-CSF, although high doses may be required, and this has had favorable impact on infectious morbidity and mortality; allogeneic stem cell transplant is another therapeutic option. An intrinsic risk of acute myeloid leukemic transformation, 15% at 20 years, accompanies many of these disorders.

Cyclic neutropenia is often considered a variant of congenital neutropenia. Neutrophil counts vary from mildly to severely low with predictable periodicity, usually every 21 days. The vast majority of cases are autosomal dominant mutations in the elastase gene (ELA2, ELANE). G-CSF, often at low dosage, has reduced the risk of serious infections.

Benign Ethnic Neutropenia

Americans of African descent may have chronic mild neutropenia not associated with infectious complications. The 1999 to 2004 National Health and Nutrition Survey found that blacks had mean leukocyte counts 900/mm^3 lower than whites, with ANCs below 1500/mm^3 in 4.5% (compared with 0.8% of whites). The neutropenia correlates in some individuals with a polymorphism in the Duffy antigen receptor chemokine (DARC), a cytokine receptor also responsible for a Duffy-negative RBC phenotype. Some report this neutropenia more common in males, but others can sometimes demonstrate autosomal dominant inheritance. Marrow granulocyte reserve or release (or both) may be compromised. Benign neutropenia has also been seen in other ethnic populations, including those of Middle Eastern or Japanese descent. Thus, an asymptomatic mildly neutropenic person of appropriate ethnicity without abnormalities on blood smear may require no further diagnostic workup. It may be reassuring to the patient (and the doctor) if prior blood counts can be retrieved to document the chronic, nonprogressive, and complication-free course of the neutropenia.

Autoimmune Neutropenia (Primary and Secondary)

Autoimmune neutropenia can be primary or secondary to an autoimmune disorder such as SLE or RA. Neutropenia can be mild or severe. Classically, it caused by antineutrophil autoantibodies, although autoreactive cytotoxic lymphocytes are also known to cause this problem. When performed, BM examination most often is normocellular or hypercellular with a late "maturation arrest" picture. Severe cases can display pure WBC aplasia (similar to drug-induced agranulocytosis, which may also be antibody mediated). There are several challenges in making the diagnosis. One is that the maturation arrest BM picture is actually nonspecific with regard to mechanism: it could indicate a true stem cell differentiation defect or early release of later precursors (as with sepsis or splenic sequestration), or it could be a true sign of immune attack aimed at antigens borne by later myeloid precursors. Another problem is the lack of validated, clinically reliable neutrophil antibody tests. Experimentally, several methods have been used, generally suffering from high false-negative rates and also false-positives results from the detection of antibodies or immune complexes that bind to neutrophil Fc receptors nonspecifically. In the absence of a definitive test, diagnosis of autoimmune neutropenia must rest largely on clinical judgment.

Neutropenia caused by antineutrophil antibodies has been seen in infants about 1 year old, usually running a benign clinical course with spontaneous remissions in 95% within 2 years. Newborns are at risk of alloimmune neutropenia in the first months of life, but this is not generally accompanied by infectious complications. Secondary autoimmune neutropenias are most common in adults, related to disorders such as SLE, RA, Sjogren Syndrome, thymoma, and common variable immunodeficiency. In SLE, neutrophil counts correlate with disease activity and have been related to the induction of TRAIL, a ligand that increased myeloid apoptosis and killing by autologous T cells. Treatment of the SLE with immunosuppression or the use of G-CSF can improve the WBC count.

Felty syndrome was classically described as severe neutropenia and splenomegaly complicating RA, and has been attributed to antineutrophil antibodies, but the distinction between this syndrome and other causes of neutropenia with RA have become blurred, in particular, classic Felty syndrome and LGL syndrome probably are representative of a disease continuum. About 1% of patients with RA develop Felty syndrome, and it predisposes many to serious infections. Effective therapies have often included methotrexate, gold salts, and rituximab. Because of some risk of exacerbating underlying inflammatory problems, G-CSF should be used cautiously at the lowest effective dose.

Large Granular Lymphocyte Syndrome and Natural Killer Cell Proliferations

Proliferations of LGLs, T-NK cells, and NK cells are covered elsewhere, but mention is required here because they are common considerations in adults with neutropenia. These are extremely heterogeneous disorders, varying from nonclonal reactive processes to indolent clonal proliferations to highly aggressive neoplasms. Both reactive and clonal increases in T-NK cells can be seen with RA, representing a form of Felty syndrome. Reactive LGLs can be seen with other autoimmune disorders, after organ transplantation, or with tyrosine kinase inhibitor therapy, or they may be idiopathic. These proliferations are associated with variable degrees of neutropenia, commonly splenomegaly, and increased infectious risks. The diagnosis is suggested on blood smear by large lymphocytes with mature chromatin, excessive cytoplasm, with or sometimes without prominent cytoplasmic granules. Flow cytometry demonstrates increased $CD3^+CD57^+$ lymphocytes with the more common T-NK proliferations or may show CD3-$CD56^+$ clones with "pure" NK cell proliferation. Variably effective treatments for indolent proliferations are corticosteroids, methotrexate, cyclosporine, intravenous immunoglobulin, purine nucleoside analogs, and G-CSF.

Neutropenia With Infectious Diseases

Leukocytosis is the expected response to most bacterial infections, but leukopenia is also well-known to occur and is actually characteristic of infection by certain organisms. Viral infections often cause transient mild leukopenia, so restraint is in order in the diagnostic approach to a newly recognized moderate leukopenia in a febrile, modestly ill patient. Nonbacterial infections in which neutropenia is frequent or even characteristic include HIV, EBV, cytomegalovirus (CMV), hepatitis A and B, measles, rubella, varicella, rickettsia, and anaplasmosis (ehrlichiosis). Bacterial infections with characteristic leukopenia include typhoid fever and brucellosis, but granulomatous infections (tuberculosis, histoplasmosis) cause neutropenia, especially when the BM is directly involved. In patients with poor BM reserve (e.g., prior chemotherapy, malnutrition, myelodysplasia), an acute

infection quite commonly lowers, rather than raises, the neutrophil count. Profound neutropenia is a known consequence of overwhelming sepsis and has been associated with poor outcomes.

Hypersplenism

Hematologists are frequently consulted for cytopenias, only to find an unappreciated large spleen as the etiology (and this is most often caused by liver disease with portal hypertension). Splenic enlargement can lead to sequestration and reduction of circulating WBCs, RBCs, platelets, or any combination of these. The degree of cytopenia is somewhat proportional to the degree of splenic enlargement. Substantial neutropenia out of proportion to depletion other cell lines and to the size of the spleen likely involves other factors, such as an autoimmune component (as can be seen with hepatitis C or autoimmune hepatitis) or medication effect (e.g., interferon).

Chemotherapy-Induced Neutropenia

The major dose-limiting toxicity of most cancer chemotherapy regimens continues to be neutropenia. This results in hospitalizations, antibiotic costs, reduced quality of life, infectious morbidity, and dose reductions and treatment delays that compromise efficacy and outcomes. Infectious complications have been blamed for 75% of chemotherapy-related mortality. Febrile neutropenia is defined as an ANC less than 500/mm^3 (or expected to decrease to <500/mm^3 over the next 48 hours) with fever (>38.3° C or sustained >38° C).

Principles of empiric antibiotic coverage for acute febrile episodes in severely neutropenic patients are covered in detail elsewhere. Basically, there is a high risk of sepsis (even when the source is occult), and a favorable outcome depends on prompt effective antimicrobial coverage, so empiric administration of broad-spectrum antibacterial agents is considered medically emergent. These must cover the aerobic gram-negative rods that were the traditional culprits, yet vigilance must be maintained for the gram-positive organisms that have emerged as major pathogens. With prolonged or repeated episodes of neutropenia, invasive fungi become common threats to survival, particularly *Aspergillus, Candida, Mucor,* and *Fusarium* spp. Published guidelines can aid in the choice of empiric antimicrobials. Because of difficulty demonstrating favorable impact, enthusiasm for granulocyte transfusion support has waned substantially in the past 30 years; clinical studies are readdressing this in the modern era.

The utility of prophylactic antibiotics is problematic because of the wide array of potential pathogens and because of concerns of inducing antibiotic resistance. A role of prophylactic quinolones has been shown in very high-risk patients after therapy for acute leukemia or stem cell transplant.

G-CSF is widely used for either primary or secondary prevention of neutropenia to decrease morbidity and mortality of febrile neutropenia. Primary prophylaxis is recommended by various guidelines if the risk of developing febrile neutropenia is greater than 20%, with this risk calculated from age, extent of primary cancer, comorbidities, and the known myelotoxicity of the chemotherapy regimen. G-CSF is begun 24 to 72 hours after the completion of myelotoxic chemotherapy. Pegfilgrastim allows prophylaxis to be given more conveniently (one subcutaneous injection per cycle).

Drug-Induced Neutropenia

Drug reactions account for a high percentage of acquired neutropenias, both mild but more so severe cases (agranulocytosis) (Table 46-2). Development of neutropenia is often abrupt, commonly within 4 weeks of initiation of a causative agent. Pathophysiology may involve immune mechanisms or more direct toxicity such as enhancement of reactive oxygen species made by NADPH (nicotinamide adenine dinucleotide phosphate) oxidase or myeloperoxidase of neutrophil precursors. The diagnosis is generally strongly suspected from an accurate history that plots leukocyte numbers against the time course of drug exposure; confirmation is leukocyte recovery after drug withdrawal. More specific confirmatory testing, such as for drug-dependent antibodies, is mainly an area of research laboratory investigation. BM examination is not usually required but may be helpful when pathophysiology and diagnosis are in doubt, when the course is atypical, and to provide prognostic information (earlier recovery anticipated with a picture of "maturation arrest" than one of myeloid aplasia). Treatment demands discontinuation of suspected offending drugs. Although the efficacy of myeloid growth factors (G-CSF) has been questioned by some, most recommend this therapy because even a modest shortening of the duration of severe neutropenia can occasionally be lifesaving. Mortality of drug-induced agranulocytosis is generally reported to be 10%.

Table 46-2 Drugs Commonly Associated With Neutropenia

1. Antibiotics: vancomycin, semisynthetic penicillins, chloramphenicol, sulfa, linezolid
2. Antithyroid drugs: methimazole, propylthiouracil
3. Cardiovascular: ticlopidine, procainamide
4. Antipsychotics: clozapine, olanzapine, chlorpromazine
5. Anticonvulsants: phenytoin, carbamazepine, valproic acid
6. Antiinflammatory agents: indomethacin, sulfasalazine, phenylbutazone
7. H2 blockers: cimetidine, ranitidine
8. Analgesics: dipyrone
9. Antineoplastic: rituximab
10. Anthelminthic: levamisole

The most commonly implicated drugs are listed in Table 46-2. Some merit additional comments. Some drugs have a direct myelotoxic effect rather than induce an idiosyncratic immune-based reaction. Neutropenia has more gradual onset related to dose and duration and may be accompanied by suppression of other hematologic cell lines. Linezolid and most instances of chloramphenicol myelosuppression are examples.

Beginning 2007, an epidemic of agranulocytosis was found among intravenous cocaine users. The adulterant levamisole was found in 71% of confiscated cocaine by the Drug Enforcement Agency, with the incidence of agranulocytosis 2.5% to 13% in those exposed. Nadir BM showed severe myeloid hypoplasia. Levamisole had long been linked to agranulocytosis, having been used as an antihelminth and as an adjuvant immune modulator in patients with autoimmune disorders and colorectal cancer.

Increasingly, severe neutropenia is recognized in patients treated with rituximab. The decrease in WBC count is unusual for its late onset, generally about 3 months after the last rituximab dose. It occurs with underlying autoimmune disorders, B-cell malignancies, and stem cell transplants—basically in all situations in which rituximab is used—usually occurring while the underlying illness is in complete remission. Moderate or severe neutropenia has been reported in about 5% of rituximab-treated patients, although much higher incidences have been reported in some series. Most patients recover quickly, usually after G-CSF therapy, but some protracted cases have been encountered. The authors and others have reported a high risk of relapse if rituximab is reinitiated. The mechanism is not definitively established, but an intriguing report implicates imbalanced recovery of B-cell clones with a deficiency of stromal-derived factor 1.

MONOCYTOSIS

Monocytosis is extremely nonspecific, usually not requiring investigation per se. Monocytosis has been defined as a sustained absolute increase in monocyte count greater than 800 to 1000/mm^3 (Table 46-3). Transient monocytosis, relative or absolute, is common with recovery from myelosuppression, such as after chemotherapy. Relative or absolute monocytosis may occur in other myelosuppressed states,

Aplastic anemia
Drugs: chemotherapy, IFN-α, glucocorticoids (transient)
Radiation therapy

CMML, Chronic myelomonocytic leukemia; IFN, interferon; *MDS,* myelodysplastic syndrome; monoMAC, Monocytopenia and mycobacterium avium complex syndrome; *MPD,* myeloproliferative disorder.

such as aplastic anemia. This is a favorable factor associated with a lower risk of neutropenic infection, perhaps because some phagocytic capacity is maintained. On the other hand, monocytosis is very common with hematologic dysplasias. In a patient with unexplained cytopenia, monocytosis can be an important clue to an underlying MDS.

Infectious Diseases

Mycobacterial infection is a common cause of monocytosis worldwide related to its propensity for intracellular infection and tissue granuloma formation. Brucellosis and subacute bacterial endocarditis have also been associated with monocytosis. Certain viral infections, such as influenza virus, varicella-zoster, CMV, and Dengue hemorrhagic fever, are reported to cause monocytosis.

Connective Tissue Disorder

Connective tissue disorders, such as SLE and RA, have been reported to be associated with monocytosis in the context of chronic inflammation.

Hematopoietic Malignancies

Monocytosis is common with MDS. CMML is defined as persistent peripheral blood monocytosis greater than 1000/mm^3, absent Philadelphia chromosome, and evidence of dysplasia in one or more hematopoietic cell lineages. Juvenile myelomonocytic leukemia (JMML), a disease of children that shares pathologic features with CMML, results from defective RAS signaling. Acute myeloid leukemias involving the monocyte line (acute myelomonocytic and acute monoblastic leukemias) may release substantial amounts of lysozyme (muramidase), which is toxic to renal tubules. Serum lysozyme has actually been used to aid in the diagnosis of these leukemia subtypes. Other myeloid leukemias and MPDs can cause monocytosis, as can lymphomas, particularly Hodgkin disease.

MONOCYTOPENIA

Monocytopenia frequently accompanies granulocytopenia with chemotherapy, aplastic anemia, or other BM suppressive insults. Isolated or disproportionate monocytopenia is rarely recognized, but observations suggest that this can have serious clinical sequelae when it occurs. In hairy cell leukemia and monoMAC syndrome, there is a clear association with often severe opportunistic infections, particularly those normally engendering a granulomatous response.

Hairy Cell Leukemia

This disorder, considered in detail elsewhere, classically presents with pancytopenia and splenomegaly, most often in middle-aged men. The WBC count may sometimes be high because of hairy cell proliferation, but monocytes are invariably severely depressed. (Monocytopenia is not seen with "variant hairy cell leukemia.") Neutropenia only partly explains the very high infectious morbidity and mortality. An extraordinary incidence of opportunistic granulomatous infections used to be encountered, including atypical mycobacteria, tuberculosis, histoplasmosis, and other fungi. These were linked to the monocytopenia, with demonstration of impaired granuloma formation. With remission induced by modern therapies, (e.g., 2-chlorodeoxyadenosine), the monocytopenia and infectious risks have been abrogated.

MonoMAC Syndrome

In 2010, investigators at the National Institutes of Health described an immunodeficiency syndrome characterized by decreased or absent monocytes, NK cells, B cells, and dendritic cells. This was largely diagnosed in young adults (median age, 33 years). All patients have opportunistic infections, particularly *Mycobacterium avium* complex, and other mycobacteria, opportunistic fungi, and viruses. Both autosomal dominant and sporadic cases are described, all linked to mutations in the hematopoietic stem cell regulator GATA-2. BM examination findings are always abnormal, usually hypocellular, with reticulin fibrosis and multilineage dysplasia. Clonal cytogenetic abnormalities are seen in most patients, particularly deletion 7 and trisomy 8. All cases have met criteria for MDS. Because leukemic progression with or without death from infection is high, stem cell transplantation is recommended when feasible.

CHAPTER 47

LYMPHOCYTOSIS, LYMPHOCYTOPENIA, HYPERGAMMAGLOBULINEMIA, AND HYPOGAMMAGLOBULINEMIA

Martha P. Mims

Any discussion of quantitative abnormalities of lymphocytes and immunoglobulins is necessarily linked because the B-cell compartment is responsible for immunoglobulin production, and the T-cell compartment helps provide the stimulus. Nevertheless, clinicians are often consulted when a quantitative disorder of one or the other is recognized. Thus, although overlapping, the defects are presented separately.

QUANTITATIVE DISORDERS OF LYMPHOCYTES

The normal number and distribution of lymphocyte subtypes in the peripheral blood varies with age, but no careful study has demonstrated gender or ethnic differences in lymphocyte count. In general, circulating T cells exceed B cells by a ratio of approximately four to one with that ratio increasing slightly with age (Table 47-1). Natural killer cells are grouped with lymphocytes but comprise only about 10% of the lymphocyte population. Infants have total lymphocyte counts between 5500 and 7000/μl, but this number declines beginning at about 1 year of age to reach 2000 to 2400/μl in adults. At birth, the total number of circulating B cells is approximately 1000/μl but decreases over the first 10 years of life to approximately 200 to 300/μl by the age of 18 years. A slow decline in circulating B cells continues throughout adulthood and is primarily accounted for by a decline in transitional and naive B cells with a stable or mild increase in circulating memory B-cell numbers with age. Circulating naïve B cells represent about two-thirds of the entire naive B-cell pool, and circulating memory B cells represent only about one third of the entire memory B-cell pool.[1]

T cells dominate the circulating lymphocyte population with approximately 3500/μl in infancy declining to 1500/μl on average in young adults, with even lower numbers (≈1200/μl) in elderly adults. In both children and adults, CD4 cells outnumber CD8 cells. Naive CD4 and CD8 T cells decline with age by two- to fourfold. In one large study, CD4 memory T cells significantly increased with age, but no such trend was seen for CD8 memory T cells.[2]

Against this background, *lymphocytosis* is defined as lymphocyte count greater than 8000/μl in young children and greater than 4000/μl in teenagers and adults. Lymphocytopenia has been defined as a total lymphocyte count of less than 1000/μl. Given the composition of the circulating lymphocyte pool, it is critically important to define which lymphocyte subsets are over- or underrepresented when there is a quantitative disorder.[2]

Lymphocytosis

As in any clinical disorder, a careful history is critical to defining the origin of lymphocytosis. Inherited causes of lymphocytosis are essentially nonexistent (with the exception of some inherited predispositions to clonal lymphoid disorders); thus the issue is usually to determine whether a lymphocyte disorder is clonal/malignant or benign and related to infection, drugs, or physiologic stress. Rarely, neither a malignancy nor an underlying condition can be identified, in which case the lymphocytosis is termed *persistent polyclonal B-cell lymphocytosis*. When an excess of B cells exists, clonality can usually be defined by examining cell surface expression of κ- and λ-light chains using antibody techniques; with T-cell proliferation, it may be important to define clonality by examining T-cell receptor gene rearrangement using molecular procedures. In the case of natural killer (NK) cell disorders, clonality can be quite difficult to determine.

Clonal Disorders

Malignant causes of peripheral blood lymphocytosis are covered in Chapters 76 to 80, 84, and 86 and include chronic lymphocytic leukemia (CLL), hairy cell leukemia, splenic marginal zone lymphoma, lymphoplasmacytic lymphoma, follicular lymphoma, mantle cell lymphoma, adult T-cell leukemia or lymphoma, and Sézary syndrome. Occasionally, precursor T-cell or precursor B-cell leukemia presents with circulating small cells, which morphologically appear more similar to mature lymphocytes than blasts.

A recently identified clonal disorder causing lymphocytosis is monoclonal B-cell lymphocytosis (MBL), an accumulation of clonal B lymphocytes that does not meet the criteria for CLL (>5000 clonal B cells/μl), but is nevertheless defined by the presence of a clonal population of B cells. Data demonstrate that up to 10% to 15% of patients with lymphocytosis have MBL. Three major subtypes of MBL exist: the CLL immunophenotype ($CD5^+$, $CD23^+$), which is by far the most common; the atypical CLL type ($CD5^+$, $CD23^-$); and non-CLL lymphoproliferative disorder ($CD5^-$). Similar to the relationship between monoclonal gammopathy of uncertain significance and multiple myeloma, only a small proportion of patients with MBL (1%-4% per year) with CLL-type MBL go on to develop progressive disease requiring treatment. Epidemiologic studies of MBL patients have demonstrated strong familial risk for CLL, and the first reports of MBL came from studies of "unaffected" CLL family members. Studies of CLL families suggest that there is an inherited abnormality that increases the risk of developing CLL, and some families exhibit anticipation with the disease occurring earlier in successive generations. The supposition that MBL is a progenitor lesion for CLL is strengthened by the observation that 6 of 10 germline single nucleotide polymorphisms known to confer increased risk of CLL are also significantly associated with MBL. MBL has been identified in up to 30% of individuals infected with HCV, and up to 50% of the HCV-associated cases demonstrate the atypical CLL immunophenotype. The presence of MBL correlates with more advanced liver disease, suggesting that the persistence of viral infection is crucial to development of the B-cell clone. Follow-up for MBL patients is not clearly defined, although it is probably reasonable to evaluate lymphocyte counts with complete blood counts and follow the clone with flow cytometry at periodic intervals depending on the pace of the lymphocyte rise, the clinical scenario, the family history, and the age of the patient.[3]

Infectious Causes

The most common infections causing lymphocytosis are Epstein-Barr virus (EBV) and cytomegalovirus (CMV). In young children, EBV infection frequently presents as an upper respiratory infection, but in

Table 47-1 Normal Lymphocyte Subsets with Age*

	Cord Blood	2 Days-11 Months	1-6 Years	7-17 Years	18-70 Years
Total lymphocyte count (× 10^3 cells/ml)	5.4 (4.2-6.9)	4.1 (2.7-5.4)	3.6 (2.9-5.1)	2.4 (2.0-2.7)	2.1 (1.6-2.4)

†Naive T cells expressed as a percentage of $CD4^+$ T cells.

adolescents and young adults, it can result in acute glandular fever with pharyngitis, splenomegaly, lymphadenitis, and profound reactive lymphocytosis. Lymphocytosis is less prominent in older adults. Although the B cells are targeted by EBV, the lymphocytosis consists of $CD8^+$ lymphocytes reacting to neoantigens expressed on the surface of infected B cells. The massive T-cell response usually clears the infection in a matter of days to one week, and the lymphocytosis resolves. CMV infection can produce a similar lymphocytosis. In the case of CMV, however, the macrophages are the target of infection, and the T-cell lymphocytosis results from a response to the macrophage neoantigen. CMV infection and lymphocytosis are more common in older adults. In both viral infections, lymphocytosis can be profound with 50% or more of the circulating white blood cells (WBCs) identified as lymphocytes. Examination of the peripheral smear reveals that up to 10% of the circulating lymphocytes are atypical and larger than normal lymphocytes with open chromatin and increased cytoplasm. It is particularly important to recognize lymphocytosis caused by these two viruses in pregnant women because congenital infection can cause fetal death and birth defects. In addition to EBV and CMV, primary infection with HIV can cause lymphocytosis and should be suspected in the presence of a viral syndrome in the proper clinical circumstance. In children, infection with Coxsackie A and B6 viruses, echovirus, and adenovirus can cause a brief but profound lymphocytosis. Infections with other viruses, including human herpesvirus 6 (HHV-6) and HHV-8 as well as rubella virus, varicella, human T-lymphotropic virus type 1 (HTLV-1), and hepatitis viruses, can cause a lymphocytosis, although much less frequently than CMV and EBV.

Important nonviral infections causing lymphocytosis include *Toxoplasma gondii* and *Bordetella pertussis*. In an immune competent host, *Toxoplasma* infection is often asymptomatic, but patients can have fever, chills, and lymphadenopathy. Mild lymphocytosis with atypical lymphocytes can be observed. As in the case of EBV and CMV, infections during pregnancy can lead to adverse effect on the fetus. In children and adults, infection with *B. pertussis* can lead to lymphocytosis with the absolute lymphocyte count frequently greater than 10,000/μl. In more severe cases, lymphocytosis is more pronounced.[4] Unlike viral infections and *Toxoplasma* infection, the lymphocytosis observed in *B. pertussis* infection is caused by increases in all lymphocyte subsets, and it appears that the pertussis toxin blocks migration of the lymphocytes from the bloodstream into lymph nodes.[4] Tuberculosis, rickettsial infection, brucellosis, and shigellosis may also cause lymphocytosis.

Physiologic Stress

Lymphocytosis related to physiologic stress is a poorly studied phenomenon. After strenuous physical exercise, subjects develop lymphocytosis, which returns to preexercise levels within 15 minutes to 1 hour of ceasing the activity. The exercise-induced rise is thought to be attributable to catecholamine and steroid hormones and their effect on expression of cell adhesion molecules and on cardiac output and shear stress.[5] Exposure to catecholamines increases the expression of β_2-adrenergic receptors on lymphocytes influencing cell trafficking. Reports suggest that a number of other physiologic stresses increase lymphocyte counts, including surgery, trauma, cardiac conditions, sickle cell crises, abdominal pain, and obstetric emergencies. In these cases, all lymphocyte subsets appear to increase, but the increase is most profound for CD4 and CD8 memory T cells. Neutrophil counts also rise in these patients, but in most cases, the lymphocytosis resolves before the peak of the neutrophil count.[6]

Drug Reactions

Drug-induced lymphocytosis can occur as part of a hypersensitivity syndrome. In these cases, the lymphocytosis is usually part of a systemic condition that includes a fever, rash, and lymphadenopathy. Elevation in other WBC counts, including eosinophils and monocytes, is common, and atypical lymphocytes are seen. The time period between drug introduction and the syndrome is usually about 3 weeks with the commonest implicated drugs being aromatic anticonvulsants and sulfonamides.[7] Some studies differentiate this syndrome from drug-induced cutaneous pseudolymphomas in which collections of nonclonal lymphocytes appear in the skin after longer periods of drug exposure, but there is no peripheral lymphocytosis.

Polyclonal B-Cell Lymphocytosis

A final entity causing lymphocytosis is persistent polyclonal B-cell lymphocytosis (PPBL). This rare disorder is seen primarily in young to middle-aged smoking women and results in mild polyclonal lymphocytosis. The lymphocytes are medium sized with abundant cytoplasm; a variable proportion is binucleate. A polyclonal increase in serum immunoglobulin M (IgM) is also observed, and there is an association with the human leukocyte antigen (HLA) DR7 phenotype. Examination of the B cells reveals that most are $CD19^+$, $CD5^-$, and $CD23^-$ with a normal kappa-to-lambda ratio and a variety of heavy chain rearrangements. Adenopathy, hepatomegaly, or splenomegaly has been observed in some, but not all, patients. Genetic analysis has demonstrated the presence of isochromosome 3q in a proportion of B cells as well as the presence of multiple *BCL2-Ig* gene rearrangements. Similar gene rearrangements have been identified in family members of PPBL patients along with increases in serum IgM, suggesting that there may be an underlying genetic defect. Cessation of smoking does not appear to resolve the lymphocytosis. Overall, the clinical course of this disorder is benign, and the lymphocytosis is not usually progressive; however, clonal B-cell disorders have been seen in a few patients with the disorder, suggesting that it may represent a preneoplastic state.[8]

Lymphocytopenia

Inherited Disorders

Although there are few, if any, inherited causes of lymphocytosis, such is not the case for lymphocytopenia, in which the genetic bases of a number of inherited immunodeficiency disorders have been identified. Chief among these disorders is severe combined immunodeficiency (SCID), which is characterized by the absence of functional T lymphocytes. T lymphocytes, B lymphocytes, and NK cells share progenitors, signaling pathways in development and function, and metabolic pathways; thus B lymphocytes, NK cells, or both are often severely affected in SCID. Moreover, in the absence of functional $CD4^+$ T-helper lymphocytes, B lymphocytes cannot function properly, and hypo- or agammaglobulinemia is observed. In most cases of SCID, the absence of T lymphocytes leads to an extremely low absolute lymphocyte count. As detailed in Chapter 49, SCID can be grouped based on the cellular pathway that is affected. In general, whereas SCID is characterized by complete loss of function of the affected gene, hypomorphic mutations of the same genes lead to quite different phenotypes (Omenn syndrome and atypical SCID). Defects in more than 30 genes are known to lead to SCID. Inheritance is primarily X-linked or autosomal recessive, but in a few cases, such as the DiGeorge anomaly and some cases of Hoyeraal-Hreidarsson syndrome (defects in telomerase), inheritance is autosomal dominant. Deficiency in cytokine-mediated signaling (*IL2RG, JAK3,* and *IL7RA* mutations) leads to T^-B^+ SCID, defects in V(D)J recombination (*RAG1, RAG2 DCLRE1C, PRKDC, LIG4, and NHEJ1* mutations) leads to T^-B^- SCID, and absent signaling through the pre-T cell receptor (*CD3D, CD3E, CD3Z, CD3G, PRPRC, ZAP70, LCK* mutations) leads to T^-B^+ SCID. Defects that lead to increased lymphocyte apoptosis (*AK2, ADA,* and *PNP* gene mutations) lead to TB^- SCID and are often associated with anomalies outside of the immune system. Defects in thymic embryogenesis and calcium flux as well as a collection of other abnormalities, including defects in telomerase activity, can also lead to SCID and are usually associated with abnormalities of other organ systems.[9]

In addition to SCID, other inherited disorders can also perturb T- and B-cell numbers. Patients with Wiskott-Aldrich syndrome, caused by mutations in *WASP* (which encodes a cytoplasmic protein responsible for transducing cell surface signals to the actin cytoskeleton), can present with low T-cell counts early in life and become profoundly lymphopenic over time. Abnormalities in immunoglobulins are also noted in this syndrome with low levels of IgM and high levels of IgA and IgE.[10] Immunodeficiency affects more than half of all patients with ataxia telangiectasia. Patients with ataxia telangiectasia have homozygous or compound heterozygous mutations in the *ATM* gene, which encodes a protein kinase with functions in the cellular response to DNA damage. Lymphopenia, especially of naive CD4 cells, is observed in about half of patients with ataxia telangiectasia with mutations leading to absent expression of ATM kinase activity.[11] Recently, a new syndrome known as monoMAC has been described.[12] Affected patients demonstrate monocytopenia; B-cell and NK-cell lymphopenia; and mycobacterial, fungal, and viral infections and alveolar proteinosis. Over time, monoMAC patients develop myelodysplasia, acute myeloid leukemia (AML), or chronic myelomonocytic leukemia (CMML). Studies indicate that this disorder is caused by mutations in *GATA2*, which appears to regulate features of monocyte, macrophage, dendritic cell, B-cell, and NK-cell development and function.

Infections

A variety of viral and nonviral infections can lead to lymphopenia. HIV is most common virus associated with lymphopenia. The target of HIV is the CD4 receptor, and the virus selectively targets and infects activated expanding CD4 T cells. Large studies in HIV-infected patients have shown that peripheral blood CD4 T-cell counts fall most rapidly in the year after seroconversion (from ≈1000/μl before seroconversion to 670/μl at 1 year after infection) and then decline more slowly by about 50/μl per year.[13] In a subset of untreated patients, viremia is absent or well controlled, and lymphocytopenia develops very slowly if at all; particular HLA class I alleles are overrepresented in this group. Lymphopenia is an early and reliable laboratory observation in adult influenza A infection and is also detected in infections caused by swine influenza (H1N1) and the highly pathogenic avian influenza (H5N1).[14] Lymphopenia has been reported in patients with severe acute respiratory syndrome (SARS) caused by the SARS-coronavirus. In children, respiratory syncytial virus (RSV) infection is associated with a reduction in lymphocyte count, which is most extreme in the sickest patients; similar effects on lymphocyte counts are seen in measles infections (also a paramyxovirus). In West Nile virus encephalitis, lymphopenia is profound and prolonged, and the initial degree of lymphopenia is predictive of outcome. A variety of other viruses can also cause lymphopenia, including herpes viruses (herpes simplex, HHV-6, HHV-8), parvovirus B19, and Dengue virus. In many viral infections, the degree of lymphopenia is correlated with the severity of the disease.[14]

A variety of nonviral infections cause lymphopenia. Infections with *Ehrlichia* (a tickborne obligate intracellular gram negative bacteria), *Salmonella typhi*, and *Leptospira* have all been reported to cause lymphocytopenia during the acute illness. $CD4^+$ T-cell depletion has been described in a subset of HIV-negative patients with tuberculosis and low albumin levels, low body weight, and more extensive disease. Recovery of CD4 count after treatment of tuberculosis suggests that the lymphopenia is caused by the tuberculosis infection.[15] Lymphocytopenia is often observed in sepsis and is thought to occur as a result of cytokine-mediated apoptosis of B cells and $CD4^+$ T cells. In fact, autopsy series have demonstrated that most deaths from sepsis occur during the prolonged hypoimmune state, and the more prolonged the sepsis, the more profound the loss of splenic lymphocytes. Retrospective studies of emergency department patients suggest that lymphopenia is a better predictor of bacteremia than leukocyte count, neutrophil count, or C-reactive protein level.[16]

Collagen Vascular Disorders

Autoimmune diseases frequently exhibit decreases in circulating lymphocytes. In systemic lupus erythematosus (SLE), lymphopenia (usually decreases in T cells but occasionally in B cells as well) is not only one of the diagnostic criteria but also a parameter used to assess disease activity. Lymphopenia in SLE seems to be more frequent in patients of African descent. Deficient expression of CD55 and CD59 has been observed in SLE-induced lymphopenia, and data suggest that acquired deficiency of these complement regulatory molecules may contribute to the destruction of lymphocytes. Antigalectin 8 antibodies have been described in patients with SLE, rheumatoid arthritis, and sepsis. In SLE, these autoantibodies are associated with lymphopenia.[17] CD4-T cells may also be decreased in rheumatoid arthritis, and increasing evidence suggests that deficiencies in DNA repair enzymes such as ATM render rheumatoid arthritis T cells sensitive to apoptosis.[18] Apoptotic loss of naive T cells results in lymphopenia-induced proliferation to preserve T-cell homeostasis; this proliferation is now thought to lead to both premature immune aging and an autoimmune-biased T-cell repertoire. In Sjögren syndrome, a minority of patients has been noted to have deficient CD4 counts, and this has been correlated with the presence of anti-CD4 antibodies. Similarly, low lymphocyte counts have been observed in patients with primary vasculitides, type I diabetes, and Crohn's disease.[17]

Malignancies

Lymphopenia is found in a variety of systemic illnesses; chief among them are cancers. In hematologic malignancies, including Hodgkin lymphoma, diffuse large B-cell lymphoma, and peripheral T-cell lymphoma, patients with lymphopenia have a worse prognosis.

Lymphopenia has also been observed in solid tumors, including breast and colon cancer, and soft tissue sarcomas, in which its presence before treatment predicts decreased overall survival. Which specific lymphocyte subsets are involved and the cause(s) of lymphopenia in these tumor types has not been described.

Systemic Disorders

End-stage renal disease (ESRD) has also been associated with lymphopenia, an observation not thought to be exclusively attributable to an effect of dialysis alone. Naive and central memory CD4 and CD8 T cells are significantly reduced in the blood of ESRD patients apparently because of increased susceptibility of these cells to apoptosis. Lymphopenia occurs in more than 50% of sarcoidosis patients and is associated with chronic disease. Sarcoidosis patients with severe organ system involvement, including neurologic, cardiac, ocular, and advanced pulmonary disease, have lower lymphocyte counts than patients with less severe manifestations. Older studies suggest that burn victims have profound decreases in T-cell counts, which may contribute to the infection risk in these patients. Interestingly, lymphopenia is a characteristic of both protein-energy malnutrition and zinc deficiency. Both of these deficiencies perturb the hypothalamic-pituitary-adrenocorticoid axis and increase glucocorticoid levels, which results in increased apoptosis of B and T cells.[19] Intestinal lymphangiectasia, which may be either congenital or secondary to processes that obstruct lymphatic drainage of the gastrointestinal tract, can cause lymphopenia because of loss of lymph fluid into the gut along with lymphocytes.

A rare cause of lymphopenia is idiopathic $CD4^+$ lymphocytopenia (ICL), which is defined as a CD4 count less than 200/μl or less than 20% of the T-cell count on two occasions that is not caused by HIV (or HTLV) infection, drug therapy, or a known immunodeficiency. Patients usually come to clinical notice when they present with opportunistic infections. CD4 T-cell counts typically remain low, but counts do not continue to drop or do not fall rapidly after diagnosis. In one large series, only about 20% of patients recovered from lymphopenia within 3 years of diagnosis. Opportunistic infections plague these patients, and autoimmune diseases occur both before and after the diagnosis of ICL. In ICL, unlike HIV infection, increased activation and turnover are observed in CD4 but not CD8 T lymphocytes.[20]

Drug Effects

A number of drugs are known to cause lymphopenia. Glucocorticoids inhibit production of a number of cytokines and rapidly deplete circulating T cells by enhancing emigration from the circulation, inducing apoptosis, interfering with growth signaling, and inhibiting release from lymphoid tissues. B cells are less affected acutely by glucocorticoid administration, but prolonged administration may result in decreased IgG levels. Antimetabolite chemotherapeutic agents such as methotrexate, azathioprine, and 6-mercaptopurine lower lymphocyte as well as neutrophil counts, and alkylating agents such as cyclophosphamide have more profound effects on lymphocytes. Purine nucleoside analogs, including cladribine, fludarabine, pentostatin, nelarabine, clofarabine, and others, inhibit DNA synthesis and repair and cause accumulation of DNA strand breaks. All of these agents are associated with profound lymphopenia, which may persist for several years after completion of treatment. In general, T cells are more affected than B cells. Nelarabine in particular is a prodrug of ara-G and is converted to ara-GTP that accumulates at higher levels in T cells.[21]

Monoclonal and polyclonal antibodies directed against lymphocytes are useful in clinical practice and can induce profound and long-lasting lymphopenia. Whereas antithymocyte globulin and alemtuzumab produce depletion of both T and B cells, the monoclonal antibodies OKT3, daclizumab, and basiliximab produce a more pronounced decrease in T cells. The drugs rituximab and ofatumumab are monoclonal antibodies directed against distinct epitopes on B cells. These drugs deplete peripheral B cells but do not routinely produce lymphopenia.

Finally, radiation exposure commonly results in lymphopenia, which occurs before depression of other cell counts. In fact, lymphopenia can develop within the first 24 hours of exposure if the dose of radiation is great enough, and a drop of 50% or more predicts an increased risk of death. B cells are more sensitive to radiation than T cells and recover more slowly than T-cell numbers.[22]

QUANTITATIVE DISORDERS OF IMMUNOGLOBULINS

In practice, there are several methods for determining serum immunoglobulin levels; thus in evaluating immunoglobulin levels, it is critical that age-adjusted normal reference ranges are provided by the laboratory. Children first achieve adult levels of IgM around 2 years of age, of IgG by 6 years of age, and of IgA during puberty. Hypogammaglobulinemia is defined as an IgG less than 2 standard deviations from normal, and agammaglobulinemia is usually defined as an IgG level less than 100 mg/dL. Low levels of IgA, IgG, and IgM are characteristic of most forms of SCID.

Hypogammaglobulinemia

Causes of hypogammaglobulinemia can be divided into primary causes related to genetic deficiencies and secondary causes related to malignancies or their treatment, infections, medications, and protein-losing states that deplete antibody.

Secondary Causes

Before embarking on a search for a primary disorder causing hypogammaglobulinemia, it is important to rule out secondary causes. Malnutrition, malabsorption, and any disease state in which large amounts of protein are lost, such as nephrotic range proteinuria, severe burns, lymphangiectasia, or protein-losing enteropathy, can overwhelm the capacity of the B cells to provide adequate immunoglobulin to maintain normal serum levels. Aside from chemotherapeutic agents, a number of medications can produce hypogammaglobulinemia; these include captopril, antiseizure medications (carbamazepine, phenytoin), gold salts, antimalarials, fenoclofenac, penicillamine, and sulfasalazine, as well as glucocorticoids. Infection with HIV and EBV and congenital infection with rubella, CMV, and *T. gondii* can produce very low immunoglobulin levels and should be ruled out as appropriate. A host of lymphoid malignancies produce hypogammaglobulinemia, but the defect is most profound in CLL, in which up to 85% of patients are said to possess hypogammaglobulinemia even in the absence of treatment.[23]

Primary Immunodeficiencies

The International Union of Immunological Societies has classified the primary immunodeficiency diseases into eight groups, including one class called *predominantly antibody deficiencies*. These disorders present in both adults and children, although some are very rare. Table 47-2 provides a simple grouping of these antibody disorders, some of which are discussed in greater detail in Chapter 49.

The first group is characterized by a severe reduction in all serum immunoglobulin isotypes with absence or profound reduction in B cells. Patients with these disorders, particularly those with a well-defined genetic basis, present with severe bacterial infections, most commonly in the respiratory tract (pneumonia, sinusitis, otitis media) as well as diarrhea caused by bacteria, parasites, and viruses. The prototypic member of this group is X-linked agammaglobulinemia (XLA) caused by a mutation in the Bruton tyrosine kinase (*Btk*) gene, which produces a block in B-cell maturation. Female carriers of *Btk*

Table 47-2 Predominant Antibody Deficiencies

	Disease	Mode of Inheritance/Genetic Locus	Clinical Features
Severe reduction in all serum immunoglobulin isotypes with absent B cells	Bruton tyrosine kinase deficiency	XL/Xq21.3-22	Severe bacterial infections (especially of the respiratory tract), absent lymphoid tissue
	μ Heavy chain deficiency	AR/14q32.3	Severe bacterial infections
	λ5 deficiency	AR/22q11.21	Severe bacterial infections
	Igα deficiency	AR/19q13.2	Severe bacterial infections
	Igβ deficiency	AR/17q23	Severe bacterial infections
	BLNK deficiency	AR/10q23.2	Severe bacterial infections
	Thymoma with immunodeficiency (Good syndrome)	None	Recurrent infection with encapsulated bacteria and diarrhea, autoimmune phenomena
	Myelodysplasia	Variable/monosomy 7, trisomy 8, dyskeratosis congenita	Recurrent infections and pancytopenia
Severe reduction in at least two serum immunoglobulin isotypes with low or normal B-cell numbers	Common variable immunodeficiency syndromes	≈10% with family history AR or AD AD and AR/17p11.2 AR/22q13	Recurrent respiratory tract infections leading to chronic sinusitis, hearing loss, bronchiectasis, autoimmune disease, lymphoproliferation, malignancy (especially non-Hodgkin lymphoma and gastric carcinoma)
	TACI alterations BAFFR alterations MSH5 alterations	Unk/6p22.1-p21.3	
	ICOS deficiency	AR/2q33	Recurrent infections
	CD19 deficiency	AR/16p11.2	Recurrent infections
	X-linked lymphoproliferative disease (mutation in SH2 domain protein 1A)	XL/Xq25-q26	Fulminant infection with EBV, lymphoma, dysgammaglobulinemia
Severe reduction in serum IgG and IgA with increased IgM and normal B-cell numbers (disorders of immunoglobulin class switching)	CD40 ligand deficiency	XL/Xq26.3-Xq27.1	Recurrent infections with bacteria and opportunistic pathogens, neutropenia, autoimmune disease
	CD40 deficiency	AR/20q11-20q13.2	Recurrent infections with bacteria and opportunistic pathogens, neutropenia, autoimmune disease
	NF-κB essential modulator (*NEMO*) hypomorphic mutations	XL/Xq28	Recurrent infections with bacteria and opportunistic pathogens, neutropenia, autoimmune disease
	AID deficiency	AR/12p13	Recurrent bacterial infections and diarrhea, marked enlargement of lymphoid organs
	UNG deficiency	AR/12q23-q24.1	Recurrent bacterial infections and diarrhea, marked enlargement of lymphoid organs
Isotype or light-chain deficiencies with normal B-cell numbers	Ig heavy-chain deficiency	AR/14q32	Most patients are healthy
	κ-Chain deficiency	AR/2p11.2	Most patients are healthy
	Isolated IgG subclass deficiency	Variable/unknown	Most patients are healthy
	IgA deficiency associated with IgG subclass deficiency	Variable/unknown	Most patients are healthy
	Selective IgA deficiency	Variable/unknown	Most patients asymptomatic, but increased prevalence of infections, autoimmune disease, atopy, and celiac disease
Specific antibody deficiency with normal immunoglobulin level and B-cell number	Inability to make antibodies to specific antigens	Variable/unknown	Recurrent sinopulmonary infection, bronchiectasis, diarrhea, autoimmune disease
Transient hypogammaglobulinemia of infancy	IgG and IgA deficiency	Variable/unknown	More likely to be male (60%–80%), mild infections and diarrhea, atopy

λ5, immunoglobulin lambda-like polypeptide (a surrogate light chain subunit that is part of the pre–B-cell receptor); *AID,* activation induced cytidine deaminase (thought to be essential for initiation of the DNA cleavage required for class switch recombination and somatic hypermutation); *BAFF-R,* B cell–activating factor receptor; *BLNK,* B linker (a cytoplasmic linker or adaptor protein that plays a critical role in B-cell development); *EBV,* Epstein-Barr virus; *ICOS,* inducible T-cell costimulator (belongs to CD28 family of costimulatory surface molecules); *Igα,* immunoglobulin-associated α (necessary for expression and function of the B-cell antigen receptor); *Igβ,* immunoglobulin-associated β (necessary for expression and function of the B-cell antigen receptor); *MSH5,* mutS homolog 5 (a protein involved with DNA mismatch repair and meiotic recombination); *NF-κB,* nuclear factor kappa-B; *TACI,* transmembrane activator and CAML-interactor; *UNG,* uracil DNA glycosylase (allows creation of single-stranded breaks essential to class switch recombination and somatic hypermutation).

mutation are generally asymptomatic, but most boys with XLA come to clinical attention by the age of 1 year. In addition to low-serum immunoglobulins, a clue to the diagnosis is the absence of lymphoid tissue, including tonsils. Autosomal recessive mutations in the μ heavy chain as well as defects in *λ5, Igα, Igβ,* and *BLNK* produce a similar phenotype. In a small percentage of patients, no clear molecular defect can be identified. Also included in this group are thymoma with immunodeficiency (Good syndrome) and myelodysplasia. Good syndrome is a poorly understood disorder that presents primarily in middle-aged adults. Immunodeficiency can precede or follow the diagnosis of thymoma and does not resolve with thymectomy. In addition to infections, patients experience autoimmune phenomena, including myasthenia gravis, immune thrombocytopenia purpura, pure red blood cell aplasia, and pernicious anemia. Myelodysplastic syndromes can also mimic XLA and generally present with low B cells and pancytopenia with monosomy 7, trisomy 8, or dyskeratosis congenita.[24]

A second group is characterized by severe reduction of at least two serum immunoglobulin isotypes with normal or low numbers of B cells. Most patients in this group can be categorized as having common variable immune deficiency (CVID), a heterogenous disorder characterized by recurrent infection and failure to make antibody to vaccine antigens. Both males and females are affected, and patients can have autoimmune and gastrointestinal disease as well as lymphoproliferative disorders. Autoimmune disease can precede the hypogammaglobulinemia. About 10% of patients with a CVID phenotype have a family history of immunodeficiency and can be shown to have mutations in one of five genes expressed on both T and B cells. Homozygous or compound heterozygous mutations in *ICOS* (inducible costimulator), which is expressed on activated T cells and plays a role in activating T-helper cells and providing B-cell help, and *CD19*, a B-cell surface molecule that participates in signaling after antigen binding to the B-cell receptor, have been shown to result in recurrent infections in childhood and hypogammaglobulinemia. Mutations in *TACI* (transmembrane activator and CAML-interactor) and *BAFF-R* (B cell–activating factor receptor) members of the tumor necrosis factor receptor superfamily, which play roles in B-cell survival and antibody production, and *MSH5*, a mismatch repair gene, are thought to predispose to CVID and IgA deficiency but are not sufficient to independently cause their onset. X-linked lymphoproliferative syndrome caused by mutation in the signaling lymphocyte activation molecular-associated protein SAP (gene, *SH2D1A*) can present atypically or later in life with a CVID phenotype.[25]

Class switch recombination defects encompass a third group of antibody deficiencies and result in hyper-IgM syndrome characterized by reductions in serum IgG and IgA with normal or elevated IgM. Mutations in the gene for CD40 ligand make up about 30% of these syndromes. CD40L on the surface of T cells interacts with CD40 on B cells, which is required for immunoglobulin class switching, and CD40 on monocytes, which is required for T-cell response. Patients with *CD40L* mutations and rarer mutations in *CD40* itself and in nuclear factor kappa-B (NF-κB) essential modulator (*NEMO*) required for CD40-induced signaling have combined antibody and cellular immune deficits, resulting in hypogammaglobulinemia and recurrent bacterial infection as well as opportunistic infections with organisms similar to those observed in acquired immune deficiency syndrome. Defects in the activation-induced cytidine deaminase gene (*AID*) produce hypogammaglobulinemia with recurrent bacterial infections and diarrhea as well as enlarged lymphoid organs filled with proliferating B cells. A similar clinical picture is produced by homozygous defects in uracil-DNA glycosylase (*UNG*). AID is thought to deaminate cytosine to uracil, and UNG subsequently deglycosylates and removes the uracil residue, creating an abasic site, which allows for creation of single-stranded DNA breaks. Deficiencies in these enzymes result in defective class switching and somatic hypermutation. Patients with similar phenotypes but without defects in *AID* or *UNG* have been described and probably have mutations in other essential genes involved in class switching.[26]

Additional groups of antibody deficiencies exist in which overall antibody levels are normal, but there are defects in specific isotypes, light chains, or specific antibodies with normal numbers of B cells; the majority of patients with these deficiencies are healthy. The commonest member of these groups is selective IgA deficiency, which occurs in about one in 500 whites. The molecular mechanisms underlying this deficiency are unknown, but there is an association with CVID. Finally, an entity termed *transient hypogammaglobulinemia of infancy* has been described in which the normal decline in immunoglobulins after maternal transfer is prolonged. This entity is poorly understood and usually affects boys who have mild infections and diarrhea. Recovery usually, but not always, occurs by 3 years of age.[27]

Hypergammaglobulinemia

Hypergammaglobulinemia results from an overproduction of immunoglobulins by plasma cells, either monoclonal and reflective of a plasma cell or lymphoproliferative disorder or polyclonal and accompanying other disease states. The distinction between polyclonal and monoclonal disorders is made by inspection of the serum protein electrophoretic pattern. Detection of one or several monoclonal bands within a polyclonal background is not unusual, and the literature suggests that small bands frequently disappear and do not become clinically relevant. No data are available to suggest that polyclonal gammopathy drives development of monoclonal gammopathy; however, if a clonal plasmaproliferative disorder is suspected, immunofixation or immunoelectrophoresis should be performed.

Disorders Producing Polyclonal Gammopathy

Polyclonal gammopathy usually reflects one of five major disorders, including liver disease, connective tissue disorders, infections, hematologic disorders, and solid tumors.[28] Interleukin-6 (IL-6) and IL-10 have been implicated in polyclonal gammopathy as have defects in T cells and chronic antigenic stimulation, but the exact sequence of events leading to polyclonal B-cell activation is not known. In general, treatment is directed at the underlying disease, but there are reports of polyclonal gammopathy leading to symptomatic hyperviscosity. In these cases, plasmapheresis and/or corticosteroids seem to be effective. It should also be noted that polyclonal elevations in serum immunoglobulins can sometimes interfere with the direct Coombs test, possibly via nonspecific antibody binding to red blood cells. The degree of gamma globulin elevation does not seem to be helpful in defining the underlying disease state.

In the largest recent review of polyclonal gammopathy, the majority of patients had liver disease, which covered the spectrum from autoimmune disorders (autoimmune hepatitis, primary biliary cirrhosis, primary sclerosing cholangitis) to viral hepatitis and alcoholic liver disease. In fact, elevation of serum gamma globulins is a distinguishing characteristic of autoimmune hepatitis, and the levels usually correlate with activity of disease. The commonest etiology for polyclonal gammopathy related to liver disease in the United States is likely infection with hepatitis C, but in any particular clinical setting, the exact distribution likely depends on the population demographic. Other diseases affecting the liver such as α-1 antitrypsin deficiency and hemochromatosis are also accompanied by increases in serum immunoglobulins.

Connective tissue diseases, including Sjögren syndrome, SLE, ankylosing spondylitis, and rheumatoid arthritis, are also accompanied by polyclonal gammopathy. In many of these diseases, the degree of gamma globulin elevation may reflect disease activity, although a causative link between the autoimmune phenomena and immunoglobulin levels has not been determined. Several of the periodic fever syndromes, which are sometimes classified with the connective tissue disorders, have elevated immunoglobulin levels as a part of their manifestations. Hyperimmunoglobulinemia D is one such syndrome and is linked to mutations in the mevalonate kinase gene. Patients with this disorder present in the first year of life with febrile attacks, lymphadenopathy, abdominal symptoms, arthritis, and oral and genital ulcers. The hallmark finding is elevated levels of polyclonal

IgD often accompanied by elevated IgA levels. Tumor necrosis factor receptor 1–associated periodic syndrome (TRAPS) results from mutation in the gene for the TNF receptor 1 (*TNRF1*) and can cause prolonged febrile attacks with abdominal pain, arthralgias, and myalgias. During attacks, polyclonal elevation of immunoglobulins (primarily IgA) is observed.[29]

Infections, usually chronic in nature, are frequently accompanied by polyclonal gammopathy. HIV infection is a common cause, and immunoglobulin levels tend to increase slowly until the diagnosis of AIDS and then decline over the ensuing 6 to 18 months. Polyclonal gammopathy can be a clue to occult infections such as subacute bacterial endocarditis, tuberculosis, perinephric abscess, Lyme disease, and a variety of parasitic infections.

Malignant B- and T-cell disorders can cause polyclonal hypergammaglobulinemia. These diseases include CLL; large granular lymphocytic leukemia; hairy cell leukemia; and angioimmunoblastic T-cell lymphoma (AITL), a rare disease characterized by rash, widespread lymphadenopathy and extranodal involvement, autoimmune phenomena, and polyclonal gammopathy. Interestingly, despite the elevated levels of immunoglobulins observed in AITL, patients exhibit immunodeficiency and a propensity to develop opportunistic infections. Patients with myeloid disorders can also have polyclonal gammopathies; in one large series, nearly 40% of patients with myelodysplastic syndrome had hypergammaglobulinemia, and patients with immunologic abnormalities had inferior survival.[30] The incidence of hypergammaglobulinemia is reported to approach 50% in CMML. Hypergammaglobulinemia has been reported in AML both in adults and children, but it appears to be a rare phenomenon. Among solid tumors, ovarian and hepatocellular cancers are the commonest associated with polyclonal gammopathy. There are case reports of cancers, particularly lung and breast tumors, producing and releasing the secretory component of IgA into the bloodstream with the binding of SC to polyclonal IgA, producing hypergammaglobulinemia of serum sIgA.[30]

A variety of other diseases, including asbestos exposure and several subtypes of hypersensitivity pneumonitis and idiopathic interstitial pneumonia, are associated with polyclonal gammopathy. In general, these disorders represent diffuse activation of B cells.

Table 47-3 Diseases Associated With Monoclonal Gammopathy

Plasma cell and related disorders	MGUS	See Chapters 85 to 87
	Solitary plasmacytoma:	
	Bone	
	Soft tissue	
	Multiple myeloma	
	Waldenström macroglobulinemia	
	Primary amyloidosis (AL)	
Lymphoid disorders	Non-Hodgkin lymphoma	Monoclonal protein observed in CLL (>20% of cases with IgM, ≈50% with IgG, light chains also observed), extranodal marginal zone lymphomas (>30% of cases and correlated with BM involvement), follicular, mantle cell, and diffuse large B-cell lymphomas also reported with serum M proteins as has AITL
	Hodgkin lymphoma	Rare but reported
	Castleman disease	<2% with monoclonal gammopathy
Other hematologic disorders	Acquired von Willebrand disease	IVIG more effective than factor concentrate in increasing factor VIII coagulant and VWF levels
	Gaucher disease	Observed in 25% in one study; M protein declined after splenectomy
	Pernicious anemia, pure RBC aplasia, hereditary spherocytosis, MPD, MDS	
Connective tissue disorders	SLE	IgG, IgM, and IgA have been observed, no difference in disease activity or outcome
	Inclusion body myositis	80% with IgG M protein
	Polymyositis, RA, scleroderma	
Neurologic disorders	POEMS syndrome	Most have M-protein of λ light chain
	Peripheral neuropathy	Most common is IgM followed by IgG and IgA
		In half, IgM protein binds to myelin-associated glycoprotein
		Size of M protein not correlated with severity of neuropathy
		Some benefit from plasma exchange for those with IgG and IgA
		Fludarabine and rituximab with some benefit for IgM
	Myasthenia gravis, ALS, Alzheimer disease	
Dermatologic disorders	Schnitzler syndrome	Neutrophilic urticarial dermatitis, monoclonal IgM protein and two of: lymphadenopathy, fever, hepatosplenomegaly, joint pain, increased ESR, increased neutrophils, or abnormal bone imaging
	Scleredema	
	Pyoderma gangrenosum	Frequently an IgA protein
Infections	HIV	Both IgG and IgM M proteins observed
	HCV	M protein present in up to 10% of patients
Immunosuppression	Renal transplant	In children CMV infection associated with M protein
	Liver and heart transplant	Most patients with posttransplant lymphoproliferative disorders have M proteins
	BM transplant	Observed in both autologous and allogeneic transplants
		Appearance of M protein correlated with GVHD

AITL, Angioimmunoblastic T-cell lymphoma; *ALS,* amyotrophic lateral sclerosis; *BM,* bone marrow; *CLL,* chronic lymphocytic leukemia; *CMV,* cytomegalovirus; *ESR,* erythrocyte sedimentation rate; *GVHD,* graft-versus-host disease; *HCV,* hepatitis C virus; *Ig,* immunoglobulin; *IVIG,* intravenous immunoglobulin; *MGUS,* monoclonal gammopathy of uncertain significance; *MPD,* myeloproliferative disorder; *POEMS,* polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes; *RA,* rheumatoid arthritis; *RBC,* red blood cell; *SLE,* systemic lupus erythematosus.

Disorders Producing Monoclonal Gammopathy

The differential diagnosis of monoclonal gammopathy includes monoclonal gammopathy of undetermined significance (MGUS), multiple myeloma, solitary plasmacytoma of bone or extramedullary plasmacytoma, Waldenström macroglobulinemia, lymphoma, CLL, and primary systemic amyloidosis. These individual disorders are described elsewhere in this text; however, there are a few points to be made about the M protein itself and MGUS. These disorders can produce intact immunoglobulins (IgG, IgM, IgD, or IgE), κ- or λ-light chains alone or in combination with intact immunoglobulins and rarely heavy chains only. The monoclonal protein is usually detected as a discrete band in the γ or β region in serum or urine protein electrophoresis (M spike) and then characterized and confirmed by immunofixation electrophoresis (IFE). Monoclonal antibodies have been associated with a wide variety of bacterial antigens as well as various antigens, including thyroglobulin, von Willebrand factor, and lactate dehydrogenase; however, for most M proteins, the antigen is not recognized. A variety of other disorders are also associated with an M protein (Table 47-3), including connective tissue disorders, neurologic disorders (including POEMS [polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes] syndrome), renal disorders, and some infections such as hepatitis C and HIV. Patients undergoing bone marrow and solid organ transplants in which there is immune suppression are also occasionally observed to have M proteins, but these are usually transient and disappear with recovery of the immune system. Acquired immune disorders such as acquired C1 inhibitor deficiency, type 2 acquired angioedema, and acquired von Willebrand syndrome have also been associated with M proteins.

CHAPTER 48

DISORDERS OF PHAGOCYTE FUNCTION

Mary C. Dinauer and Thomas D. Coates

Phagocytic leukocytes are an essential component of the innate immune system that has evolved to rapidly respond to the presence of invading bacteria, fungi, and parasites. This first line of host defense also includes natural killer (NK) lymphocytes, complement, and other plasma proteins. As reviewed in Chapters 17 and 25, phagocytes are responsible for ingesting, killing, and digesting pathogens. Granulocytic phagocytes (neutrophils and eosinophils) circulate in the bloodstream until they sense chemotactic signals from infected tissues, resulting in adhesion to the vascular endothelium and subsequent migration into the site of infection. Mononuclear phagocytes (macrophages and their circulating precursor, the monocyte), on the other hand, function primarily as resident cells in a variety of tissues such as the lungs, liver, peritoneal cavity, and spleen, where they perform a surveillance role and also interact closely with lymphocytes to promote specific immune responses. Microbial killing is accomplished by two types of mechanisms: (1) de novo synthesis of highly toxic and often unstable derivatives of molecular oxygen by an enzyme known as the respiratory burst oxidase and (2) preformed polypeptide "antibiotics" and proteases stored within several types of lysosomal granules that are delivered into phagocytic vacuoles containing the ingested microbes.

This chapter reviews the major congenital and acquired disorders of phagocyte function, which from the clinical standpoint largely involve neutrophils. As would be predicted, these disorders manifest clinically by recurrent bacterial and fungal infections, often with atypical pathogens or unusual presentations. Interestingly, the converse of this is only rarely observed. Most patients with recurrent infections do not have any identifiable abnormality in their phagocytes. There are at least two explanations for the clinical rarity of phagocyte disorders. First, given their critical role in host defense, nature may be quite intolerant of major abnormalities in phagocytes. Before the modern antibiotic era, patients with severe disorders probably did not survive into their childbearing years. Second, there is a remarkable redundancy in the antimicrobial machinery of the phagocytes that permits one system to compensate for a defect in another. For example, the host does not rely on a single chemotactic signal or neutrophil membrane receptor to ensure that phagocytes accumulate at sites of infection. Instead, multiple chemotactic signals and receptors are used. A similar phenomenon is seen in the reactions that kill microbes as both oxidative and nonoxidative systems are used.

This chapter is organized according to the cellular functions outlined above: disorders of the respiratory burst microbicidal pathway, abnormalities of phagocyte adhesion and chemotaxis, and defects in the structure and function of lysosomal granules. The chapter is not meant to be an encyclopedic review of the numerous papers published on phagocyte abnormalities. It is important to note that many of these reports describe marginal in vitro defects, with little evidence that they are responsible for a clinical problem. Comprehensive reviews offering additional information on phagocyte disorders are available.[1,2]

APPROACH TO DIAGNOSIS OF PHAGOCYTE FUNCTION DISORDERS

Inherited and acquired clinical disorders of phagocyte function result from defects in one or more of the major steps leading to microbial killing—adhesion, chemotaxis, ingestion, degranulation, and production of microbicidal oxidants (Fig. 48-1). Patients with inherited disorders typically present in infancy or childhood with recurrent, unusual, or recalcitrant bacterial and fungal infections, and it is usually not difficult to determine that these are outside the range of normal. The presentation of these different inherited disorders can overlap, so that a specific diagnosis cannot be made on clinical grounds alone. Infections commonly seen include those of skin or mucosa, lung, lymph node, deep tissue abscesses, or childhood periodontitis. These can often have an indolent presentation with only low-grade fevers. Bacterial sepsis is an unusual initial symptom and usually reflects dissemination from an infected site. Inherited defects in phagocyte function are rare and represent only about 20% of the primary immunodeficiencies.[1] Thus, children with suspected disorders of host defense should also be screened for defects in humoral, cellular, and complement-mediated immunity. An approach to evaluating the patient with significant recurrent infections is shown in Figure 48-2. Patients in whom a defect is identified should be referred to a center specialized in care of such patients.

In clinical practice, although nearly all patients with well-characterized phagocyte abnormalities have recurrent or unusual infections, the majority of individuals with histories of persistent or recurrent infections do not have identifiable phagocyte disorders or other immune defects. In some cases, these reflect another underlying medical condition or nonimmunologic problem related to an anatomic or obstructive defect. This chapter focuses largely on disorders in which a good correlation exists between the clinical condition and an identifiable defect in phagocyte function.

DISORDERS OF THE RESPIRATORY BURST PATHWAY

Reactive oxygen species generated by the phagocyte respiratory burst are critical for microbial killing. The enzyme responsible for the initial reaction in this pathway is a nicotinamide adenine dinucleotide phosphate (NADPH) oxidase found in plasma and phagolysosomal membranes. Upon activation by inflammatory stimuli, the NADPH oxidase catalyzes the transfer of an electron from NADPH to molecular oxygen, thereby forming superoxide (as the O_2^- ion) (Fig. 48-3, reaction 1).[2-4] This NADPH oxidase, along with enzymes and reactions that are directly involved in the production or metabolism of O_2^-, constitutes the respiratory burst pathway as depicted in Fig. 48-3. Superoxide is the precursor to numerous microbicidal oxidants, including hydrogen peroxide and hypochlorous acid. Five clinically significant defects have been identified in the respiratory burst, involving the following enzymes: NADPH oxidase (reaction 1), leukocyte glucose-6-phosphate dehydrogenase (G6PD) (reaction 8), myeloperoxidase (MPO) (reaction 4), glutathione reductase, and glutathione synthetase (reaction 9). These reactions are involved in the production of O_2^- (reactions 8 and 1) in the conversion of O_2^- and hydrogen peroxide to other toxic derivatives (reaction 4) or in the detoxification of excess hydrogen peroxide needed to protect the phagocyte during the respiratory burst (reactions 7 and 9). Of note, NOX homologues to the leukocyte NADPH oxidase have recently been discovered in the gut, vascular cells, and other tissues, which may generate oxidants for local host defense or for regulation of other cellular functions.[5]

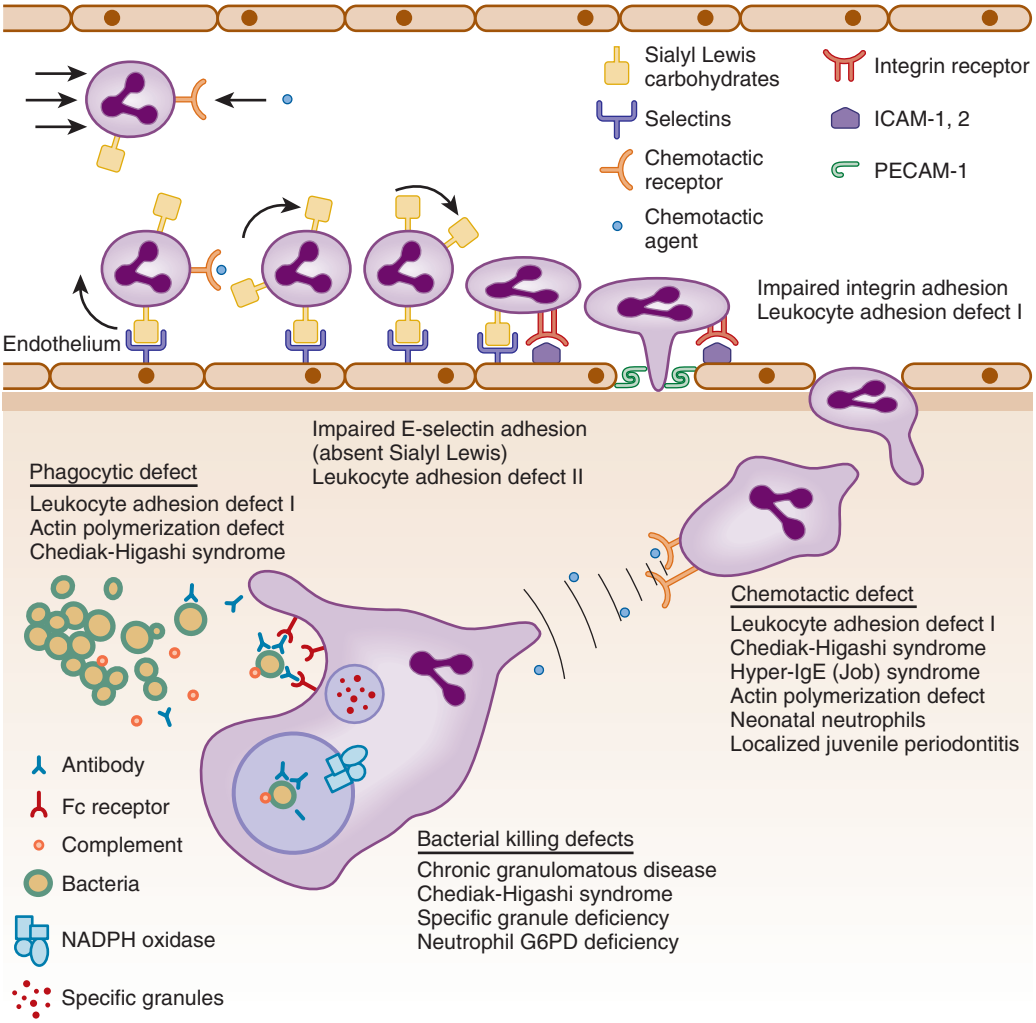

Figure 48-1 STEPS IN THE RESPONSE OF CIRCULATION NEUTROPHILS TO INFECTION. The adhesion molecule E-selectin is upregulated on endothelial cells in response to inflammatory mediators (interleukin-1 [IL-1], endotoxin, tumor necrosis factor-α [TNF-α]), resulting in rolling attachment and margination through interaction with sialyl Lewis carbohydrates on its surface. Chemoattractants such as IL-8 cause upregulation of neutrophil β2 integrins that, in turn, mediate tight adhesion to intercellular adhesion molecule 1 (ICAM-1) and platelet endothelial cell adhesion molecule 1 (PECAM-1) on endothelial cells. Activated neutrophils can detect as little as a 2% change in the chemoattractant gradient and move to the site of infection. Neutrophils phagocytose bacteria opsonized by antibody and complement. Both oxidative and nonoxidative antimicrobial mechanisms are then used to kill bacteria. Disorders of phagocyte function associated with each of these steps are noted. *G6PD,* Glucose-6-phosphate dehydrogenase; *NADPH,* nicotinamide adenine dinucleotide phosphate. *(Modified from Kyoto W, Coates TD: A practical approach to neutrophil disorders.* Pediatr Clin North Am *49:929, 2002, with permission.)*

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) is a genetically heterogeneous group of defects that share in common the failure of neutrophils, monocytes, macrophages, and eosinophils to undergo a respiratory burst and generate O_2^-.[2,6,7] CGD is relatively rare, having an estimated incidence of between one in 200,000 and one in 250,000 live births based on data from the United States CGD Registry,[7] although it is still the most common inherited phagocyte disorder of clinical significance (MPO deficiency is more common, but affected patients are rarely symptomatic). The absence of respiratory burst-derived oxidants results in recurrent, often life-threatening bacterial and fungal infections and is also associated with formation of inflammatory granulomas.[2,6-9] The disease was first described in 1957 as a syndrome characterized by severe recurrent infections in boys who also had visceral granulomas containing pigmented histiocytes. The disease was termed *fatal granulomatous disease* owing to this distinguishing histologic feature and the grim clinical course in most patients. It was not until the late 1960s and early 1970s that the defect in oxygen consumption and O_2^- production was identified and a convenient diagnostic assay, the nitroblue tetrazolium (NBT) test, was developed. In the 1980s a combination of biochemical and molecular genetic approaches led to the identification of four critical subunits of the NADPH oxidase and the recognition that mutations in the corresponding genes are responsible for four different genetic subgroups of CGD (Fig. 48-4). Recently, a fifth genetic subgroup was identified in a single patient.[10] Databases for the main four genetic subgroups of CGD have been developed that are accessible through the website http://bioinf.uta.fi/idr. Recent publications on disease manifestations and genotypes in large patient registries are also available (see references 9, 11, and 12) and support earlier reports.[7]

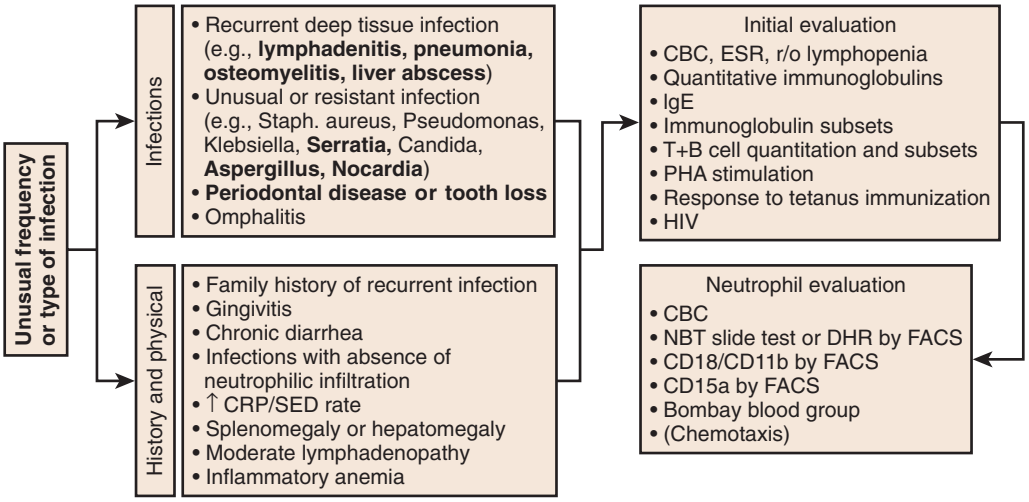

Figure 48-2 EVALUATION OF PATIENTS WITH RECURRENT BACTERIAL OR FUNGAL INFECTIONS. The history, physical examination, and infections episodes in patients with a possible primary neutrophil dysfunction syndrome are noted. The initial evaluation can be done in most clinical laboratories. A qualified reference laboratory with special expertise in this area should do the neutrophil evaluations. Chemotaxis is very difficult to evaluate clinically and should only be attempted in a qualified research laboratory with extensive experience.

Clinical Approach to Patients With Disorders of Phagocyte Function

Index of Suspicion

Patients with disorders of phagocyte function usually present at a young age with recurrent, deep-seated bacterial and fungal infections. Unlike patients with severe neutropenia caused by bone marrow failure, these patients usually do not have sepsis. Blood cultures are often negative. The major diagnostic problem faced by the clinician is to determine if the history of infection is unusual enough to warrant consideration of an underlying neutrophil dysfunction defect. The first point to remember is that primary immunodeficiency disorders are rare and primary neutrophil dysfunction syndromes form only a small percentage of all primary immunodeficiency syndromes. The patient is more likely to have recurrent community-acquired *Staphylococcus* infection than chronic granulomatous disease.

Specific features that may suggest a phagocytic defect are shown in Figure 48-2. Excellent discussions of this problem have been published (see Kyono and Coates[1] and Dinauer and Newburger[2]). Four aspects of each patient's infection history should be considered: frequency, severity, location, and responsible pathogen. Patients with unusual features in at least one of these aspects should alert the clinician to a possible underlying phagocyte disorder. When considering frequency, the patient's age and associated medical conditions must be taken into account. For example, recurrent otitis media in a 2-year-old patient is far less worrisome than a similar history in a 40-year-old patient. The more unusual or severe the infections, the less frequently these have to occur before a phagocyte evaluation is indicated. Infections in unexpected anatomic locations, such as hepatic, pulmonary, and rectal abscesses, may indicate an underlying phagocyte defect. Childhood periodontal disease or gingivitis is distinctly uncommon, and in the absence of neutropenic conditions, strongly suggests underlying neutrophil dysfunction. The identification of certain pathogens (e.g., *Serratia marcescens, Klebsiella* spp., *Aspergillus* spp., *Nocardia* spp., *Burkholderia cepacia*, invasive candidiasis) in children and young adults can provide the strongest indications for pursuing further studies. A history of delayed separation of the umbilical cord is often mentioned as a sign of phagocytic defect. This is fairly common as an isolated finding and is usually of no significance. However, this is in conjunction with omphalitis or other pyogenic infections raises the possibility of LAD or chemotactic defects. A child with nystagmus, fair skin, and recurrent staphylococcal infections should be evaluated for CHS.

Evaluation

Performing a good history and physical examination to eliminate common causes of recurrent infection is important before looking for rare syndromes. For example, is the recurrent pneumonia caused by an aspirated foreign body in the bronchus? In general, patients should first be evaluated for lymphocyte or complement defects. A useful algorithm is presented in Figure 48-2. Note that testing described in this algorithm is not exhaustive, and patients with truly striking histories of unusual kinds of infections should be referred for further evaluation by specialized research laboratories.

Molecular Genetics of Chronic Granulomatous Disease

Chronic granulomatous disease results from mutations in any of the five genes encoding essential subunits of the NADPH oxidase (Table 48-1).[11,12] In turn, the biochemical and genetic analysis of CGD has been instrumental in characterizing this complex enzyme. The oxidase subunits are referred to by their apparent molecular mass (kDa) and have been given the designation *phox,* for *ph*agocyte *ox*idase. A b-type cytochrome known as flavocytochrome b_{558}, a membrane bound heterodimer composed of $gp91^{phox}$ and $p22^{phox}$, is the redox center of the oxidase. Approximately two-thirds of CGD cases result from defects in the X-linked gene encoding the $gp91^{phox}$ subunit of flavocytochrome b_{558}, which contains both the flavoprotein and heme-binding domains responsible for electron transport. A rare autosomal recessive (AR) form of CGD is caused by mutations in the gene encoding $p22^{phox}$, the smaller subunit of flavocytochrome b_{558}, which provides a critical docking site for $p47^{phox}$, a regulatory subunit. The remaining cases of AR CGD involve genetic defects in $p47^{phox}$, $p67^{phox}$, or $p40^{phox}$, three regulatory proteins associated with

each other in the cytosol of unstimulated cells but rapidly move to the membrane to activate flavocytochrome b_{558} and superoxide formation when neutrophils are exposed to inflammatory or phagocytic stimuli. The p40^{phox} subunit appears to play a selective role in stimulating high-level superoxide production within phagosomes via membrane-bound phosphatidylinositol-3-phosphate.[10] Formation of the active NADPH oxidase complex also involves the activation of the small GTP-binding protein Rac, which then binds to the plasma membrane and p67^{phox}.[2] No cases of CGD have been identified resulting from genetic defects in Rac, although a mutation in the blood cell-specific Rac2 isoform was found in an infant with recurrent infections and abnormal neutrophil adhesion, motility, and partial NADPH oxidase defects.[2]

The gene for gp91^{phox}, termed *CYBB*, spans approximately 30 kb in the Xp21.1 region of the X chromosome. More than 600 distinct mutations have been identified in the gp91^{phox} gene in X-linked CGD (MIM306400), which include deletions, frameshifts, splice site, nonsense, and missense mutations that are distributed throughout the gene (Table 48-2).[11] Approximately 10% to 15% of X-linked CGD

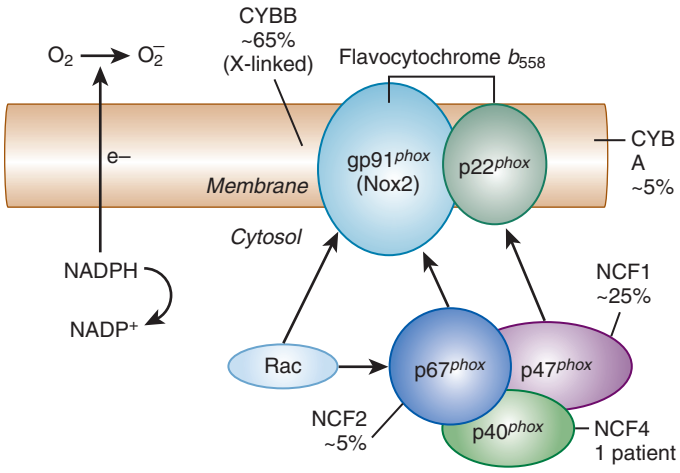

Figure 48-4 NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADPH) OXIDASE AND MOLECULAR GENETICS OF CHRONIC GRANULOMATOUS DISEASE (CGD). Shown are the membrane and soluble subunits of the NADPH oxidase, indicating how these correspond to the five different genetic subgroups of CGD and their approximate incidence. Flavocytochrome b_{558} is the redox center of the enzyme and is located in plasma, specific granule, and phagolysosomal membranes. This heterodimer is composed of the gp91^{phox} and p22^{phox} subunits of the NADPH oxidase, which are affected in X-linked and an autosomal recessive form of CGD, respectively. The soluble regulatory proteins p47^{phox}, p67^{phox}, and p40^{phox} are found in the cytosol until phagocyte activation by soluble or particulate inflammatory stimuli, after which they move to the membrane where p47^{phox} and p67^{phox} bind flavocytochrome *b558,* binds Rac, and p40^{phox} binds phosphatidylinositol-3-phosphate, a phosphoinositide present on phagosome membranes. Mutations in the genes encoding p47^{phox}p67^{phox} and p40^{phox} account for other autosomal recessive forms of CGD. Another essential regulatory component of the NADPH oxidase is the small GTPase, Rac, which in its active guanosine triphosphate–bound state, becomes membrane bound, and associates with the oxidase. By a mechanism that is not fully understood, binding of these multiple regulatory subunits activates the flavocytochrome to catalyze the transfer of electrons from cytosolic NADPH across the membrane via the FAD and heme redox centers to molecular oxygen, thereby forming superoxide in the extracellular or intraphagosomal compartment. No cases of CGD have been described owing to mutations in Rac.

Table 48-1 Classification of Chronic Granulomatous Disease

Component Affected	Gene Symbol	Gene Locus	Inheritance	Subtype*	NBT Score (% Positive)	O_2^- Production (% Normal)	Flavocytochrome *b* Spectrum (% Normal)	Defect in Cell-Free NADPH Oxidase Assay	Frequency (% of Cases)†

Table 48-2 Summary of Mutations in the *CYBB* Gene Encoding gp91^{phox} in 261 Kindreds With X-linked Chronic Granulomatous Disease

Type of Mutation	Number of Kindreds	Frequency (%)	Phenotype
Deletions	63	24.2	X91^0
Insertions	27	10.3	X91^0
Splice-site mutations	42	16.1	X91^0
Missense mutations	59	22.6	X91^0, X91–, X91+
Nonsense mutations	70	26.8	X91^0

Data from Roos D, Curnutte J, Hossle JP, et al: X-CGDbase: A database of X-CGD-causing mutations. *Immunol Today* 17:517, 1996.

is caused by new germline mutations. In most X-linked CGD, gp91^{phox} is completely absent, and there is no measurable flavocytochrome *b* or superoxide production (the X91° subtype). In about 5% of X-linked cases, gp91^{phox} can be present in normal levels but be nonfunctional (X91+), mutated in such a way that gp91^{phox} is poorly functional (X91–), or expressed in only a small fraction of phagocytes (X91+). The first two "variant" forms of X-linked CGD result from coding sequence mutations, and the latter are caused by mutations in the regulatory portion of the gp91^{phox} gene. Some X-linked CGD patients have large deletions that affect not only the gene encoding gp91^{phox} but also portions of or all the flanking gene loci for the McLeod hemolytic anemia syndrome (absence of the Kell erythrocyte antigen, Kx), Duchenne muscular dystrophy, and X-linked retinitis pigmentosa. Two kindreds with point mutations in *CYBB* leading to marked impairment of flavocytochrome b expression and activity in macrophages with less effect on neutrophils were recently reported.[13] Affected patients were susceptible to mycobacterial infections but did not have other bacterial and fungal infections characteristic of CGD, highlighting the importance of macrophages for controlling mycobacteria.

Autosomal recessive CGD involving p22^{phox} (MIM 233690) occurs in approximately 5% of CGD patients and usually involves the complete absence of cytochrome *b* (A22°), encoded by CYBA. Mutations in A22 CGD are heterogeneous and range from large interstitial gene deletions to point mutations associated with missense, frameshift, or RNA splicing defects.[12] Because the full expression of flavocytochrome *b* in the membrane requires the production of both subunits, a primary deficiency of either component leads to a secondary loss of the other. Thus, neither subunit can be detected on immunoblot analysis in either X91° or A22° CGD. A single patient with A22$^+$ CGD has been described, who has a missense mutation disrupting the binding site for p47^{phox}.

Autosomal recessive patients with p47^{phox} deficient CGD (MIM 233700) account for approximately one-fourth of cases in the United States and Europe but only about 7% of cases in Japan. The p47^{phox} subunit is encoded by the NCF1 gene. A limited number of mutations have been identified in the p47^{phox} gene.[12] Virtually all patients are either homozygotes or compound heterozygotes for a mutant allele with a GT deletion at the beginning of exon 2 that predicts a premature stop codon following amino acid residue and results in absence of the p47^{phox} protein. The high frequency of the p47^{phox} GT deletion mutation appears to reflect the existence of at least one closely linked highly conserved p47^{phox} pseudogene(s) that contains this GT deletion. This close physical proximity leads to recombination events between the wild-type gene and pseudogene(s).

A heterogenous group of mutations in the p67^{phox} gene, NCF2, are responsible for A67 CGD, a rare AR form of CGD (MIM233710) accounting for about 5% of cases overall.[12] Almost all of mutations identified to date in A67 CGD lead to absent expression of the p67^{phox} protein. However, one A67$^+$ patient has been reported in which a nonfunctional form of p67^{phox} with an amino acid deletion is expressed but is unable to translocate to the membrane or bind to Rac.

Finally, a boy with AR p40^{phox} defects (MIM613960) was recently reported.[10] This patient was a compound heterozygote for two null alleles in NCF4. Although NADPH oxidase activity on the plasma membrane was normal, phagosome oxidant production was markedly impaired. The main clinical manifestation in this patient was chronic granulomatous inflammation of the intestinal tract rather than opportunistic infections characteristic of CGD, perhaps related to the more selective role of p40^{phox} in regulating NADPH oxidase activity.

Even though more than 90% of patients with CGD have respiratory burst defects that result in undetectable levels of O_2^- production, there is a surprising heterogeneity in the clinical manifestations of the disease.[7] At one end of the spectrum are patients who begin to have severe bacterial and fungal infections during infancy and who rarely have more than 4 to 12 months between such serious infections. At the other end of the spectrum are patients who are well for many years and then unexpectedly develop a serious infection typical of CGD, such as a staphylococcal hepatic abscess or *Aspergillus* pneumonia. After their first major infection, some of these patients may be relatively healthy again for another 3 to 10 years before the next severe infection occurs. As a group, patients with X-CGD, A22 CGD, and A67 CGD seem to have a more severe clinical course compared with patients with A47 CGD,[7,9] who have a small amount of detectable oxidant production even in the complete absence of this subunit (Fig. 48-5, *G*). Individuals with partial respiratory burst activity less than 10% of normal (most X91– patients; see Table 48-1) also tend to have disease of intermediate severity. Polymorphisms in oxygen-independent antimicrobial systems or other components[9] regulating the innate immune response are also likely to play an important role in modifying disease severity. Specific polymorphisms in the MPO, mannose binding lectin, and FcγRIIa genes are associated with a higher risk for granulomatous or autoimmune or rheumatologic complications.[2,8] Because of this heterogeneity, the diagnosis of CGD should be entertained, not only in young children with recurrent severe infections, but also in adolescents and young adults who experience exceptionally severe or unusual infections.

Clinical Manifestations

In approximately two-thirds of patients, the first symptoms of CGD appear during the first year of life with the onset of recurrent, purulent bacterial and fungal infections.[7] Table 48-3 summarizes the types of infections and infecting organisms most frequently encountered in CGD. The most common types of infections are those that involve sites in contact with the outside world, which is consistent with the role of neutrophils as a first line of defense against infection. *Staphylococcus aureus,* enteric gram-negatives, *Serratia marcescens, Burkholderia cepacia, Nocardia* spp., and *Aspergillus* spp. represent the most frequently encountered pathogens in North American patients, but *Burkholderia* and *Nocardia* spp. are less frequently seen in Europe.[8] *S. aureus* is the most frequently isolated organism overall. The most common causes of death have been pneumonia or sepsis caused by *B. cepacia* and *Aspergillus* spp., although use of newer azole antifungals has markedly improved the outcome of the latter in recent years.[7,8]

Most CGD pathogens share the property of being catalase negative and as such inadvertently "lend" H_2O_2 secreted from the pathogen to the peroxide-starved CGD phagocyte, which in turn uses it (after being converted to hypochlorous acid [HOCl] by MPO; see Fig. 48-3) to kill the microbe. It also appears that at least some of the CGD pathogens are resistant to the nonoxidative killing mechanisms of the phagocyte. It is somewhat surprising how often one fails to identify the infecting organism in CGD—perhaps greater than half the time despite aggressive culturing. In this situation, one treats empirically with the antibiotic that should work and if it fails, one then aggressively pursues more invasive diagnostic procedures looking for one (or more) of the less commonly seen microbes such as *Nocardia* spp., *Candida* spp., mycobacteria, and a host of other bacteria and fungi (see Table 48-3). Other unusual organisms that cause infection in CGD include other members of the Burkholderia family,

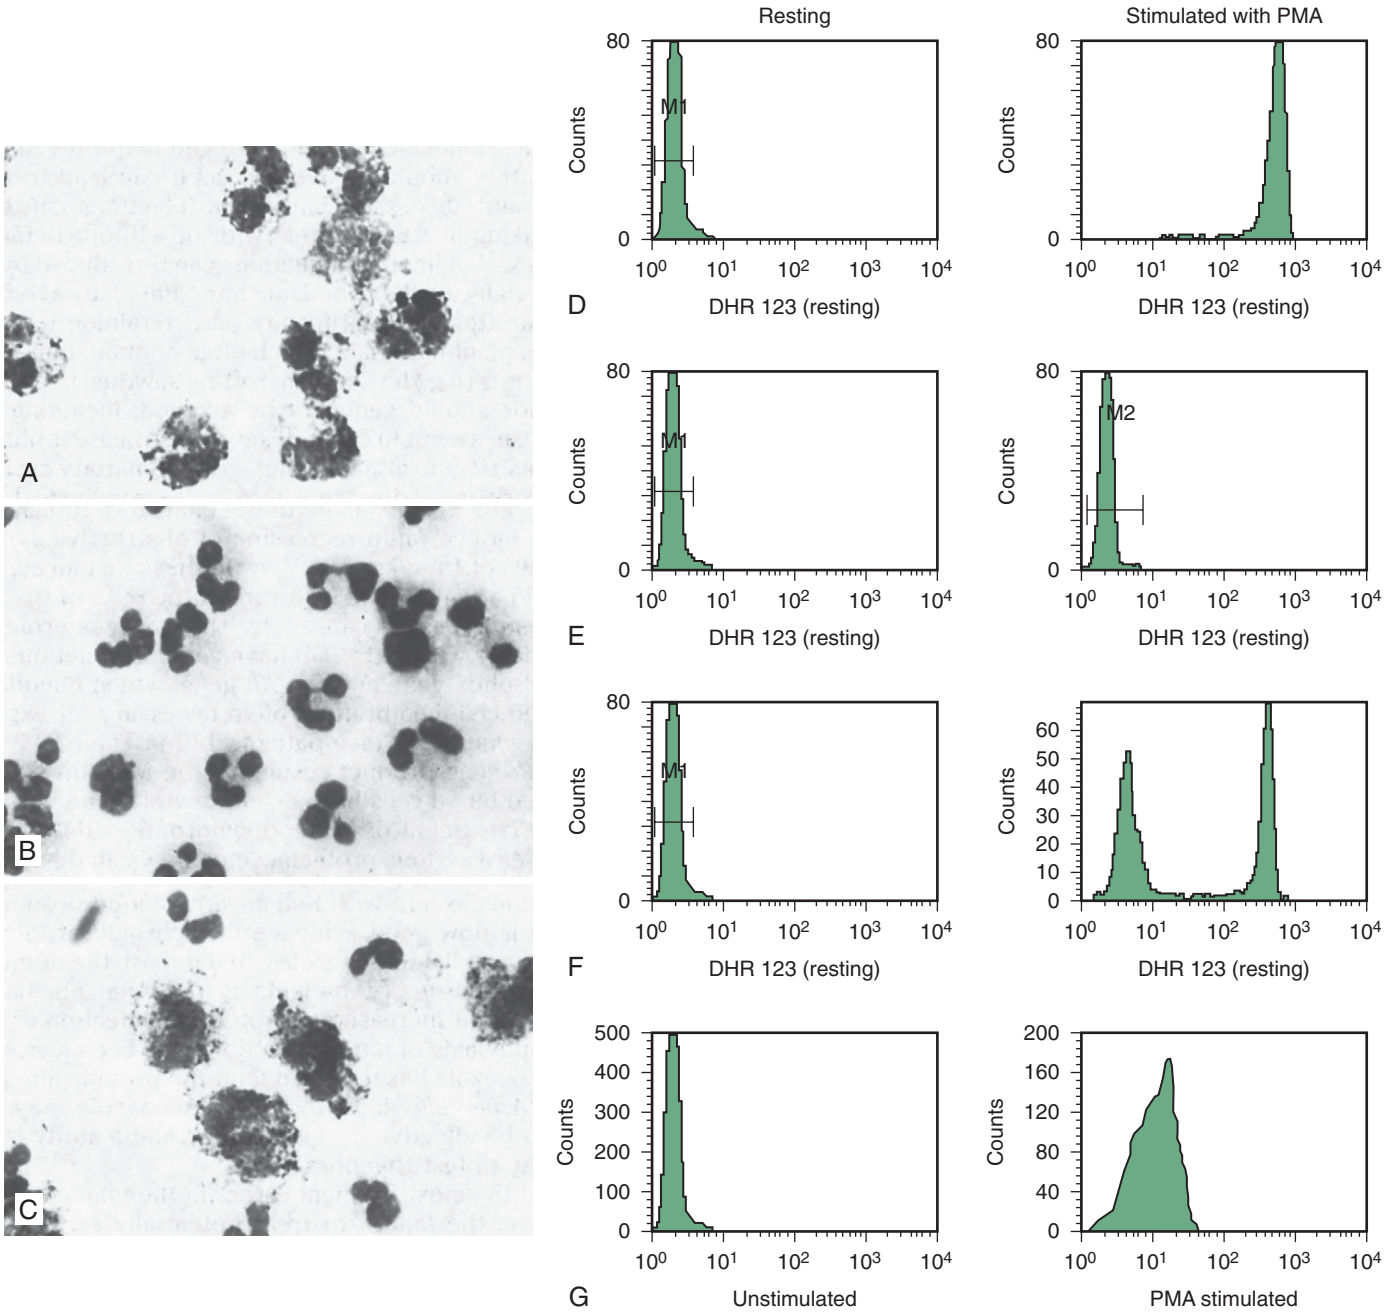

Figure 48-5 ANALYSIS OF NEUTROPHIL NICOTINAMIDE ADENINE DINUCLEOTIDE PHOSPHATE (NADPH) OXIDASE ACTIVITY FOR THE DIAGNOSIS OF CHRONIC GRANULOMATOUS DISEASE (CGD). **A** to **C,** Nitroblue tetrazolium (NBT) slide test. Peripheral blood neutrophils and monocytes from a drop of fresh whole blood were made adherent to glass slides and stimulated with phorbol myristate acetate. **A,** Normal neutrophils and monocytes, all of which are NBT positive. **B,** Neutrophils and monocytes from an X-linked CGD patient, which are all NBT negative. **C,** A mixture of NBT-positive and NBT-negative neutrophils from the X-linked carrier mother of the patient in part **B. D** to **G,** Dihydrorhodamine (DHR) 123 flow cytometry test. Nonfluorescent DHR 123 is taken up by neutrophils and become fluorescent after reaction with reactive oxygen species produced in the respiratory burst. **D,** Normal neutrophils. **E,** Neutrophils from an X-linked CGD patient, which do not fluoresce after stimulation. **F,** A mixture of nonfluorescent and fluorescent neutrophils from an X-linked CGD carrier. **G,** Neutrophils from a $p47^{phox}$-deficient patient, which show weak fluorescence after stimulation.

including *Burkholderia cenocepacia, Burkholderia Gladioli,* and *Burkholderia mallei* (the causative agent in melioidosis, a septic illness common in East Asia) and *Chromobacterium violaceum,* found in brackish fresh water and that can cause a febrile illness with bacteremia in CGD. A previously unknown gram-negative bacteria, *Granulobacter bethesdensis,* was recently identified in a CGD patient with recurrent fevers associated with chronic necrotizing deep lymphatic infection. This organism is a member of the *Acetobacteraceae* family, which has previously not been linked to invasive human disease.

Pneumonia is the most common type of infection seen in CGD with *S. aureus, Aspergillus* spp., *B. cepacia,* and enteric gram–negative organisms as the major pathogens. It is noteworthy that *B. cepacia* has emerged as a particularly lethal organism in CGD. This organism often is not covered with the first line of antibiotics used for *S. aureus* and most gram–negative organisms and can quietly proliferate (with persistent fevers) to the point of quick, explosive collapse caused by endotoxic shock. Intravenous trimethoprim–sulfamethoxazole (TMP-SMX) has been most effective in treating patients if given

Table 48-3 Infections in Chronic Granulomatous Disease

Infections	Percent of Infections	Infecting Organisms
Pneumonia	70-80	*Aspergillus, Staphylococcus, Burkholderia cepacia, Pseudomonas, Nocardia, Mycobacterium* (including atypical), *Serratia, Candida, Klebsiella, Paecilomyces*
Lymphadenitis	50-60	*Staphylococcus, Serratia, Candida, Klebsiella, Nocardia*
Cutaneous infections/ impetigo	50-60	
Hepatic or perihepatic abscesses	20-30	*Staphylococcus, Serratia, Streptococcus viridans, Nocardia, Aspergillus*
Osteomyelitis	20-30	*Serratia, Aspergillus, Paecilomyces, Staphylococcus, B cepacia, Pseudomonas, Nocardia*
Perirectal abscesses or fistulae	15-30	Enteric gram-negatives organisms, *Staphylococcus*
Septicemia	10-20	*B. cepacia, Pseudomonas, Salmonella, Staphylococcus, Serratia, Klebsiella*
Urinary tract infections or pyelonephritis	5-15	Enteric gram-negative organisms
Brain abscesses	<5	*Aspergillus, Staphylococcus*
Meningitis	<5	*Candida lusitaniae, Haemophilus influenzae, B. cepacia*

The relative frequencies of different types of infections in chronic granulomatous disease are estimated from data pooled from several large series of patients in the United States, Europe, and Japan: (1) Mouy R, Fischer A, Vilmer E, et al: Incidence, severity, and prevention of infections in chronic granulomatous disease. *J Pediatr* 114:555, 1989; (2) Bemiller LS, Roberts DH, Starko KM, et al: Safety and effectiveness of long-term interferon gamma therapy in patients with chronic granulomatous disease. *Blood Cells Mol Dis* 21:239, 1995; (3) Forrest CB, Forehand JR, Axtell RA, et al: Clinical features and current management of chronic granulomatous disease. *Hematol Oncol Clin North Am* 2:253, 1988; (4) Hitzig WH, Seger RA: Chronic granulomatous disease, a heterogeneous syndrome. *Hum Genet* 64:207, 1983; (5) Tauber AI, Borregaard N, Simons E, et al: Chronic granulomatous disease: A syndrome of phagocyte oxidase deficiencies. *Medicine (Baltimore)* 62:286, 1983; (6) Cohen MS, Isturiz RE, Malech HL, et al: Fungal infection in chronic granulomatous disease. The importance of the phagocyte in defense against fungi. *Am J Med* 71:59, 1981; (7) Hayakawa H, Kobayashi N, Yata J: Chronic granulomatous disease in Japan: A summary of the clinical features of 84 registered patients. *Acta Paediatr Jpn* 27:501, 1985; and (8) Johnston RB, Newman SL. Chronic granulomatous disease. *Pediatr Clin North Am* 24:365, 1977. These series encompass approximately 550 patients with CGD after accounting for overlap between reports. Unpublished data from the United States CGD Registry encompassing 368 patients was also used to estimate the relative frequencies of infections and the responsible organisms. The infecting organisms are arranged in approximate order of frequency for each type of infection. Note: *B. cepacia* was previously classified as *Pseudomonas cepacia.*

Table 48-4 Chronic Conditions Associated With Chronic Granulomatous Disease*

Condition	Relative Frequency (%)
Lymphadenopathy	98
Hypergammaglobulinemia	60-90
Hepatomegaly	50-90
Splenomegaly	60-80
Anemia of chronic disease	Common†
Underweight	70
Chronic diarrhea	20-60
Short stature	50
Gingivitis	50
Dermatitis	35
Hydronephrosis	10-25
Granulomatous ileocolitis	10-15
Gastric antral narrowing	10-15
Ulcerative stomatitis	5-15
Granulomatous cystitis	5-10†
Pulmonary fibrosis	<10†
Esophagitis	<10†
Granulomatous cystitis	<10
Chorioretinitis	<10
Glomerulonephritis	<10
Discoid lupus erythematosus	<10

*The relative frequencies of chronic conditions associated with chronic granulomatous disease (CGD) were estimated from the series of reports listed in Table 48-3.
†The incidence is estimated from the 50 cases of CGD followed at Scripps Research Institute and Stanford University (unpublished data).

before widespread dissemination of the infection. Proven or suspected *Aspergillus* infections were treated with amphotericin B therapy, but new azole antifungal agents are now typically used.

Lymphadenitis is the second most common infection and is usually caused by gram-negative organisms, *S. aureus,* or *Serratia marcescens.* Incision and drainage should not be delayed if the lesion fails to respond to parenteral antibiotics. Cutaneous abscesses should be similarly managed. Recurrent perinatal impetigo is almost a signature infection in CGD and often requires months of therapy (mostly oral antibiotics) to clear. Hepatic (and perihepatic) abscesses are also common in CGD and are usually, but not always, caused by *S. aureus*. Most lesions require drainage (needle or surgical) to permit efficient healing to occur. Bone infections, most commonly caused by *Serratia* spp. or *Aspergillus* spp., are particularly problematic in CGD and arise from either hematogenous or contiguous spread (as often is the case with *Aspergillus* infections in the lung invading ribs, vertebral bodies, or the diaphragm). Perirectal abscesses are difficult to treat, even with months of therapy, and can lead to fistula formations.

Chronic inflammation with granuloma formation is a distinctive hallmark of CGD and contributes to some of its more problematic complications.[8,14] In some cases, this results from imperfectly controlled infections in which stalemates develop between the pathogen and the patient's leukocytes. These lesions become granulomas as the host uses lymphocytes and activated macrophages to assist in containing the pathogens. However, this complication is not always clearly linked to persistent infection and in these cases has been speculated to involve a dysregulated inflammatory response, inefficient degradation of debris, or both. In the absence of oxidant production, excessive production of cytokines and delayed neutrophil apoptosis at inflammatory sites appear to contribute as underlying mechanisms.

As a result of persistent inflammatory stimulation, CGD patients can have from a variety of more chronic complications (Table 48-4). Lymphadenopathy, hepatosplenomegaly, eczematoid dermatitis, and anemia of chronic disease (hemoglobin levels usually 8-10 g/dL) are common manifestations of this process and are most prominent in the first 5 to 10 years of life in those with CGD. Throughout the body, granuloma formation can lead to dysfunction and obstruction in the

esophagus, urinary bladder, and kidneys. In the stomach, the gastric antral narrowing can be severe enough in infants and children to resemble pyloric stenosis. Inflammatory involvement of the gastrointestinal tract can be seen in up to one-third of CGD patients, typically in association with the X-linked form. A chronic ileocolitis resembling Crohn disease occurs in about 10% of patients and can range from mild diarrhea to a debilitating syndrome of bloody diarrhea and malabsorption that can necessitate a colectomy. Interestingly, antigliadin antibodies suggesting Crohn disease are positive in more than 50% of CGD patients. Other types of chronic inflammation include gingivitis, chorioretinitis, destructive white matter lesions in the brain, and glomerulonephritis. Discoid lupus has been reported in 10% to 20% of patients, and occasional patients may develop systemic lupus erythematosus, sarcoidosis, or rheumatoid arthritis. The underlying mechanisms are poorly defined, although recent studies suggest that these manifestations may be partly related to subtle defects in the absence of the NADPH oxidase in memory B or T cells.

Carriers of CGD, whether the X-linked form or any one of the AR forms, are usually asymptomatic with two important exceptions. First, about one-fourth of X-linked carriers are at risk of developing mild to moderately severe discoid lupus erythematosus characterized by discoid skin lesions and photosensitivity.[2,14] The onset is usually in the second decade of life. The disease does not progress to systemic lupus nor does one find serologic evidence of even subclinical disease. Those with severe discoid lupus can be treated with Plaquenil. Recurrent stomatitis, significant gingivitis, or both have also been noted in as many as half of X-CGD carriers. A few also have from arthralgias, polyarthritis, and Raynaud phenomenon. The second important complication of the X-linked CGD carrier state is serious infection in women who have a usually high degree of inactivation of the normal X chromosome in their myeloid cells. If the circulating neutrophil population is skewed to the point that fewer than 10% to 15% of the cells function, then the carrier has an increased risk of bacterial infections that in some cases have been severe.[2] Those with fewer than 5% oxidase positive cells have full-blown CGD.

Diagnosis

The diagnosis of CGD is usually suggested by the unusual clinical histories outlined earlier or by a family history of CGD. The NBT slide test on fresh blood is the classic diagnostic test. A typical result is shown in Fig. 48-5. Fig. 48-5, *A* shows the normal positive staining of a group of seven neutrophils and one monocyte. Fig. 48-5, *B* shows the complete absence of NBT staining in a patient with X91° CGD, the classic X-linked form of the disease. Fig. 48-5, *C* shows the mixed population of NBT-positive and -negative cells observed in that patient's mother, reflecting random X chromosome inactivation. Because nearly 100% of the normal cells in this test are positive, the carrier state in X-linked CGD can be detected when as few as 5% of the cells are NBT negative. This test also permits detection of diffuse populations of weakly positive cells such as those seen in X91$^-$ CGD, which are characterized by a partial deficiency of flavocytochrome *b*. Because X-linked CGD can arise by new mutations in the maternal germ line, one does not always see NBT-negative cells in the mother. Flow cytometric assays of oxidase activity, such as those based on the conversion of dihydroxyrhodamine (DHR) 123 to rhodamine 123, can also provide both quantitative measurements of oxidant generation and the cell-by-cell distribution of activity (see Fig. 48-5, *D* to *G*). The DHR 123 assay for oxidase activity is now available in many referral centers and through reference laboratories. In addition to X91$^-$ CGD neutrophils, weak staining in the NBT test or a small but measurable level of DHR fluorescence can be seen in A47^0 cells (see Fig. 48-5, *H*) because of a small amount of residual oxidant production. Regardless of diagnostic assay used, is important to have these tests performed on appropriately handled blood samples and by experienced laboratories to avoid inconclusive or false normal results.

Genetic classification is useful primarily for purposes of genetic counseling and prenatal diagnosis. With the exception of classic X-linked disease in a male whose mother is a carrier, determining the

Diagnosis of Chronic Granulomatous Disease

The diagnosis of CGD is easily established by doing an NBT slide test or flow cytometry of DHR 123 fluorescence to detect neutrophil NADPH oxidase activity. The NBT slide test is very easy to set up, as is DHR flow cytometry. However, because the probability of getting an abnormal result is very low, there may be confusion in interpretation because of a lack of experience. In the authors' experience, incorrect positive and negative results have been reported for both assays. Thus, if the index of suspicion is high, consultation should be obtained from a center with extensive experience with the test and with the disorder.

Neutrophil respiratory burst activity is preserved in anticoagulated blood maintained at room temperature for several days; thus, DHR testing can be done 1 to 2 days later after shipping to a commercial laboratory. A normal control should always be shipped with the patient specimen to eliminate problems in specimen handling during transport.

NBT Slide Test

- No NBT reduction (absence of cells with dark blue formazan deposits) in both X-linked and AR forms of CGD (see Fig. 48-5, *B*).
- Usually no reduction in 50% of cells and normal in 50% for X-linked carrier. The percent positive cells can vary if there is unequal X inactivation and may appear normal or like CGD with extreme lyonization (see Fig. 48-5, *C*).
- False-positive results can occur (i.e., apparent failure to reduce NBT supporting the diagnosis of CGD) if the neutrophils do not adhere to the slide. This happens with greasy slides or with some cases of LAD. Using PMA to stimulate the cells will avoid this.

DHR Flow Cytometry

- This approach has replaced the NBT slide test in many laboratories. It has the advantage of assessing large numbers of cells and can give quantitation of the amount of oxidant production.
- The change in fluorescence channel number with stimulation is the critical number and not the percent positive cells.
- X-linked CGD patients will not respond at all and show no increase in fluorescence with stimulation (see Fig. 48-5, *F*).
- X-linked carriers will show about 50% of the cells that respond with a normal increase in fluorescence, and the other half will have no response. Degrees of unequal X inactivation are much more accurately quantified by this assay (see Fig. 48-5, *G*).
- AR patients, particularly those with absent p47^{phox}, have some response to stimulation and show a small increase in fluorescence (see Fig. 48-5, *H*). This level of oxidant production is usually not visible on the NBT test.
- AR carriers have a good response, but the histogram may be broader than normal and may even appear bimodal with a weakly fluorescent peak and a strongly fluorescent peak. This is not distinguishable on the NBT slide test.
- Falsely negative results not supporting the diagnosis of CGD have been reported in specimens that have been run a few days after phlebotomy.
- Falsely abnormal results suggesting CGD can be seen in patients with MPO deficiency because MPO is required to generate strong DHR fluorescence.

Genetic Analysis

- Genetic analysis for X-linked and AR CGD is clinically available and should be performed on at least the proband in each kindred.

specific oxidase gene affected in a given CGD patient (see Table 48-1) requires additional laboratory studies. Genetic testing for the four most common genetic subgroups is commercially available. Laboratories specializing in neutrophil biochemistry can also perform immunoblot analysis of neutrophil extracts, flavocytochrome *b* spectroscopy, or functional analysis of membrane and cytosol fractions in the cell-free oxidase assay. In a male with absent flavocytochrome *b* without clear evidence for a maternal carrier, it is necessary to search for the mutation in both the $gp91^{phox}$ and $p22^{phox}$ genes by DNA sequencing or another method of analysis.

Testing for the McLeod red cell phenotype should be done in all patients diagnosed with X-linked CGD. This causes a mild hemolytic anemia. More importantly, there can be serious problems with development of hemolytic antibodies if these patients are transfused.

Prognosis and Treatment

The cornerstones of therapy in CGD are currently (1) prevention and early treatment of infections, (2) aggressive use of parenteral antibiotics for most infections, (3) use of prophylactic TMP-SMX (5 mg/kg/day of trimethoprim) or dicloxacillin (25-50 mg/kg/day) for sulfa-allergic patients, (4) prophylactic itraconazole (200 mg/day if 13 years of age or older or if weighing at least 50 kg or 100 mg daily if younger than 13 years of age or weighing less than 50 kg), and (5) use of prophylactic recombinant human interferon-γ (rIFN-γ) (0.05 mg/m^2 or 0.0015 mg/kg if less than 0.5 m^2 three times per week).[6,8] Using these guidelines, the prognosis for patients with CGD has improved dramatically since the disorder was first described in the 1950s, when almost all patients died in childhood. In a large study based on data collected by a CGD registry in the United States in the 1990s, the overall mortality rate was estimated to be 5% per year for X-CGD and 2% per year for AR CGD,[7] and a more recent single-institution study on 76 patients reported an overall mortality rate of 1.5% per year.[8] There is a general consensus that a large majority of newly diagnosed children should survive well into their adult years with aggressive and careful management. As already noted, patients with deficiency of $p47^{phox}$ have a tendency for milder disease compared with those with flavocytochrome-negative CGD. On the other hand, some patients (usually X-linked) prove to have more frequent serious infections or inflammatory complications (or both), likely because of the effects of modifier genes; these patients may warrant more aggressive treatment such as bone marrow transplantation (BMT; see later).

Several approaches can be used to prevent infections. Patients with CGD should receive all their routine immunizations on schedule (including live virus vaccines), with influenza vaccine administered each year as well. Cuts and skin abrasions should be cleansed promptly with soap and water and a topical antiseptic applied (2% hydrogen peroxide, Betadine ointment, or both). Frequent brushing, flossing, use of antibacterial mouthwash, and professional cleaning of teeth can help prevent gingivitis. Constipation should be avoided because it can lead to rectal or anal fissures and abscesses. Early anal infections can be treated with soaking in soapy water (with or without Betadine). The frequency of pulmonary infections can be reduced by not using commercially available bedside humidifiers; avoiding smoking (cigarettes and marijuana); and refraining from handling decaying plant materials (e.g., hay, mulch, rotting sawdust), which often contain numerous *Aspergillus* spp. Avoidance of construction sites, especially demolition of old buildings that may harbor fungi, is recommended. There have been clear outbreaks of *Aspergillus* pneumonias in immunosuppressed children visiting hospitals undergoing renovation.

There is clear evidence that chronic prophylactic TMP-SMX can decrease the number of bacterial infections in CGD patients by more than half without a concomitant increased risk of fungal infection. In addition, itraconazole is an effective agent for prophylaxis for fungal infections in CGD. Liver function tests should be monitored in patients receiving itraconazole.

Prophylactic rIFN-γ has been another mainstay of current management of CGD.[2,8] The clinical benefit of rIFN-γ is probably related to generally enhanced phagocyte function and killing by nonoxidative mechanisms because its use is not accompanied by any measurable improvement in NADPH oxidase activity in the vast majority of CGD patients. In the original multicenter trial, patients were randomized in a double-blind fashion to receive either placebo or rIFN-γ (0.05 mg/m^2 three times per week). As summarized in Table 48-5, there was a substantial decrease in the number of serious infections in the rIFN-γ arm. Side effects were observed in some of the patients but typically were restricted to mild fever and flulike symptoms. No additional adverse reactions, including any increased incidence of chronic inflammatory complications, have been noted with more prolonged courses of prophylactic rIFN-γ (more than 10 years), and the patients continued to have a substantial benefit with fivefold fewer serious infections compared with the placebo group in the phase III study in Table 48-5. On average, this group of patients averaged one serious infection per patient every 4 to 5 years. However, rIFN-γ is used less frequently in Europe as nonrandomized data did not suggest much benefit, and the usage in a cohort followed at the National Institutes of Health was recently reported to be only 36% because of either lack of access or because of side effects (fever, myalgia); the availability of more potent antifungals and oral antibiotics may be a mitigating factor for reducing serious infectious complications in the absence of prophylactic rIFN-γ.

Table 48-5 Efficacy of Interferon-γ in Preventing Serious Infections in Chronic Granulomatous Disease

	Clinical Study				
Variable	**Phase III Placebo***	**Phase III IFN-γ***	**Phase IV (U.S.) IFN-γ†**	**Phase IV (Europe) IFN-γ‡**	**Phase IV IFN-γ§**

One of the most frequent errors in the management of CGD patients is the failure to treat potentially serious infections promptly and aggressively with appropriate parenteral antibiotics. Even the best antibiotics can be rendered ineffective if given too late in the course of an infection in CGD. Therefore, early intervention is advisable. Although many of the minor infections and low-grade fevers in CGD patients can be managed on an outpatient basis, episodes of consistently high fever over a 24-hour period or clearly established infections (e.g., pneumonia or lymphadenitis) should be treated with parenteral antibiotics that cover, at least initially, *S. aureus* and enteric gram-negative organisms. Reasonable attempts to define the source of the infection and the responsible microbe should also begin promptly. Monitoring markers of inflammation such as the erythrocyte sedimentation rate (ESR) or C-reactive protein (CRP) can be very useful, both as a clue to the presence of a significant infection as well as following the patient's response to therapy. If the patient fails to respond, then more aggressive diagnostic procedures should be instituted (computed tomography, bone, and gallium scans; open biopsies if indicated) and empirical changes in the antibiotics used to broaden coverage to *Pseudomonas cepacia*. If fungus is identified or strongly suspected, amphotericin B has been the drug of choice in the past, but newer azole antifungal agents such as voriconazole are supplanting its use. Even with appropriate antibiotics, certain types of infections respond slowly and may require many months of therapy. Surgical drainage or resection can sometimes play a key role in accelerating healing of certain types of infection such as lymphadenitis, osteomyelitis, and abscesses of visceral organs such as the liver or lung. Finally, granulocyte transfusions may be of benefit in the treatment of stubborn or life-threatening infections.[7]

Recurrent fever in CGD always raises the possibility of infection in these patients; however, the macrophage activation syndrome (MAS)–hemophagocytic lymphohistiocytosis (HLH) spectrum of disorders should be considered, especially if the patient has splenomegaly, leukopenia, or thrombocytopenia. As in inflammatory disorders like rheumatoid arthritis, secondary MAS-HLH has been reported in CGD and is probably often overlooked. Specific treatment may be indicated, especially if the patient has significant cytopenias or evidence of hepatic dysfunction.

Use of corticosteroids should generally be avoided, including extensive topical use, except in cases of severe asthma, esophageal strictures, gastric antral narrowing, granulomatous cystitis, inflammatory bowel disease, or certain cases of pneumonia. Clear evidence shows that corticosteroids are beneficial in these clinical settings because the steroids induce rapid regression of obstructive symptoms at low oral doses (e.g., 1 mg/kg/day of prednisone). Steroids can be lifesaving in young children with airway obstruction because of inflammation. Because of the exaggerated inflammatory reaction seen in CGD, there can be significant swelling in the airway and compression by pulmonary nodes that can block air movement and impede drainage. In these cases, the physician and patient should be aware of the risks of the additional immunosuppression caused by the corticosteroids.

Rare patients with X91° CGD have genomic deletions that span the $gp91^{phox}$ gene and the Xk gene, which encodes a membrane protein necessary for expression of the Kell genes.[2] Absence of the Xk gene product results in the McLeod syndrome, in which red blood cells have weak Kell antigens and variable acanthocytosis along with nerve and muscle disorders related to its expression in nonerythroid tissues. Transfusion of patients with McLeod syndrome poses a serious problem because they can develop alloantibodies of wide specificity that can preclude any further transfusions except with Kell-negative blood products. McLeod-matched blood is extremely rare, and patients with this syndrome should have their own blood frozen in case it is needed. Note that use of maternal blood does not solve the problem because only 50% of the mother's blood will match. Because of the difficulty in finding blood, transfusion with non-McLeod blood is likely to occur. Although management is difficult and use of steroids is necessary, the hemolytic anemia can be managed successfully.

Allogeneic BMT can be used to treat CGD, including using matched unrelated donors.[6,8] Because of the risks associated with this procedure, BMT had generally considered only for patients who have a fully human leukocyte antigen–matched sibling and frequent and severe infections despite aggressive medical management. However, reduced-intensity conditioning regimens for allogeneic transplantations have now been successfully used for BMT in CGD, including several cases with ongoing fungal infections.[6,8] Despite improved success rates and decreased complications, which patients with CGD should undergo transplantation remains an individualized decision, particularly for those with residual NADPH oxidase activity and little or no history of serious infection or other complications.[8] Finally, genetic therapies aimed at correcting the defective gene in bone marrow (BM) stem cells hold promise for the future if obstacles can be solved to achieve effective and safe gene delivery and their transplantation.[6] Observations on female carriers of X-linked CGD with skewed X-inactivation and preclinical studies in murine CGD models suggest that complete correction of NADPH oxidase activity in 10% of circulating neutrophils will lead to clinically relevant improvements in host defense.

Neutrophil Glucose-6-Phosphate Dehydrogenase Deficiency

NADPH, the primary substrate for the respiratory burst oxidase, is generated by the first two reactions of the hexose monophosphate shunt pathway, which are catalyzed by G6PD (see Fig. 48-3, reaction 8) and 6-phosphogluconate dehydrogenase (6PGD).[15] The leukocyte and erythrocyte G6PD are encoded by the same gene. Thus, a severe deficiency of G6PD in neutrophils can result in a greatly attenuated respiratory burst because of low levels of NADPH. However, the vast majority of individuals with inherited G6PD deficiency do not have problems with a decreased respiratory burst or recurrent infections. A CGD-like syndrome has very rarely been observed in G6PD-deficient patients who have congenital nonspherocytic hemolytic anemia (CNSHA), in whom hemolysis occurs in the absence of redox stress.[2,15] Even in CNSHA, most G6PD mutations cause the enzyme to decay over a period of days and weeks, so that levels in the short-lived neutrophil usually do not become critically low even in some of the most unstable G6PD variants. A few rare and poorly understood G6PD mutations that cause CNSHA are associated with extremely low (<5% of normal) levels of G6PD in the neutrophil, resulting in a deficient respiratory burst and CGD-like symptoms. The combination of chronic, severe hemolytic anemia, recurrent infections, and the laboratory demonstration of extremely low G6PD levels in neutrophils and erythrocytes serves to distinguish this disease from CGD. The treatment for neutrophil G6PD deficiency is the same as for CGD except that the efficacy of rIFN-γ has not been demonstrated in the former. The chronic hemolytic anemia is treated by supportive means, including transfusions.

Disorders of Glutathione Metabolism

As depicted in Fig. 48-3 (reaction 6), the reduced form of glutathione (GSH) serves to protect the neutrophil from the harmful effects of hydrogen peroxide on NADPH oxidase and other neutrophil proteins. Adequate intracellular levels of reduced glutathione are maintained by recycling oxidized glutathione (GSSG) to GSH by glutathione reductase (see Fig. 48-3, reaction 7) as well as by de novo synthesis of glutathione by glutathione synthetase (see Fig. 48-3, reaction 9). Severe deficiencies in either of these enzymes are extremely rare and are apparently inherited in an AR manner.[2] In the case of glutathione reductase deficiency, the respiratory burst terminates prematurely, presumably owing to the toxic effects of accumulating hydrogen peroxide on NADPH oxidase. This brief burst of O_2X91^-, however, appears to be sufficient for adequate microbial killing because the few patients reported have not had problems with recurrent infections. However, they do have a congenital hemolytic anemia during periods of oxidant stress caused by diminished levels of glutathione reductase in erythrocytes. In glutathione synthetase

deficiency, the respiratory burst proceeds normally. Patients have a severe metabolic acidosis caused by elevated levels of 5-oxoproline, which is the product of the first step in glutathione synthesis and is present in increased levels because of a lack of feedback of GSH on the synthetic pathway. Patients with glutathione synthetase deficiency also have intermittent neutropenia (perhaps caused by the acidosis) as well as oxidant-induced hemolysis. There are mild problems with recurrent infections. Therapy with vitamin E (400 IU/day) has been found to be beneficial in patients with severe glutathione synthetase deficiency with hemolysis and infections.

Myeloperoxidase Deficiency

Myeloperoxidase deficiency is the most common inherited disorder of phagocytes but is almost always asymptomatic.[16] MPO is present in azurophilic granules of neutrophils and monocytes and catalyzes the production of a potent antimicrobial agent, HOCl from chloride and hydrogen peroxide (see Fig. 48-3, reaction 4).[3,4] HOCl in turn reacts with a variety of primary and secondary amines to form chloramines, some of which can be toxic. Moreover, HOCl is capable of activating latent metalloproteinases (e.g., collagenase) and inactivating antiproteinases.

Complete MPO deficiency is seen in approximately one in 4000 individuals, and partial deficiency is even more common (one in 2000 persons). The key features of MPO deficiency are summarized in Table 48-6. The disorder is inherited in an AR manner. In the few cases reported, several different mutations have been identified, which generally appear to affect the posttranslational processing of a precursor polypeptide for MPO. Acquired forms of MPO deficiency are also seen. The gene that encodes for MPO is located on chromosome 17 at q22-q23 near the breakpoint for the 15 to 17 translocation of promyelocytic leukemia. Subpopulations of MPO-deficient cells can be seen not only in the M3 (promyelocytic) form of acute myeloid leukemia but also in the M2 and M4 forms. MPO-deficient cells are also seen in approximately 25% of patients with chronic myeloid leukemia and myelodysplastic syndromes.

One of the most curious features of MPO deficiency is the remarkable lack of clinical symptoms in affected persons, given the prediction that severe MPO deficiency would cripple important antimicrobial reactions catalyzed by HOCl. In vitro, an impressive defect in killing *Candida albicans* and hyphal forms of *Aspergillus fumigatus* is observed.[16] Bacterial killing in vitro is also abnormal in being somewhat slower than normal, but eventually it is complete. MPO-deficient mice also exhibit abnormalities in host defense against *Candida* and *Klebsiella* spp. Excessive or unusual infections in MPO-deficient patients, however, are uncommon, except for rare individuals who also have diabetes mellitus.[16] In these individuals, disseminated fungal infections (usually candidiasis) are seen.

The discrepancy between the in vitro and in vivo manifestations of MPO deficiency in most patients can be explained in several ways. First, the respiratory burst in MPO-deficient neutrophils is substantially augmented, presumably from the absence of HOCl-mediated toxic effects on the NADPH oxidase. Second, other products of the respiratory burst, together with the oxygen-independent antibacterial proteins, appear to have sufficient potency to compensate for the loss of MPO-dependent reactions. Finally, residual amounts of MPO coupled with the normal levels of eosinophil peroxidase may provide at least some degree of peroxidative activity at the sites of infection.

Treatment is usually not required for MPO deficiency except in those individuals with fungal infections. In these patients, aggressive use of antifungal antibiotics is indicated. The prognosis is excellent in the majority of patients with MPO deficiency.

Table 48-6 Summary of Myeloperoxidase Deficiency

Incidence	On in 2000 (partial deficiency) On in 4000 (total deficiency)
Inheritance	Autosomal recessive with variable expression; MPO gene on chromosome 17 at q22-q23
Molecular defect	Defective posttranslational processing of an abnormal MPO precursor polypeptide; eosinophil peroxidase encoded by different gene and levels normal
Pathogenesis	Partial or complete MPO deficiency leads to diminished production of HOCl and HOCl-derived chloramines; MPO products are necessary for rapid killing of microbes (especially *Candida* spp.) but not absolutely required
Clinical manifestations	Usually clinically silent Disseminated candidiasis or fungal disease (rare; usually in conjunction with diabetes mellitus) Acquired deficiency in M2, M3, and M4 AMLs and myelodysplasia
Laboratory evaluation	Deficiency of neutrophil and monocyte peroxidase by histochemical analysis (eosinophil peroxidase normal) Delayed, but eventually normal, killing of bacteria in vitro Failure to kill *Candida albicans* and hyphal forms of *Aspergillus fumigatus* in vitro
Differential diagnosis	Acquired partial MPO deficiency seen in M2, M3, and M4 AML; MDS; and Batten disease
Therapy	None in asymptomatic patients Aggressive treatment of fungal infections when they occur Control of blood glucose levels in diabetics
Prognosis	Usually excellent

AML, Acute myeloid leukemias; *HOCl,* hypochlorous acid; *MDS,* myelodysplastic syndromes; *MPO,* myeloperoxidase.

DISORDERS OF PHAGOCYTE ADHESION AND CHEMOTAXIS

Since 1970, numerous investigators have found in vitro chemotactic abnormalities in neutrophils from patients with a wide variety of clinical disorders associated with increased susceptibility to bacterial and fungal infections.[2] In most circumstances, the chemotactic abnormality identified was only marginal and not always clearly related to the clinical status of the patient. In other instances, clear and major defects were identified in vitro that correlated with the in vivo propensity for infection. Extensive classification systems have been devised to categorize the numerous acquired defects in chemotaxis. The problem in many of these reports is that it is unclear whether the infections were caused by the in vitro chemotactic abnormality or by the medical complications of the underlying disorder (e.g., acidosis, malnutrition, or exposure to nosocomial infections). A further complicating factor is that there are inherent limitations in the in vitro chemotaxis assay, which is subject to laboratory artifacts both as a result of neutrophil purification procedures as well as the assay itself. Furthermore, the extent to which these in vitro chemotactic assay systems faithfully reflect prevailing in vivo conditions is not known. Our understanding of chemotactic disorders has been hampered by the limitations of these assays, just as the elucidation of respiratory burst defects was obscured when the major available assay was in vitro bacterial killing. In this section, the most important and best characterized of the chemotactic disorders, leukocyte adhesion deficiency (LAD), is discussed in detail. A brief discussion of several other clinically significant chemotactic disorders is also provided.

Leukocyte Adhesion Deficiency Type I

Leukocyte adhesion deficiency type I (LAD I) is a rare AR disorder of leukocyte adhesion, chemotaxis, and ingestion of C3bi-opsonized microbes as a result of decreased or absent expression of the leukocyte β_2 integrins (Table 48-7).[17,18] The hallmark of LAD I is the occurrence of repeated, often severe bacterial and fungal infections without the accumulation of pus despite persistent granulocytosis (see Table 48-7). The molecular basis for LAD was first suggested by Crowley and colleagues, who found that neutrophils from a patient with this clinical syndrome lacked a high-molecular-weight membrane glycoprotein (see Dinauer and Newburger[2]). The patient's neutrophils could not be made to adhere to plastic surfaces or to respond to serum-opsonized particles in terms of ingestion and respiratory burst activity.

The molecular basis of LAD I is now known to result from mutations in the gene for the common CD18 β2 subunit for these three leukocyte glycoproteins, now termed *β2 integrins,* that belong to the integrin superfamily of adhesion molecules. Integrins are noncovalently linked heterodimeric glycoproteins consisting of an α and a β subunit. Within each of the eight known integrin subfamilies the β subunit is identical (and defines the subfamily), but the α subunit varies and confers the functional specificity on the integrin. The molecular defect in LAD involves all members of the β2 integrin subfamily: αL β 2 (CD11a/CD18), αm β 2 (CD11b/CD18), and αx β 2 (CD11c/CD18). CD11a/CD18 is often referred to as LFA-1 while CD11b/ CD18 is also called Mac-1, Mo1, or CR3. LAD I patients have an absent, diminished, or structurally abnormal β 2 subunit (CD18) (see later), and as a result, the three types of α chains in the β 2 integrin subfamily cannot assemble into normal α-β heterodimers. Thus, all three β 2 integrins are moderately to severely deficient on all leukocytes in LAD.

Table 48-7 Summary of Leukocyte Adhesion Deficiency Type 1

Incidence	More than 60 patients described in literature
Inheritance	AR
Molecular defect	An absent, diminished, or structurally abnormal β subunit (CD18) caused by one of several types of mutations in the β gene; in the absence of a normal β subunit, the three types of α chains in the β_2 integrin subfamily (CD11a, b, c) cannot assemble into normal α-β heterodimers
Pathogenesis	All three β_2 integrins (CD11a/CD18, CD11b/CD18, and CD11c/CD18) are deficient on all leukocytes, causing multiple abnormalities in cell function: adherence; chemotaxis; and C3bi-mediated ingestion, degranulation, and respiratory burst
Clinical manifestation	Persistent granulocytosis (neutrophil count, 12,000-100,000/mm^3) Severe or moderate phenotypes depending on severity of deficiency Recurrent pyogenic infections with absent neutrophil infiltration Delayed umbilical cord separation Severe gingivitis or periodontitis
Laboratory evaluation	Flow cytometric measurement of surface CD11b in stimulated neutrophils with monoclonal anti-CD11b
Differential diagnosis	CGD May be associated with severe neutrophil actin dysfunction
Therapy	Hematopoietic stem cell transplant in clinically severe patients (CD11b < 0.3% of normal) Aggressive use of parenteral antibiotics Possible benefit of prophylactic TMP-SMX
Prognosis	Severe: high incidence of death before age 2 years unless transplantation is performed Moderate: can survive into 20s and 30s but with recurrent infections

AR, Autosomal recessive; *CGD,* chronic granulomatous disease; *TMP-SMX,* trimethoprim–sulfamethoxazole.

The β2 integrins serve as receptors for the opsonic complement fragment C3bi, the intercellular adhesion molecules 1 and 2 (ICAM-1 and ICAM-2) that are expressed on endothelial cells and leukocytes, and fibrinogen. The diminished or absent expression of β2 integrins in LAD I leukocytes results in the failure of phagocytes to emigrate from the blood stream to sites of infection. The early interactions with the endothelium, termed *rolling,* are normal in LAD I because these are mediated by a different family of adhesion molecules known as selectins. However, β2 integrins are responsible for the subsequent tight binding of neutrophils and monocytes to cytokine-activated endothelium, and this step is therefore severely defective in LAD I. Transendothelial migration is also impaired. A second major functional defect in LAD is the failure of phagocytes to bind C3bi opsonized microbes. Because CD11b/CD18 is the predominant phagocyte receptor for this complement fragment, C3bi-mediated ingestion, degranulation, and respiratory burst activity are severely affected in LAD. Finally, β2 integrin-dependent signals play a key role in activating neutrophils for enhanced migration, phagocytosis of antibody-opsonized microbes, and degranulation.

Despite in vitro defects in lymphocyte responses dependent on LFA-1 (CD11a/CD18), patients with LAD I rarely have clinical manifestations related to impaired lymphocyte function. It is believed that the role CD11a/CD18 plays in lymphoid cell function can be compensated by other adhesion proteins (CD2, CD4, CD8, and so on).

Molecular Genetics of Leukocyte Adhesion Deficiency Type I

The fact that LAD I involves a deficiency of all leukocyte β2 integrins focused attention on the common β2 chain (CD18), and mutations in the corresponding gene, *ITGB2,* have been identified in all LAD I patients who have been analyzed at the molecular level to date.[17,18] Although expression of the leukocyte integrin α subunits is normal in LAD I, these are not transported to the cell surface because the β2 chain is absent or contains mutations that disrupt its structure or its interaction with the α subunit. Mutations in the α subunits have not been found thus far in patients with LAD I. The CD18 glycoprotein has a large extracellular domain at the N terminus, a single transmembrane domain, and a 46-residue cytoplasmic tail. As with X-linked CGD, CD18 mutations in LAD I are heterogeneous in nature and family specific and can lead to either undetectable or low (9%-20% of normal) levels of α-β dimer expression that correlates with the clinical severity of the disease. More than 50 different mutations have now been characterized in more than 100 families.[17] These include missense mutations, mRNA splicing defects, small deletions, and a premature termination signal. Many patients are compound heterozygotes and have two different mutant alleles for CD18. About half of patients with LAD I in whom the genetic defect has been identified have point mutations in a stretch of 250 amino acids in the extracellular domain of CD18. This region is highly conserved among all β subunits and appears to be important for interaction with the α subunit.

Clinical Features

The key features of LAD I are summarized in Table 48-7. The clinical presentation of LAD is heterogeneous and is related to the severity of the deficiency of the β2 integrins. The severe clinical phenotype

is associated with less than 0.3% of the normal amount of these glycoproteins on the leukocyte surface; the moderate phenotype has 2.5% to 6% of normal levels. In both the severe and moderate forms of the disease, persistent granulocytosis (neutrophil count of 12,000-100,000/mm^3) is a constant finding, as are recurrent cutaneous abscesses and aggressive periodontitis and gingivitis. Additional clinical features seen more often in the severe clinical phenotype include delayed umbilical cord separation, omphalitis, perirectal cellulitis, severe ulcerative stomatitis, and bacterial sepsis. A striking finding in LAD I is that abscesses and other sites of infections are devoid of pus despite the marked neutrophilia because neutrophils are unable to emigrate to tissues. *S. aureus* and gram-negative enteric bacteria cause the majority of infections in LAD I. Fungal infections can also occur, particularly from *C. albicans* and *Aspergillus* spp.

Note that infants with delayed separation of the umbilical cord who are healthy and have normal blood counts are very unlikely to have LAD I. Although the mean age of cord separation ranges from 7 to 15 days, 10% of healthy infants can have cord separation at 3 weeks of age or later.

Diagnosis

The diagnosis of LAD I is made by flow cytometric measurement of surface CD11b (Mac1) (or the shared CD18 subunit) in unstimulated and stimulated neutrophils using commercially available monoclonal antibodies directed against CD11b or CD18 (see Fig. 48-6). Neutrophils contain an intracellular pool of CD11b/CD18 in their secondary (specific) and tertiary granules, which can be mobilized to the cell surface during stimulation. Therefore, the deficiency of CD11b can be more dramatically demonstrated by using stimulated neutrophils. Carriers of LAD I can be identified by this method because they have been found to express approximately 50% of normal levels of CD11b on the surface of their stimulated neutrophils (see Fig. 48-6).

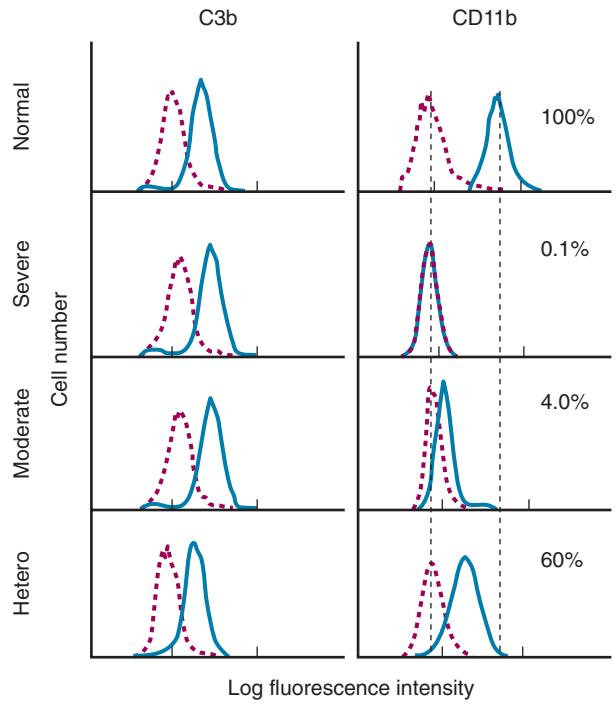

Figure 48-6 EVALUATION OF ADHESION MOLECULE EXPRESSION FOR DIAGNOSIS OF LEUKOCYTE ADHESION DEFICIENCY (LAD). Fluorescence of C3b specific antibody labeled neutrophils *(solid line)* increases compared with a nonspecific control *(dashed line)* after 30-minute exposure to 10-nM fMLP in healthy donors, subjects with severe and moderate forms of LAD-I, and a heterozygous LAD-1 carrier. However, the increase in CD11b fluorescence *(solid line)* is markedly diminished in LAD-1 patients. The respective percent of normal stimulated mean channel number is shown in the *right column*. Note that these results are expressed as percent of normal fluorescence intensity, not as percent of positive cells as is the case in most flow cytometry assays.

Prognosis and Treatment

Treatment for LAD I depends on the clinical severity of the disorder. In patients with the moderate clinical phenotype, cutaneous and oral infections can be managed as they occur. The use of prophylactic antibiotics such as TMP-SMX appears to be beneficial, as does aggressive prophylactic treatment of periodontal disease. It is important to note that even patients with the moderate phenotype can die of overwhelming infection. In patients with severe LAD I, aggressive management is indicated because of the high incidence of death before the age of 2 years, and hematopoietic stem cell transplantation is recommended. LAD I should also be amenable to gene replacement therapy in the future.

Leukocyte Adhesion Deficiency Types II and III

Leukocyte adhesion deficiency type II is a very rare clinical syndrome closely related to LAD I but caused by a defect in selectin-mediated adhesion events from a deficiency in leukocyte Siayl-Lewis X ligands.[17,18] It was first reported by Etzioni and colleagues in two unrelated boys of Muslim Arab origin and has since described in a total of five individuals (four Arab and one Turkish). The disease is inherited in an AR manner. Patients presented with neutrophilia, recurrent bacterial infections, and periodontitis, similar to LAD I, although these symptoms were generally not as severe. In addition, LAD II is associated with dysmorphic features and psychomotor retardation. LAD II neutrophils express normal levels of CD18. A clue as to the molecular cause of LAD II came from the observation that LAD II red cells were Lewis antigen negative and also had the rare Bombay (hh) erythrocyte phenotype, in which red blood cells express a nonfucosylated variant of the H antigen. These antigenic defects share in common the failure to form certain fucose carbohydrate linkage. The defect in fucose metabolism in LAD II has now been shown to result from mutations in the Golgi guanosine diphosphate–fucose membrane transporter. This leads to a generalized loss of expression of fucosylated glycans on the surface of cells, particularly the sialylated and fucosylated tetrasaccharide, SleX (CD15a), on the neutrophil surface. As a result, LAD II neutrophils are unable to bind to E- and P-selectin receptors on endothelium and therefore have an impairment in the early steps of rolling and loose binding to blood vessel walls before tight adhesion and emigration into infected tissues. Fucose supplementation has been partially successful in increasing expression of SLeX and decreasing clinical problems.

Leukocyte adhesion deficiency type III has recently been described in a handful of patients with severe, recurrent infections similar to LAD I as well as a bleeding tendency similar to Glanzmann thrombasthenia (a β3 integrin-related disorder).[17,18] This disorder results from AR defects in KINDLIN-3, a regulatory protein required for "inside-out" activation of multiple classes of integrins in blood cells. Because the clinical manifestations are typically severe, early BMT may be indicated for patients with LAD III (see Etzioni[18]).

Hyperimmunoglobulin E Syndrome

The hyperimmunoglobulin E syndrome (HIES) is a complex disorder characterized by markedly elevated serum IgE levels, serious recurrent staphylococcal infections, mucocutaneous candidiasis, chronic dermatitis, and skeletal and dental abnormalities.[19,20] Although not a primary phagocyte defect, neutrophils from patients with this syndrome exhibit a variable and at times profound chemotactic defect. HIES was first described in 1966 and was called Job

syndrome, in reference to the biblical description of Job as being affected by "sore boils from the soles of his feet unto his crown." The skin abscesses in patients with HIES lack the erythema that is typical of such lesions and are referred to as *cold abscesses*. The key features of HIES are described in Table 48-8.

Most cases of HIES result from inherited or sporadic autosomal dominant (AD) mutations in signal transducer and activator of transcription 3 (STAT3), a Janus kinase (JAK)–activated transcription factor activated in response to many cytokines and growth factors. These mutations, which are located primarily in regions of the protein that interact with other proteins or with DNA, inhibit the activity of the wild-type STAT3 allele and result in a complex pattern of altered cytokine signaling and impaired T helper type 17 (Th17) cell differentiation. Mutations in *DOCK8,* a guanine nucleotide exchange factor, or *TYK2*, a JAK family member, result in the more rare AR forms of HIES that have more profound impairments in lymphocyte function, leading to a broader risk of infection and other immune dysregulation.

Insights into how STAT3 signaling defects lead to the clinical syndrome characteristic of AD HIES are now emerging. Defective responses to IL-6 may account for the minimal inflammatory responses characteristic of HIES, and the enhanced IgE production may reflect dysregulated immune responses secondary to impaired signaling by IL-10, a negative regulator. TH17 cells are important for control of mucocutaneous *Candida* infection, which is problematic in many patients. In addition, keratinocytes and bronchial epithelial cells are particularly dependent on TH17 cytokines to produce chemokines and antimicrobial peptides, which may explain the predilection for skin and lung infections. The dental and skeletal abnormalities may be related to defective STAT3 signaling in osteoblasts and osteoclasts.

Clinical Manifestations

The clinical manifestations of HIES are at times dramatic. Onset is generally in the first 2 months of life and is manifested by chronic dermatitis. By 5 years of age, patients have a history of recurrent skin abscesses, pneumonias, chronic otitis media, and sinusitis. As patients grow older, recurrent staphylococcal pneumonia is a common problem and can be complicated by the formation of pneumatoceles. Septic arthritis, cellulitis, and osteomyelitis are also observed and are

Table 48-8 Summary of Hyperimmunoglobulin E Syndrome

Incidence	More than 200 patients reviewed in the literature
Inheritance	AD with incomplete penetrance; sporadic forms, AR (rare)
Molecular defect	Dominant-negative mutations in STAT3 (AD inheritance; sporadic), Dock8 or Tyk2 kinase (AR)
Clinical manifestations	Staphylococcal pneumonia Pneumatoceles Fungal superinfection of lung cysts "Cold" cutaneous skin abscesses and furuncles Chronic eczematoid dermatitis Mucocutaneous candidiasis Chronic cutaneous viral infections (AR) Severe allergies (AR) Coarse facies, growth retardation (AD) Osteopenia, recurrent fractures (AD) Sinusitis, keratoconjunctivitis Scoliosis (AD) Hyperextensible joints (AD) Delayed shedding of primary teeth (AD) Vascular disease (AD)
Laboratory evaluation	Serum IgE > 2,500 IU/mL Peripheral blood eosinophilia
Differential diagnosis	Atopic dermatitis Wiskott-Aldrich syndrome, DiGeorge syndrome Hypergammaglobulinemia Chronic granulomatous disease
Therapy	Prophylactic anti–*Staphylococcus aureus* antibiotics Aggressive treatment of acute infections with parenteral antibiotics Surgical drainage of deep infections and resection of lung cysts Monitor for scoliosis, fractures, vascular disease
Prognosis	Generally good if managed aggressively Some patients develop lymphoid malignancies; patients with AR HIES have an increased risk and broader spectrum of cancer susceptibility

AD, Autosomal dominant; *AR,* autosomal recessive; *HIES,* hyperimmunoglobulin E syndrome; *IgE,* immunoglobulin E.

Diagnosis of Chemotactic Disorders

The direct measurement of neutrophil chemotaxis in a clinical setting is very difficult and requires a specialized research laboratory. Because the assays are biologic assays, the laboratory must run the tests at least monthly to maintain competence and have acceptable normal ranges. Neutrophil chemotaxis is significantly affected by inflammation, complement activation, and medications, making it very difficult, especially in a patient with infection, to determine if the infection is attributable to a chemotactic defect or if the defect is attributable to the infection. This is further complicated by the fact that inflammation activates the neutrophils and affects which populations actually come off of the density gradients required to separate the cells for assay. Unlike the respiratory burst, chemotaxis must be done on fresh cells, so samples cannot be reliably shipped.

The neutrophils from patients with primary chemotactic defects have almost no motility in standard biologic assay systems. Some chemotactic disorders can be diagnosed by assays of other characteristic features.

LAD-1

- LAD-1 has a significant chemotactic defect as well as phagocytic defect and is characterized by leukocytosis. The diagnosis can be made by flow cytometry of the CD11b complex on the surface.
- Fig. 48-6 indicates surface expression of C3b and CD11b on neutrophils. C3b is used as a positive control and is normal in LAD1. With stimulation, CD11b increases *(top panel).*
- The results in this assay are expressed as percent of normal stimulated control mean channel number. It is important to note that this is not the percent positive cell, as is the case for most flow cytometry assays.
- Severe LAD1 has no increase with stimulation.
- Moderate LAD1 shows some shift of fluorescence with stimulation.
- Genetic analysis for this disorder is clinically available.

Other chemotactic disorders: Genetic analysis is available for several primary neutrophil defects, and this approach should be pursued before attempting assay of chemotaxis in a clinical setting.

No other primary chemotactic defects are readily diagnosed by a routine clinical laboratory. Measurement of neutrophil chemotaxis itself to look for secondary defects for any kind of clinical decision making is difficult if not impossible to interpret.

usually caused by *S. aureus,* although other bacterial pathogens have also been found. Patients can have chronic mucocutaneous candidiasis and occasionally exhibit keratoconjunctivitis, sometimes complicated by corneal scarring. One feature noted in the majority of patients by the time they reach the teenage years is the presence of coarse facial features (broad nasal bridge, prominent nose). Dental and bone abnormalities are also common features of HIES. Delayed or failure to shed primary teeth occur in the majority. Hyperextensible joints and scoliosis are frequent. Osteopenia of unknown etiology is observed in most patients, and there is an increased risk of fractures to the long bones and vertebral bodies even in the absence of osteopenia. Vascular disease, including aneurysms, tortuosity of middle-sized arteries, and hypertension is also frequently seen.

Patients with the AR form of HIES, the majority of whom have defects *DOCK8,* which is also referred to as *DOCK8* immunodeficiency syndrome, also have recurrent sinopulmonary infections, skin abscesses, and dermatitis, with the latter often the first symptom and developing in infancy. Unlike AD HIES, patients with *DOCK8* defects can develop asthma; severe allergies, including to foods, and chronic cutaneous viral infections with human papilloma virus, molluscum contagiosum virus, and herpes family viruses is a distinctive feature seen in approximately 90% of patients. These patients are also at high risk for a variety of malignancies in late childhood to early adulthood, believed to be caused by loss of immune surveillance for tumors.[19] AR HIES patients do not have the nonimmunologic skeletal and dental abnormalities characteristic of AD HIES.

Diagnosis

The diagnosis of HIES should be entertained in any child or young adult who has the above-described clinical picture or simply a history of recurrent infections. The hallmark laboratory finding is a marked elevation of serum immunoglobulin E (IgE), almost always greater than 2500 IU/mL. Levels can be as high as 150,000 IU/mL. Most patients also have peripheral eosinophilia. However, there is no correlation of clinical disease activity with the level of either IgE or peripheral eosinophilia. Atopic dermatitis is the major differential diagnosis because comparably high serum levels of IgE can be seen in patients in this disorder, as well as superficial skin infections. The severe and recurrent nature of the staphylococcal furuncles and pneumonias usually seen in HIES can help distinguish these patients from those with atopic dermatitis. Patients with other primary immunodeficiency syndromes may also manifest elevated IgE levels. Scoring criteria predictive of STAT3 mutations, including recurrent pneumonia, pathologic bone fractures, and lack of Th17 cells, are helpful.[19] DNA testing should be used to make a definitive diagnosis.

Therapy

The therapy for AD HIES is largely supportive.[19] Prophylactic antibiotics (e.g., dicloxacillin or TMP-SMX) can be effective in preventing *S. aureus* infections. Dermatitis can be treated with topical steroids. Bathing in diluted bleach can diminish colonization by *S. aureus.* Prophylactic antifungals can be helpful in patients with chronic mucocutaneous candidiasis. Intravenous antibiotics are used for deep-seated infections or for resistant cutaneous infections. Surgical resection of persistent pneumatoceles is sometimes indicated to prevent superinfection by fungal and gram-negative organisms. Intravenous Ig infusions have shown some success in the management of HIES. Attention should also be paid to blood pressure and other vascular complications. Although a role for hematopoietic stem cell transplantation in AD HIES is unclear, two children with STAT3 mutations who underwent transplantation for non-Hodgkin lymphoma are alive 10 and 14 years later with resolution of all immunologic and nonimmunologic features of HIES.[20] Patients with AR HIES may need prophylaxis for viral infections, and hematopoietic stem cell transplant may be a consideration in selected patients.

Miscellaneous Chemotactic Disorders

It is extremely rare to have primary defects in neutrophil actin polymerization as a cause of abnormal chemotaxis and recurrent infections.[1,2] In one case, neutrophils had diminished actin polymerization, chemotaxis, and phagocytosis of serum opsonized particles. Family members had decreased CD11b/CD18 expression and a partial decrease in actin polymerization, which suggested that this disorder might be a variant of LAD I; however, no similar cases have otherwise been described. An apparent AR disorder of actin polymerization has been described in a male infant of Tongan descent who presented with severe skin infections, recurrent pulmonary infiltrates, thrombocytopenia, and invasive *Candida tropicalis* infection. Neutrophil actin polymerization was markedly abnormal and associated with increased expression of an actin binding protein. Finally, a heterozygous point mutation in β-actin affecting binding to actin-regulatory proteins was discovered in a female patient with recurrent infections, photosensitivity, and mental retardation. Neutrophils had a marked impairment in chemotaxis and in the formyl peptide-induced respiratory burst.

A new syndrome of severe neutrophil dysfunction caused by a dominant-negative mutation in Rac2, a small GTPase expressed in blood cells that acts in many signal transduction pathways, was recently described in an infant boy born to unrelated parents (see Dinauer and Newburger [2]). This baby presented with rapidly progressive and deep-seated soft tissue infections, along with neutrophilia and poor formation of pus but normal expression of β2 integrins and fucosylated proteins. Neutrophils had marked defects in actin polymerization, chemotaxis, degranulation, and the respiratory burst in response to chemoattractants. Neutrophil responses to other agonists were normal, suggesting that the dominant negative Rac2 mutation produces a selective intracellular signaling defect.

Localized juvenile periodontitis (LJP) is a heterogeneous disorder of unknown etiology characterized by chronic and recurrent periodontal infections and severe alveolar bone loss with onset at the time of puberty.[21] Many patients with LJP have been reported to have defective neutrophil chemotaxis in vitro. At present, it appears that LJP is an acquired disorder in some patients and a genetic disorder in others. It may also be a combination of both in certain patients because they may inherit an unusual sensitivity to the chemotactic inhibitors released by certain periodontal microorganisms. The diagnosis of the disorder is made on the basis of severe periodontal disease and destructive alveolar bone loss involving the first molars and incisors developing during adolescence. It is important to note that many qualitative and quantitative neutrophil disorders are also associated with severe periodontal disease. Therefore, the differential diagnosis should include neutropenia (both chronic and cyclic), LAD, CGD, and Chédiak-Higashi syndrome (CHS).

One of the most consistently observed chemotactic abnormalities is seen in neonatal neutrophils.[22] These cells exhibit impaired chemotaxis in vitro in response to a wide variety of chemotactic factors. It appears as though this abnormality is caused, at least in part, by defects in cellular adhesion as a result of diminished mobilization of intracellular adhesion-promoting molecules to the cell surface. Defective neutrophil chemotaxis can be seen in normal neonates between birth and 5 days of age. In severely ill infants, the defect may persist for a longer time.

DEFECTS IN THE STRUCTURE AND FUNCTION OF LYSOSOMAL GRANULES

Two major disorders of neutrophil granules have been described, CHS and specific granule deficiency (SGD). A great deal has been learned about the structural and functional abnormalities of neutrophils from patients with these conditions. Although rare, these disorders are also obligatory components in the differential diagnosis for any patient with recurrent bacterial and fungal infections.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is a rare AR, multisystem disease resulting from widespread defects in granule morphogenesis, with giant lysosomes in leukocytes and other cells throughout the body.[23,24] The disorder is characterized by partial oculocutaneous albinism, frequent (and sometimes fatal) bacterial infections, a mild bleeding diathesis, and peripheral as well as cranial neuropathies associated with defects at the optic chiasm. Those who survive the recurrent infections develop an "accelerated phase" of the disease; one of the hereditary forms of HLH, which, if untreated, is eventually fatal because of a profound pancytopenia that develops.

The most dramatic granule defects are manifested in the various blood cells. Neutrophils contain a highly inhomogeneous population of huge granules derived from coalescence of azurophilic (primary) granules. The giant granules are often more prominent in the BM than in the peripheral blood because many of the abnormal myeloid precursors are apparently destroyed before they leave the BM, resulting in moderate neutropenia with absolute neutrophil counts ranging from 500 to 2000 cells/mm^3. Granules are also markedly deficient in antimicrobial granule enzymes such as cathepsin G and elastase, consistent with a defect in granule morphogenesis. Degranulation is delayed and incomplete in Chédiak-Higashi neutrophils, resulting in impaired bacterial killing. Chemotaxis is also defective, perhaps related to poor deformability because of the presence of the large granules. Monocytes and macrophages exhibit similar giant cytoplasmic granules, with resultant abnormalities in their phagocytic functions. Giant granules are also seen in lymphocytes and are associated with defects in cytotoxic T-lymphocyte and NK cell function. Eosinophils contain large granules, the functional significance of which is not known. Platelets in this disorder have a storage pool deficiency of adenosine diphosphate and serotonin, presumably caused by the abnormal granule morphogenesis in megakaryocytes, leading to a defect in platelet aggregation.

Abnormal giant granules are also present in other cell types. These include melanocytes, which contain abnormal melanosomes that cannot transfer their contents to adjacent keratinocytes; Schwann cells; astrocytes; and certain cells in the liver, spleen, pancreas, gastric mucosa, kidney, adrenal gland, and pituitary gland.

Table 48-9 Summary of Chédiak-Higashi Syndrome

Incidence	More than 200 cases described
Inheritance	AR
Molecular defect	A defect in granule morphogenesis in multiple tissues resulting from mutations in the *CHS1 (LYST)* gene encoding a lysosomal trafficking regulator protein
Pathogenesis	Giant coalesced azurophil granules in neutrophils, resulting in ineffective granulopoiesis and neutropenia, delayed and incomplete degranulation, and defective chemotaxis; abnormal granules in other cells (NK cells, cytotoxic T cells, platelets, melanocytes, neurons)
Clinical manifestations	Partial oculocutaneous albinism Recurrent severe bacterial infections (usually *Staphylococcus aureus*) Cranial and peripheral neuropathies (muscle weakness, ataxia, sensory loss) HLH (accelerated phase)
Laboratory evaluation	Giant granules in peripheral blood granulocytes and in BM myeloid progenitor cells Widespread lymphohistiocytic infiltrates in accelerated phase
Differential diagnosis	Other genetic forms of partial albinism Giant granules can be seen in acute and CMLs
Therapy	Prophylactic TMP-SMX Parenteral antibiotics for acute infections Ascorbic acid (200 mg/day for infants; 6 g/day for adults) HSCT before or at beginning of HLH
Prognosis	Most patients die from infection or complications of HLH during the first or second decade of life unless transplantation is performed

AR, Autosomal recessive; *BM,* bone marrow; *CML,* chronic myeloid leukemia; *HLH,* hemophagocytic lymphohistiocytosis; *HSCT,* hematopoietic stem cell transplant; *NK,* natural killer; *TMP-SMX,* trimethoprim–sulfamethoxazole.

Molecular Genetics

A gene termed *CHS1* or *LYST* (for its presumed function as a lysosomal trafficking regulatory protein) affected in the majority of CHS cases has recently been identified and is on the long arm of chromosome 1.[24] The encoded protein is very large (3801 amino acids); its specific function is unknown, but recent studies suggest that it may inhibit lysosome fusion with other intracellular membrane vesicles. A variety of frameshift and nonsense mutations that predict synthesis of truncated forms of the protein have been identified in most, but not all, CHS patients studied to date. There is no correlation between the length of the truncated CHS1 protein and the severity of the disease. Disorders similar to human CHS have also been described in many mammalian species, including Aleutian mink, *beige* mice, blue foxes, cats, killer whales, and Hereford cattle. Identification of the human CHS1 gene was aided by positional cloning of the mouse *lyst* homolog affected in *beige* mice.

Clinical Manifestations

The key features of CHS are summarized in Table 48-9. The disease usually presents in infancy or early childhood, with infections involving the lungs, skin, and mucous membranes being most commonly encountered. Dental caries and periodontal disease are also common. The most frequent offending organism is *S. aureus*. Gram-negative bacteria, *Aspergillus* spp. and *Candida* spp. also are responsible for many infections. Platelet granule defects result in easy bruising and epistaxis. There is partial oculocutaneous albinism and photosensitivity. Patients may have a white forelock or an ashen or grayish silver sheen to the hair, which can vary from blond to dark brown. In younger patients, there may be a cartwheel distribution of pigment in the iris and an abnormal red reflex. Neurologic manifestations include peripheral or cranial neuropathies, gait abnormalities, muscle weakness, sensory loss, seizures, or spinocerebellar degeneration. Neurologic symptoms worsen with age.

Approximately 85% of children surviving into the second decade of life develop an accelerated phase of the disease, with fever, lymphadenopathy, and progressive pancytopenia, that is now recognized to be a genetic form of HLH caused by impaired lymphocyte and NK cell function.[25] The development of HLH can sometimes be precipitated by Epstein-Barr virus infection. A reactive-appearing lymphohistiocytic proliferation occurs in the liver, spleen, lymph nodes, and BM, and the prognosis is uniformly fatal unless patients undergo BMT.

Diagnosis

The diagnosis of CHS is made on the basis of the giant peroxidase-positive lysosomal granules in the peripheral blood granulocytes or in BM myeloid cells. Identification of large, acid phosphatase–positive lysosomes in amniocytes and chorionic villus cells has been used to diagnose CHS prenatally. Other clinical features characteristic of CHS can support the diagnosis, including mild oculocutaneous

albinism; silvery hair, in which microscopic examination reveals giant melanin granules; and a bleeding diathesis. The development of HLH is characterized by diffuse infiltrates of lymphohistiocytic cells seen on biopsy and by pancytopenia. Occasionally, giant granules that resemble those of CHS can be seen in both acute and chronic myelogenous leukemias.

Therapy

The treatment for the stable phase of CHS is similar to that for other neutrophil disorders. Prophylactic antibiotics such as TMP-SMX appear to be beneficial. Parenteral antibiotics are indicated for acute infections, and responses are often slow. Treatment with high-dose ascorbic acid (200 mg/day for infants; 6 g/day for adults) has been found to improve the clinical status of some patients. Although there is some controversy regarding the efficacy of ascorbic acid, given the safety of this medication, it seems prudent to administer it to all patients. The treatment of HLH (accelerated phase) includes combinations of drugs that suppress the function of activated macrophages and T cells followed by allogeneic hematopoietic stem cell transplantation.[25] Indeed, transplantation is ideally performed before or at the beginning of the accelerated phase. Note that transplantation does not prevent the progressive neuropathy of CHS.

Specific Granule Deficiency

Neutrophil SGD is an extremely rare congenital disorder characterized by recurrent bacterial and fungal infections, primarily involving the skin, ears, and lungs.[2,26] Infections are often indolent and smoldering, and *S. aureus, P. aeruginosa,* enteric gram-negative bacteria, and *C. albicans* are the major pathogens. Family studies suggest that it is inherited in an AR manner. Neutrophils from patients with SGD have atypical bilobed nuclei, absent specific granules, and multiple deficiencies of secondary and tertiary granule mRNAs and proteins, including lactoferrin, vitamin B_{12}-binding protein and gelatinase B; although azurophil granules in this disorder are present and contain MPO and lysozyme, they are markedly deficient in defensins. Monocytes display cell surface and functional defects, eosinophils lack eosinophil-specific granule proteins such as eosinophil cationic protein and platelets have abnormal α granules, suggesting that the underlying defect may be related to regulation of the synthesis of certain granule and membrane proteins. This defect in synthesis is confined to BM-derived cells because lactoferrin secretion is normal in the glandular epithelia of SGD patients despite the severe deficiency in the neutrophils.

The recurrent skin and pulmonary infections characteristic of SGD appear to be caused by two fundamental defects in the neutrophils. One defect is the marked deficiency of at least two important microbicidal granule proteins, lactoferrin and defensins. The other defect is a relatively severe chemotactic abnormality presumably caused by the absence of the intracellular pool of leukocyte adhesion molecules that normally reside in the specific granules. As discussed earlier, these β2 integrins play a key role in phagocyte chemotaxis.

The molecular defect responsible for most cases of SGD has recently been shown to involve a myeloid transcription factor known as C/EBPε that regulates expression of certain genes activated during granulocyte differentiation.[2,26] This came about serendipitously when it was recognized that mice with a targeted deletion in the C/EBPε gene characteristics similar to those of SGD patients, including neutrophils with bilobed nuclei, absent secondary granules, and impaired chemotaxis along with increased susceptibility to bacterial infections. To date, mutations in the C/EBPε gene have been identified in two SGD patients that encode truncated, nonfunctional proteins. However, DNA sequencing of the C/EBPε gene of several other SGD patients has not revealed abnormalities, suggesting that SGD is a genetically heterogeneous disorder.

The diagnosis of SGD can be readily made by microscopic examination. Wright-stained neutrophils are devoid of specific granules but contain normal numbers of azurophilic granules. Electron microscopy reveals small peroxidase-negative vesicles, which presumably represent empty specific granules. The diagnosis of SGD can also be established by demonstrating a severe deficiency in either lactoferrin or vitamin B_{12}-binding protein. An acquired form of SGD can be seen in burn patients or in individuals with various myeloproliferative disorders. The treatment for SGD is similar to that for other neutrophil disorders. If medical management is aggressive, the prognosis appears quite good, with patients surviving into their adult years.

MISCELLANEOUS INHERITED AND AQUIRED DISORDERS OF PHAGOCYTE FUNCTION

Rare inherited defects in phagocyte production or response to inflammatory cytokines are manifested as recurrent infections.[27,28] HIES also falls into this category (see earlier discussion). A distinctive group of disorders referred to as *Mendelian susceptibility to mycobacterial diseases* (MSMD) involve inherited defects in macrophage IL-12/23–dependent IFN-γ–mediated immunity. Macrophage production of IL-12 and IL-23 after ingestion of mycobacteria triggers IFN-γ production by T and NK lymphocytes, which in turn activates crucial genes in macrophages. MSDM (MIM 20990) can be caused by inherited AR, AD, or X-linked defects leading to impaired T-cell production of IFN-γ, expression of the IFN-γ receptor, or downstream signaling, which results in a spectrum of recurrent and severe atypical mycobacterial infections, as well as susceptibility to *Salmonella* and, in some subgroups, viral infections.[27,28] A variety of genetic defects in a scaffolding protein known as IKK-γ or NEMO that is important for activation of the nuclear factor kappa-B (NFκB) signaling pathway have been reported in patients with anhydrotic ectodermal dysplasia and immunodeficiency; affected children have recurrent pyogenic infections with a minimal systemic inflammatory response and can also develop opportunistic infections with atypical mycobacteria or *Pneumocystis carinii.*[28] Several other kindreds have been described with genetic deficiency of another protein, IRAK-4, important for NFκB activation by pyogenic bacteria via the Toll-like receptor/IL-I receptor superfamily. Affected children also had recurrent infections with *S. pneumonia* and *S. aureus* and a poor inflammatory response but no dysmorphic features or opportunistic infections.

Patients with glycogen storage disease type Ib (GSD-Ib), which results from absence of a glucose-6-phosphate transporter, have impaired neutrophil functions and neutropenia.[29] Neutrophil defects include depressed chemotaxis, phagocytosis, and NADPH oxidase activity. Although neutropenia appears to result from increased neutrophil apoptosis, how impaired glucose homeostasis leads to abnormal neutrophil function is uncertain. Interestingly, the BM in the face of neutropenia shows marked hypercellularity with increased mature neutrophils in some patients. The neutrophil count increases within hours of granulocyte colony-stimulating factor (G-CSF) administration, suggesting it is acting in part by releasing neutrophils from the BM. GSD-Ib patients can have infections as well as inflammatory bowel disease. Therefore, in addition to management of the metabolic disruption, these patients are also often treated with G-CSF to improve neutropenia.

There are a variety of noncongenital defects in phagocyte function that can be associated with an increased risk of bacterial or fungal infection. Several have already been mentioned, including neonatal neutrophil dysfunction manifested as poor adhesion and chemotaxis. Patients with myelodysplastic syndromes and acute nonlymphoblastic lymphoma can have subpopulations of neutrophils variably defective in adhesion, migration, production of reactive oxidants, and microbicidal activity that has correlated with an increased risk of infection. Similar defects have been described in diabetes mellitus, Gaucher disease, and renal failure. Severe bacterial infections, surgical trauma, and severe burns can also result in transient depression of a variety of neutrophil functions. The underlying mechanism(s) are incompletely defined and may be related to effects of high levels of inflammatory mediators produced in response to infection or trauma or to products released by bacteria.

Management of Infections

The management of infections in patients with primary neutrophil dysfunction syndromes is quite different than in the normal population and for the most part different from patients with neutropenias.

- Patients tend to present with relatively low fevers and chronic inflammatory processes associated with marked elevation of ESR and CRP. Unless they have untreated abscesses or inflammatory masses, they tend not to present with frank sepsis and positive blood cultures.
- The frequency of infections decreases somewhat with age in children as their normal T and B cell-mediated immunity develops.
- Although one should always attempt to obtain culture proof of an infection, more often than not, it is not possible to identify an organism, and it is necessary to treat empirically.
- Because these patients tend to develop deep seated tissue infections, the ESR can be of great value even though it is quite nonspecific. Elevation in the ESR suggests deep tissue inflammation; CRP is more acute and suggests monocyte activation. Persistent significant elevation of the ESR (>15-20 mm/hr) even in the absence of fever or other symptoms may warrant radiologic search for deep-seated infection.
- The authors advocate an "antibiotic sensitivity by ESR response" approach to empiric therapy in stable patients. One can start at parenteral anti-staphylococcus and gram-negative therapy and monitor the ESR daily. A monotonic decrease in the ESR within several days that is clear-cut suggests the process is sensitive to the antibiotic selected. Although complete resolution of inflammatory response may take many weeks, usually there is some clear change in the ESR within 1 week. If there is worsening or no clear response, then an antifungal can be added and the ESR monitored in the same fashion. Return of an elevated ESR can be a sign of development of organism resistance.
- If a patient with CGD is particularly ill appearing or febrile, it is important to make sure that *B. cepacia* complex bacteria are covered.
- There is no fixed duration of therapy for any infections in these patients. If the infections are not completely extinguished, they will return and will contribute to development of chronic pulmonary and hepatic fibrosis. Parenteral antibiotics or antibiotics that can deliver very high tissue levels should be continued significantly past normalization of the ESR and disappearance of any radiographic evidence of deep tissue infection. This can take many months for some pneumonias and liver abscesses.
- Short pulses of steroids (4-6 days) can be lifesaving, particularly for pulmonary infections in young children with CGD. They reduce airway inflammation and promote drainage.
- Young children are susceptible to infections with routine childhood viruses and infections and tend to do well with standard therapeutic approaches and courses of treatment that are 2 to 3 times longer than the usual recommended course. Again, monitoring with the ESR can be a guide.
- All standard childhood immunizations and influenza vaccinations are strongly recommended. Prophylactic antibiotics may be appropriate (see text).

CHAPTER 49

CONGENITAL DISORDERS OF LYMPHOCYTE FUNCTION

Sung-Yun Pai and Luigi D. Notarangelo

More than 150 molecular defects that result in impairment of T- and B-cell development or function have been identified in the past several decades. Although the existence of the most severe disorders, such as severe combined immunodeficiency (SCID) and Wiskott-Aldrich syndrome (WAS), was known since the 1930s and 1950s, the definition of the genes responsible for primary immunodeficiencies (PIDs) has occurred mostly in the past 2 decades. Moreover, characterization of the molecular basis of these diseases has also revealed unanticipated heterogeneity of the clinical and immunologic phenotype. The study of patients with PIDs has illustrated the critical role played by many of these genes for immune system development and function. This chapter reviews disorders of thymus organogenesis, SCID, other combined immunodeficiencies and disorders of T-cell regulation, and disorders of humoral immunity.

DEFECTS OF THYMUS ORGANOGENESIS

The thymus is the primary organ where T lymphocytes are generated and educated. Endoderm-derived thymic stem cells derived from the third pharyngeal pouch differentiate into cortical and medullary epithelial cells, which in turn induce the differentiation of hematopoietic precursors into T cells. Thus defects of thymus organogenesis have important consequences on immune function.

DiGeorge Syndrome

DiGeorge syndrome (DGS) is attributable to developmental anomalies of the third and fourth pharyngeal pouches and is characterized by thymic hypoplasia, hypoparathyroidism, conotruncal heart malformations, and facial dysmorphisms.

Between 50% and 90% of patients with DGS carry a hemizygous deletion of chromosome 22q11, which occurs in about one in 3000 newborns, most arising de novo. More rarely, DGS is associated with CHARGE (coloboma of the eye, heart defects, atresia of the nasal choanae, retardation of growth or development, genital or urinary abnormalities, and ear abnormalities and deafness) syndrome; chromosome 10p deletion; or mutations of the *TBX1* gene, contained within the 22q11 interval.

Typical cases of DGS are diagnosed at birth because of the association of heart defect (especially interrupted aortic arch type B or truncus arteriosus) with hypocalcemic seizures. Micrognathia, hypertelorism, an antimongoloid slant of the eyes, cleft palate, and ear malformations are also common. Feeding problems, microcephaly, speech delay, neurobehavioral problems (including bipolar disorders, autistic spectrum disorders, and schizophrenia later in life), and scoliosis are frequently observed. Fluorescent in situ hybridization (FISH) readily identifies the 22q11del in most cases.

Immunologic investigations should include analysis of T-lymphocyte subsets and function. Most patients have "partial DGS," manifested by mild T-cell lymphopenia and immunodeficiency. Such patients may be asymptomatic; may have oral thrush and recurrent infections; or may develop autoimmune disease such as juvenile idiopathic arthritis, immune thrombocytopenic purpura, and Raynaud phenomenon. Approximately 1% of DGS patients have "complete DGS" with absence of circulating T cells. Some DGS patients may develop few oligoclonal T lymphocytes that undergo activation in vivo and infiltrate target tissues, causing skin rash, liver dysfunction, and lymphadenopathy. This condition is known as "complete atypical DGS."

Treatment of DGS includes correction of severe heart defects and supplementation with calcium and vitamin D for hypocalcemia. If a significant immune defect is present, prophylaxis against *Pneumocystis jiroveci* pneumonia with trimethoprim–sulfamethoxazole (TMP-SMZ) is indicated. Live-attenuated vaccines can be safely administered to patients with partial DGS who have good cellular immunity (with $CD8^+$ count >300 cells/μL); however, these vaccines are contraindicated in patients with complete DGS. Use of immunosuppressive drugs is indicated in patients with the complete atypical form of the disease.

Ultimately, survival in patients with complete DGS requires immune reconstitution. Bone marrow transplantation from human leukocyte antigen (HLA)–identical donors may allow engraftment of mature T cells contained in the graft. However, because of the absence of thymic tissue, no newly developed T cells are generated, and the patient may remain susceptible to pathogens that are not recognized by donor-derived T cells contained in the graft.

By contrast, thymic transplantation represents the treatment of choice for patients with complete DGS, including the atypical variant. The thymus is obtained as discarded tissue from unrelated infants undergoing heart surgery. It is sliced and cultured in vitro; sterility and viability tests are performed before implanting the thymus slices in the quadriceps muscles of the infant. Using this approach, 36 of 50 infants with complete DGS treated by Markert at Duke University were reported to survive. In most cases, naive T cells appear at around 4 to 7 months; these cells are tolerant to donor thymic cells, display a polyclonal repertoire, and have normal proliferative capacity. Although the number of $CD3^+$ T cells in transplanted patients often remains lower than normal, their diversity and function are sufficient to prevent life-threatening infections.

FOXN1 Deficiency

The transcription factor FOXN1 (whose gene is mutated in the *nude* mouse) plays a critical role in thymus and eccrine glands development. *FOXN1* mutations in humans cause athymia, profound T-cell lymphopenia, alopecia totalis, and nail dystrophy. Similar to DGS, reconstitution of T-cell immunity can be achieved with thymic transplantation.

SEVERE COMBINED IMMUNODEFICIENCY CAUSED BY EARLY DEFECTS IN T-LYMPHOCYTE DEVELOPMENT

Severe combined immunodeficiency includes a heterogeneous group of genetic disorders that affect development of T, and in some cases also of B or natural killer (NK) lymphocytes. The presence or absence of the main lymphocyte subsets serves as the basis for SCID classification. The frequency of SCID is estimated to be one in 50,000 to one in 100,000 live births.

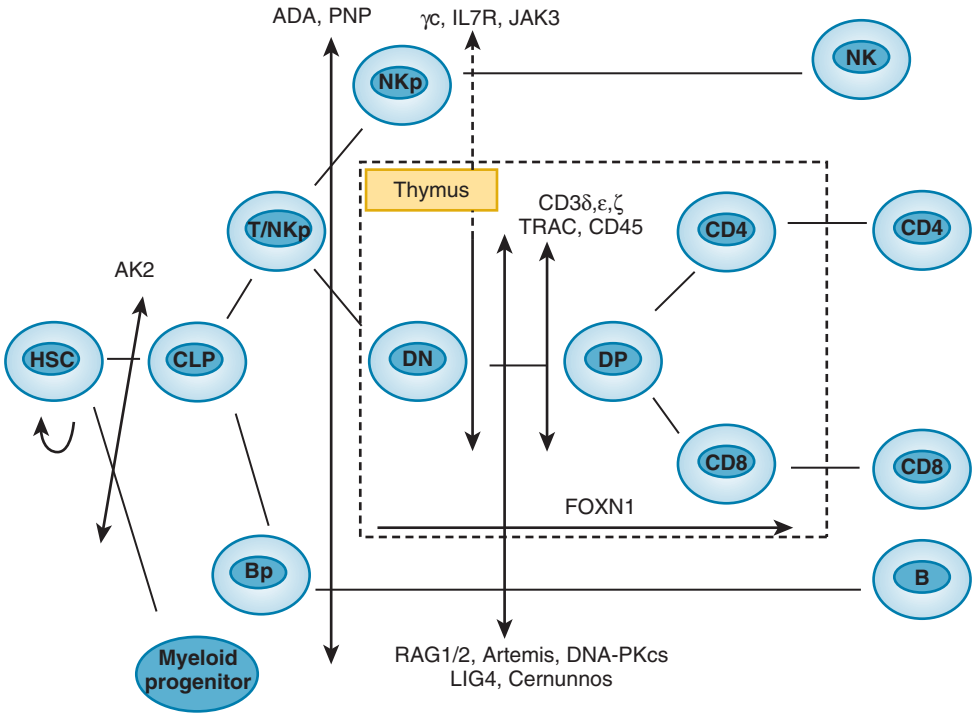

Figure 49-1 GENETIC DEFECTS ASSOCIATED WITH SEVERE COMBINED IMMUNODEFICIENCY (SCID). Schematic representation of blocks *(arrows)* in lymphoid development associated with genetic defects responsible for SCID. *Dashed line* indicates that generation of natural killer (NK) lymphocytes is compromised in γc and Janus-activated kinase 3 (JAK3) deficiency but not in interleukin-7 receptor (IL7R) deficiency. *ADA,* Adenosine deaminase; *AK2,* adenylate kinase 2; *Bp,* B-cell progenitor; *CLP,* common lymphoid progenitor; *DN,* double-negative thymocyte; *DNA-PKcs,* DNA protein kinase catalytic subunit; *DP,* double-positive thymocyte; *γc,* common gamma chain; *HSC,* hematopoietic stem cells; *LIG4,* DNA ligase IV; *NKp,* natural killer cell progenitor cell; *PNP,* purine nucleoside phosphorylase; *RAG,* recombinase activating gene; *T/NKp,* common progenitor of T and NK lymphocytes; *TRAC,* T-cell receptor α constant chain.

Pathobiology and Genetics

Genetic defects that cause SCID affect various stages in T-cell development (Fig. 49-1) and can be grouped in three major categories: (1) defects in cytokine receptor signaling, (2) defects in lymphocyte survival, and (3) defects of expression and function of the pre–T-cell receptor (TCR).

Cytokine Receptor Signaling Defects

The most common form of SCID in humans is the X-linked form caused by mutations of the *IL2RG* gene that encodes for the common gamma chain (γc). This protein is shared by receptors for interleukin-2 (IL-2), IL-4, IL-7, IL-9, IL-15 and IL-21 and signals through the intracellular kinase Janus-activated kinase 3 (JAK3). Patients with mutations in *IL2RG* or *JAK3* lack both T and NK cells because development of these subsets depends on IL-7– and IL-15–mediated signaling, respectively. B lymphocytes are present, but antibody production is impaired because of the lack of T cells and of defective signaling through IL-21R.

Defects in Lymphocyte Survival

Proliferation and survival of lymphoid progenitor cells are essential to permit generation of a normal number of mature lymphocytes. Some forms of SCID are associated with increased apoptosis. Adenosine deaminase (ADA) converts adenosine to inosine (and deoxyadenosine to deoxyinosine). In patients with ADA deficiency, accumulation of toxic phosphorylated derivatives of deoxyadenosine causes cell death and results in extreme lymphopenia, with virtual absence of T, B, and NK lymphocytes. Reticular dysgenesis (RD) is a form of SCID characterized by the association of severe lymphopenia, agranulocytosis, and sensorineural deafness. RD is due to defects in adenylate kinase 2 (AK2), resulting in increased apoptosis.

Defects of Expression and Signaling Through the Pre–T-Cell Receptor and the T-Cell Receptor

Rearrangement of the TCR genes by means of VDJ recombination allows expression of the pre-TCR (composed of the pre-Tα and the TCRβ chain) and of mature TCRs (either as TCRαβ or TCRγδ).

The lymphoid specific recombinase activating gene (RAG) 1 and RAG2 proteins initiate VDJ recombination by recognizing recombination-specific sequences that flank the variable (V), diversity (D) and joining (J) elements of the TCR and of immunoglobulin genes, introducing DNA double-strand breaks. These are then repaired through the ubiquitously expressed nonhomologous end-joining (NHEJ) pathway. Mutations of the *RAG1* and *RAG2* genes, and of genes that encode for Artemis, DNA ligase IV, and DNA-PKcs (all components of the NHEJ pathway), result in SCID with lack of T and B lymphocytes (Figs. 49-1 and 49-2) but a normal number of NK lymphocytes. Mutations of Cernunnos/XLF, another component of the NHEJ pathway, severely impair but do not completely abrogate T- and B-cell development. Because NHEJ is involved in general mechanisms of DNA repair also in nonlymphoid cells, patients with defects of this pathway also show increased cellular radiation sensitivity, are at higher risk of tumors, and may present with neurological problems.

Signaling through the pre-TCR is essential to promote progression from $CD4^-$ $CD8^-$ double-negative (DN) thymocytes to $CD4^+$ $CD8^+$ double-positive (DP) cells and is mediated by the CD3

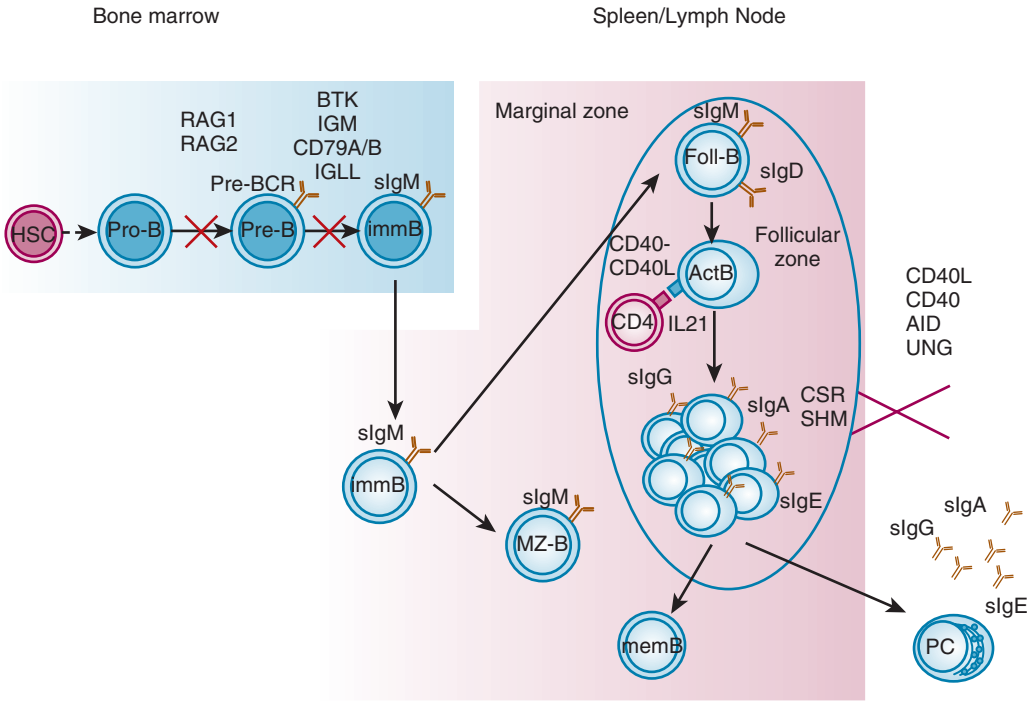

Figure 49-2 GENETIC DEFECTS ASSOCIATED WITH HYPOGAMMAGLOBULINEMIA. Schematic of B-cell development in bone marrow and secondary lymphoid organs, including migration of B cells into the follicular zone, where they undergo activation, class switch recombination (CSR), and somatic hypermutation (SHM). *X* denotes maturation steps at which the genes indicated are required, resulting in a block in differentiation at that stage when the gene is deficient. *ActB,* Activated B cell; *AID,* activation-induced cytidine deaminase; *BTK,* Bruton tyrosine kinase; *HSC,* hematopoietic stem cell; *IL-21,* interleukin-21; *immB,* immature B cell, also termed transitional B cell; *memB,* memory B cell; *MZ-B,* marginal zone B cell; *pre-B,* precursor B cell; *pre-BCR,* pre–B cell receptor; *pro-B,* progenitor B cell; *RAG,* recombination activating gene; *sIgA,* surface IgA; *sIgD,* surface IgD; *sIgG,* surface IgG; *sIgM,* surface IgM; *UNG,* uracil-DNA glycosylase.

complex. Mutations of the CD3δ, CD3ε, and CD3ζ chains interfere with this process and result in SCID. In contrast, mutations of *CD3G* are more often associated with a milder phenotype that includes autoimmunity. Finally, mutations of the CD45 phosphatase, also involved in cell signaling, cause T^- B^+ SCID.

Clinical Manifestations

Typical clinical features of SCID include early-onset severe infections caused by bacteria, viruses, fungi, and opportunistic pathogens (including *P. jiroveci* pneumonia) along with protracted diarrhea, candidiasis, and failure to thrive. Engraftment of maternally derived T lymphocytes is common in SCID, occurring in 40% to 56% of infants with the disease. It may be asymptomatic or may manifest similarly to graft-versus-host disease (GVHD), including skin rash, elevation of liver enzymes, diarrhea, cytopenias. Hypomorphic mutations in SCID-causing genes may lead to residual development of T cells that undergo peripheral expansion and infiltrate target organs, causing various symptoms (erythroderma, diarrhea, hepatosplenomegaly, lymphadenopathy, diarrhea). This clinical phenotype is also known as Omenn syndrome.

Some forms of SCID may present with additional clinical features (see earlier section on defects in thymic development). In patients with ADA deficiency, accumulation of toxic metabolites may cause cupping and flaring of the ribs, liver dysfunction, sensorineural deafness, and neurobehavioral problems. Microcephaly is typically seen in forms of SCID associated with cellular radiosensitivity and impairment of DNA double-strand break repair. Sensorineural deafness is observed in RD.

Diagnostic Approach and Laboratory Manifestations

A thorough family history (including investigation of consanguinity, deaths in infancy, and genders of other affected family members) should be part of the diagnostic approach to infants with possible SCID. Absolute lymphocyte counts (ALCs) should be measured and compared with the normal range for infants (2000–10,000 cells/μL). Lymphopenia is common. Analysis of the distribution and absolute number of $CD3^+$ T lymphocytes, $CD4^+$ and $CD8^+$ T-cell subsets, $CD19^+$ B lymphocytes, and NK ($CD16^+/CD56^+$ NK lymphocytes) will not only confirm the diagnosis of SCID in most cases but will also orient toward specific gene defects. Most SCID patients have profound T-cell lymphopenia; however, $CD3^+$ cells are present in infants with maternal T-cell engraftment or with hypomorphic mutations that allow residual T-cell development. In both of these situations, the T cells have an activated or memory ($CD45RO^+$) phenotype; T cells in normal infants are predominantly naive ($CD45RA^+$). In vitro proliferative response to mitogens is drastically reduced in patients with SCID but may be partially preserved in infants with Omenn syndrome.

Other diagnostic tests that may support the diagnosis of SCID include lack of a thymic shadow in chest radiography and low or undetectable serum IgA and IgM. IgG serum levels may be normal early in life, reflecting the transplacental passage of maternally derived antibodies.

Severe combined immunodeficiency can be diagnosed at birth by measuring levels of TCR excision circles (TRECs). TRECs are a byproduct of V(D)J recombination and are present as circularized DNA fragments in newly generated naive T lymphocytes that express the αβ form of the TCR. Levels of TRECs in circulating lymphocytes are particularly high in newborns and infants and can be detected by PCR amplification of DNA extracted from the Guthrie card.

Diagnostic Approach to Severe Combined Immune Deficiency

- SCID presents early in life with severe infections of bacterial, viral, or fungal origin.
- Opportunistic infections are common in infants with SCID.
- Respiratory infections, protracted diarrhea, and failure to thrive are typical signs at presentation.
- Lymphopenia is present in 50% to 70% of infants with SCID. Age-specific norms must be used in evaluating the ALC because infants and children have much higher ALCs than adults (3500–13,000 cells/mcL in very young infants versus 1000–2800 cells/mcL in adults).
- T-cell lymphopenia is the hallmark of the disease; abnormalities of the absolute count of B and NK lymphocytes are observed in some forms of SCID. However, T lymphocytes may be present in SCID infants with maternal T-cell engraftment or with hypomorphic mutations in SCID-associated genes that allow residual T-cell development. Thus a normal ALC does not rule out SCID.
- Maternally engrafted T cells proliferate in the infant with SCID in vivo, but the vast majority of the time do not proliferate in vitro when stimulated with traditionally used mitogens such as concavalin A and phytohemagglutinin, as measured by thymidine incorporation. Thus, if SCID is suspected but T cells are detectable, maternal engraftment studies and proliferation to mitogens must be done.
- Universal newborn screening has now been piloted in a growing number of states since 2009. The analyte is detection of TRECs by quantitative polymerase chain reaction. TRECs are high in newly generated T cells and low when T cells are absent or when maternally engrafted T cells are present.
- SCID is genetically heterogeneous. The most common form in Western countries is inherited as an X-linked trait and is $T^- B^+ NK^-$.
- The lack of all lymphocytes ($T^- B^- NK^-$ SCID) is highly suspicious for the ADA form of SCID in which toxic metabolites result in death of all lymphocytes. Testing for ADA enzyme level is critical because if confirmed to be absent, treatment with PEG-ADA can often result in sufficient reconstitution of T-cell immunity to protect the baby from infection.

Ultimately, infants with SCID should be evaluated for specific gene defects. However, definitive treatment of SCID (typically, by hematopoietic cell transplantation [HCT]) should not await demonstration of a specific gene defect because this may take some time. An exception to this general principle is ADA deficiency that can be easily diagnosed by measuring enzyme activity in red blood cells, allowing prompt initiation of enzyme replacement therapy (ERT).

Prognosis, Therapy, and Future Directions

Supportive Management

Management of patients with SCID includes observance of strict hygiene measures, prevention of *P. jiroveci* pneumonia with TMP-SMZ, prompt investigation and aggressive treatment of infections, immunoglobulin replacement, and adequate support with enteral or parenteral nutrition. Infections caused by cytomegalovirus (CMV) (causing interstitial pneumonia, hepatitis, or gastroenteritis) and Epstein-Barr virus (EBV) (responsible for lymphoproliferative disease) require active surveillance and preemptive therapy. To prevent transmission of viral infection, blood products from CMV-seronegative donors or leukofiltered products should be used and must be irradiated to prevent transfusion-associated GVHD. Immunosuppression with steroids and cyclosporine A may be needed to treat GVHD-like manifestations associated with Omenn syndrome or maternal T-cell engraftment. Administration of live vaccines must be avoided in infants with SCID. Despite these measures, SCID is inevitably fatal within the first few years of life unless immune reconstitution is achieved with treatment.

Weekly intramuscular injection of pegylated bovine ADA (PEG-ADA) is another therapeutic approach for infants with ADA deficiency. PEG-ADA acts extracellularly to transform adenosine and deoxyadenosine into inosine and deoxyinosine, respectively, thus preventing accumulation of toxic phosphorylated derivatives. ERT for ADA-SCID allows immune reconstitution but is very expensive and must be continued indefinitely. Therapeutic effect may wane over time, and some patients have developed neutralizing antibodies to PEG-ADA.

General Principles of Hematopoietic Cell Transplantation for Severe Combined Immunodeficiency

Hematopoietic cell transplantation is the treatment of choice to obtain long-term immune reconstitution in infants with SCID. HCT for other conditions is generally performed with chemotherapy or radiation conditioning to prevent graft rejection and eliminate or reduce host hematopoietic stem cells (HSCs), favoring donor hematopoiesis. Because of the lack of T lymphocytes, infants with SCID (especially the NK^- forms) are generally considered to have inherent inability to reject the graft and may therefore receive HCT from an HLA-identical related donor without conditioning. T-cell reconstitution in this case is generally prompt, with initial reconstitution in the first 1 to 3 months mediated by expansion of mature T cells present in the donor bone marrow and later reconstitution derived from newly generated T cells that mature in the thymus from donor HSC and progenitors. GVHD prophylaxis is not needed. Unconditioned HCT may also be performed from mismatched related donors, with T-cell depletion of the graft to avoid fatal GVHD. Here the reconstitution is slower because the generation of T cells is entirely dependent on thymic ontogeny and can take 4 to 6 months. Engraftment of T cells may not always occur in this setting, and up to 25% of patients may require repeat transplantation. GVHD prophylaxis is not needed if the T-cell depletion is sufficiently rigorous. These approaches to HCT without conditioning can lead to sustained T-cell immune reconstitution because of the selective advantage for donor cells differentiating into the T lineage. However, this approach rarely results in significant donor HSC engraftment, which is generally less than 1%, and thus may fail to correct impairment of humoral immunity.

Hematopoietic cell transplantation from matched unrelated adult or cord blood donors has been generally performed with myeloablative conditioning, similar to that used for other nonmalignant disorders. In the case of unrelated donor adult HCT, memory T cells present in the graft can expand in the host similarly to the matched related donor situation and can already provide some protection against infection (according to their antigen specificity) in the first few weeks after transplantation. In contrast, cord blood contains mostly naive T lymphocytes and is therefore less efficient in providing antigen-specific immunity early after HCT. Conditioning before unrelated donor HCT or before mismatched related HCT improves the rate of HSC engraftment but exposes the patient to short- and long-term toxicity and to an increased risk of GVHD. Reduced-intensity conditioning regimens have been proposed, with the aim to facilitate stem cell engraftment while reducing the risk of treatment-related toxicity; however, there is no clear evidence that such regimens are associated with better outcomes in patients with SCID treated by HCT.

Survival and Long-Term Outcome After Hematopoietic Cell Transplantation for Severe Combined Immunodeficiency

Survival after HCT for SCID has improved with time because of advances in early diagnosis and supportive care for infants with SCID, as well as in prevention and treatment of GVHD and other complications, including infections and posttransplant lymphoproliferative disease. The type of donor remains the most important determinant of survival. In the largest series of SCID patients treated by HCT in Europe in from 1968 to 2005, 10-year survival was 84% for recipients of HCT from HLA-identical related donors, 66% for those treated with HCT from unrelated donors, and 54% for patients who had received HCT from related HLA-mismatched donors. A single-center study from Buckley and collaborators showed that 16 of 16 recipients of HLA-identical related donors (100%) and 108 out of 145 recipients of HLA-mismatched related donors (74%) with SCID were alive after HCT, with a median follow-up of 10 years. Thus survival remains best for recipients of transplant from HLA-identical related donors.

Respiratory infections at the time of transplant are associated with a poorer outcome. Consistent with this, transplantation at a young age is associated with improved survival, which may be a proxy for the lack of infection at the time of diagnosis or the inherent capacity of the thymic epithelium to support T-cell neogenesis. In the series by Buckley and collaborators, 94% of SCID infants who received HCT during the first 3.5 months of life survived. Use of a protected environment and prophylaxis of infections with TMP-SMZ are also associated with better outcomes after HCT for SCID include. The specific type of SCID may also affect the outcome: survival after HCT for SCID is better in patients with B^+ than B^- SCID.

Complications may occur after HCT for SCID. Acute GVHD (aGVHD) occurs in 35% to 45% of the patients and is more common after HCT from unrelated and HLA-mismatched donors. Limited or extensive chronic cGVHD occurs in approximately 10% of the patients and is more common after haploidentical and unrelated donor transplantation; typical target organs include the skin, gastrointestinal (GI) tract, and liver. The long-term requirement for nutritional support has been reported in up to 20% of patients with SCID who survived at least 2 years after HCT. Certain forms of SCID are associated with a higher risk of long-term complications and sequelae, including nutritional problems, poor growth and development, and cGVHD in patients with Artemis deficiency and neurologic complications (mental retardation, motor dysfunction, sensorineural hearing deficits) in patients with ADA deficiency.

In infants with SCID, donor-derived stem cells present a strong selective advantage versus autologous stem cells during T-cell development, and long-term T-cell reconstitution may also be achieved from committed lymphoid progenitors that seed to the thymus even in the absence of engraftment of bona fide stem cells. Consistent with this, donor T-cell chimerism and T-cell reconstitution after HCT are achieved in more than 90% of infants with SCID, and the majority have a polyclonal repertoire. Some reports have indicated that in the absence of donor stem cell engraftment, there is a progressive decline of thymic function after HCT for SCID. Others have shown that the decline of TREC levels (hence of thymic function) with age follows a similar rate as in normal individuals. Patients with poor T-cell reconstitution are at risk for viral and opportunistic infections; autoimmunity (especially cytopenias and hypothyroidism) has been reported in 10% to 20% of these patients, particularly in those with cGVHD.

Reconstitution of humoral immunity after HCT for SCID is less uniform. Engraftment of donor B cells is usually associated with humoral immune reconstitution. Inadequate B-cell function (requiring immunoglobulin replacement therapy) is often observed in patients with γc and JAK3 deficiency who remain with autologous B cells, because of intrinsic defects in the host B cells to respond to γc-dependent cytokines such as IL-4 and IL-21.

Therapeutic Approach to Severe Combined Immune Deficiency

- HCT is the mainstay of treatment. Optimal survival is achieved when the transplant is performed early in life. This is now possible with newborn screening.
- Transplantation for SCID can be performed without conditioning because of the profound absence of T cells and inability to reject. Thus the bone marrow of a fully HLA-matched sibling can be infused without manipulation and without giving any conditioning to the baby. GVHD prophylaxis is also not necessary. Haploidentical bone marrow from a parent can also be infused without conditioning but must first be T-cell depleted.
- Such transplants without conditioning can result in T-cell reconstitution that lasts for decades. In the case of a matched sibling graft, initial T-cell reconstitution is rapid, generally within the first 1 to 3 months, because of proliferation of mature T cells. In the case of a haploidentical graft, mature T cells are removed, so 4 to 6 months is required for HSCs to develop and emerge from the thymus as mature T cells.
- Without conditioning, few long-lived HSCs from the donor engraft, which may lead to a lack of donor B-cell reconstitution and a lack of humoral immunity. With conditioning, donor HSCs are more likely to engraft and give rise to donor B cells. Currently, matched unrelated donor transplants are performed with conditioning.
- Enzyme replacement may be used in patients with adenosine deaminase deficiency. Gene therapy has offered promising results, but it is also associated with an increased risk of leukemic proliferation because of insertional mutagenesis.

The number of circulating NK lymphocytes often remains low in patients with γc and JAK3 deficiency and may contribute to the increased risk of warts.

Gene Therapy for Severe Combined Immunodeficiency

Gene therapy, in which the gene of interest is introduced into the patient's own cells, is an attractive therapeutic option for SCID, particularly for infants who do not have an HLA-identical related donor. Expression of the normal copy of the gene in $CD34^+$ stem cells confers a selective advantage to the gene-corrected cells during T-cell differentiation. Furthermore, there is no risk of GVHD. Gene therapy has been used successfully to correct SCID in patients with ADA deficiency and with X-linked SCID. Since 2000, more than 30 patients with ADA-deficient SCID have been treated with gene therapy worldwide. The largest experience reported from Milan, Italy, describes 15 patients, all alive, with progressive reconstitution of T-cell counts and sufficient T-cell function in 13 of the 15 patients to stop ERT. In the Milan protocol, engraftment of gene-corrected stem cells has been facilitated by use of a reduced-intensity chemotherapy regimen with low-dose busulfan.

Twenty patients with X-linked SCID have been treated by gene therapy in Paris and London. In both protocols, no chemotherapy was used. Eighteen patients are alive, and 17 of them show normalization of T-cell count and function, with demonstration of reconstituted thymic output, diversified T-cell repertoire, and ability to mount antigen-specific T-cell responses. In some cases, improvement of humoral immunity has also been observed. However, leukemic T-cell proliferation caused by insertional mutagenesis has been observed in five of 20 patients. Novel and potentially safer vectors for gene therapy in X-linked SCID have been recently developed, and a new multicenter trial with a self-inactivating γ-retroviral for X-linked SCID started in 2010.

LATE DEFECTS IN T-CELL DEVELOPMENT

Upon expression of a functional TCR, double-positive thymocytes migrate to the thymic medulla and continue their differentiation into single-positive ($CD4^+$ or $CD8^+$) cells that eventually egress from the thymus and are exported to the periphery. Several genetic defects have been identified that affect late stages in T-cell development. At variance with classical forms of SCID, these disorders are characterized by residual number or function of T cells, consistent with partially preserved thymic architecture and function. Because these patients' thymuses are not empty, use of chemotherapy is required to facilitate engraftment and T-cell differentiation with donor-derived cells.

ZAP-70 Deficiency

This autosomal recessive disease is caused by mutations of the zeta-associated protein of 70 kDa (ZAP-70) tyrosine kinase, that phosphorylates the CD3 chains and thus participates at TCR-mediated signaling. The immunologic phenotype of ZAP-70 deficiency in humans is characterized by virtual lack of $CD8^+$ lymphocytes; the number of $CD4^+$ cells is preserved, but they are unable to proliferate in response to mitogens and antigens. In contrast, both $CD4^+$ and $CD8^+$ lymphocytes are absent in *Zap70*$^{-/-}$ mice; an inability of the T cells to respond to antigens in patients with ZAP-70 deficiency causes increased susceptibility to severe infections, resulting in a clinical phenotype that is indistinguishable from that of SCID. Rarely, ZAP-70 deficiency has been associated with clinical features of Omenn syndrome. Prevention of infections is based on antimicrobial prophylaxis and use of intravenous immunoglobulins; however, ultimate treatment requires HCT.

Human Leukocyte Antigen Class II Deficiency

Expression of HLA class II molecules on the surfaces of thymic epithelial and dendritic cells is essential to promote positive selection of $CD4^+$ lymphocytes. HLA class II deficiency includes a group of autosomal recessive disorders in which mutations in transcription factors (CIITA, RFXAP, RFX5, and RFXANK) that regulate HLA class II gene expression result in a profoundly reduced number of $CD4^+$ lymphocytes. The clinical phenotype consists of recurrent infections since infancy that may also be caused by opportunistic pathogens. Treatment is based on antimicrobial prophylaxis and regular use of immunoglobulins, but the prognosis remains severe. HCT does not correct defective expression of HLA class II molecules by thymic epithelial cells, causing persistence of CD4 lymphopenia in a large fraction of transplanted patients. However, HCT from HLA-matched donors may allow reconstitution of the $CD4^+$ cell compartment by mature cells contained in the graft, with little or no contribution by newly generated $CD4^+$ cells.

Human Leukocyte Antigen Class I Deficiency

Presentation of antigens in association with major histocompatibility class I molecules is important for thymic development of $CD8^+$ lymphocytes and for the development of antigen-specific cytotoxic T-cell responses. In addition, HLA class I molecules also modulate the function of NK cells that express several HLA class I–binding molecules. HLA class I molecules are assembled and loaded with peptides in the endoplasmic reticulum by a transporter associated with antigen presentation (TAP) proteins (TAP1 and TAP2) and the Tapasin protein. Mutations of TAP1, TAP2, or Tapasin cause defective expression of HLA class I molecules, associated with a severe reduction in the number of circulating $CD8^+$ $TCR\alpha\beta^+$ lymphocytes. NK cells expressing killer inhibitory receptors may not receive HLA class I–dependent inhibitory signals and hence may mount cytotoxic responses to uninfected cells, causing inflammatory lesions in the lungs and in the skin. There is no definitive treatment for this disease, and management is based on supportive care.

OTHER COMBINED IMMUNODEFICIENCIES

Several other conditions are known that affect the ability of T lymphocytes to respond to activating signals or to interact with other cells during immune responses. Despite the presence of peripheral T cells, these conditions often have a poor prognosis, and use of HCT should be carefully considered.

CD40LG Deficiency

CD40 ligand (CD40LG) is expressed by activated $CD4^+$ cells. Interaction of CD40LG-expressing $CD4^+$ cells with B lymphocytes that constitutively express CD40 delivers a signal for B-cell proliferation and class switch recombination in combination with appropriate cytokines (see Fig. 49-2). Furthermore, interaction between CD40LG-expressing $CD4^+$ lymphocytes and $CD40^+$ dendritic cells and macrophages promotes secretion of IL-12 and thus enables development of Th1 responses against intracellular pathogens.

The *CD40LG* gene is located on the X chromosome (at Xq26). Males with *CD40LG* mutations have a combined immunodeficiency characterized by recurrent infections. Opportunistic infections are common. *P. jiroveci* pneumonia may mark the clinical onset of the disease in the first year of life. *Cryptosporidium parvum* infection may cause chronic watery diarrhea and is often responsible for sclerosing cholangitis. Chronic or intermittent neutropenia has been frequently observed. Patients with CD40LG deficiency are also uniquely prone to peripheral neuroectodermal tumors, especially of the GI tract.

Levels of serum IgG and IgA are markedly reduced or undetectable; IgM may be normal or increased, and for this reason, the disease is also known as X-linked hyper-IgM syndrome. The number of memory B cells is also markedly reduced.

In vitro activation of T cells with phorbol myristate acetate and ionomycin fails to induce expression of CD40LG on the surface of $CD4^+$ cells, but other activation markers (e.g., CD69) are normally expressed.

The prognosis is severe. Death may occur early in life secondary to infections or during late childhood and young adulthood because of severe liver disease and tumors. Clinical management is based on continuous prophylaxis of *Pneumocystis* infection with TMP-SMZ, regular use of intravenous immunoglobulins, and hygiene measures to limit the risk of exposure to *Cryptosporidium* spp. HCT represents the only definitive cure. In a series of 38 patients transplanted in Europe, 26 (68.4%) survived. Preexisting pulmonary disease and *Cryptosporidium* infection are risk factors for a less favorable outcome.

CD40 Deficiency

This is a rare autosomal recessive disorder whose clinical and immunologic phenotype is indistinguishable from CD40LG deficiency (see Fig. 49-2). The diagnosis is based on the lack of expression of CD40 on the surface of circulating B lymphocytes. Management is as for CD40LG deficiency.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome is an X-linked disorder characterized by thrombocytopenia with small-sized platelets, eczema, and immunodeficiency. Autoimmune manifestations are common, and there is an increased risk of hematologic malignancies (primarily non-Hodgkin lymphoma [NHL], sometimes EBV driven). This X-linked disease is estimated to occur in one in 100,000 births. The defect is caused by mutations in the *WAS* gene that encodes for an intracytoplasmic protein (WASp) expressed in hematopoietic cells and involved in cytoskeleton reorganization and immune synapse formation. Deficiency of WASp results in impaired T-cell activation; poor production

of antibodies, particularly to carbohydrate antigen; defective NK function; impaired phagocytic cell migration; and defective antigen presentation, thus explaining the immunodeficiency of the disease.

Boys with WAS typically present in infancy with bleeding, prompting the discovery of low numbers of small platelets, with mean platelet volume typically 4 to 5 fL. Bleeding manifestations can range from petechiae and bruising to severe GI and intracranial hemorrhages. Eczema can be mild to severe. Common infections in patients with WAS include otitis, sinusitis, pneumonia, and cellulitis. Viral infections (especially from herpesviruses, including CMV, EBV, and herpes simplex virus 1 [HSV-1]) and opportunistic infections, such as *P. jiroveci* pneumonia, are also frequent. Approximately 40% of patients with WAS develop autoimmunity, including autoimmune hemolytic anemia, autoimmune thrombocytopenia, thyroiditis, colitis, vasculitis, nephropathy, and arthritis. In addition to thrombocytopenia, typical laboratory findings include an inability to mount responses to polysaccharide antigens, low or absent isohemagglutinin titers, high IgE, and poor proliferation of T cells when stimulated with anti-CD3 antibody. Other immune findings are more variable, including progressive T lymphopenia with age, low IgM, and high IgA. Analysis of WASp protein expression and demonstration of *WAS* gene mutations confirm the diagnosis.

Supportive treatment for WAS consists of monitoring and treatment for bleeding, antimicrobial prophylaxis, immunoglobulin replacement therapy, and treatment of eczema and of autoimmune manifestations with immunosuppressive drugs. Splenectomy can be effective in many to correct thrombocytopenia but leads to increased risk of sepsis.

Allogeneic HCT (typically with myeloablative regimens) for WAS has become standard at many institutions and may be indicated early in life, especially in patients with severe mutations that abrogate protein expression.

Hematopoietic cell transplantation is usually associated with robust T-cell engraftment, but some patients develop mixed chimerism in the B and myeloid lineages, indicating differential requirement for normal WAS protein to promote lineage-specific development or survival. Poor myeloid chimerism is associated with the risk of persistent thrombocytopenia, and mixed chimerism may favor autoimmune manifestations.

Survival after HCT for WAS is influenced by donor type and age at transplantation. An international retrospective review of 170 boys transplanted from 1968 to 1996 showed that survival after HLA-identical sibling HCT recipient (87%) was similar to that of matched unrelated donor HCT recipients who were transplanted before the age of 5 years, but those transplanted after age 5 years had a high relative risk of death. In a multi-institutional retrospective survey of 194 patients transplanted from 1980 to 2009, this trend was confirmed, although the absolute survival of these high-risk patients has improved substantially.

Because outcome after HCT is not uniformly good and many patients lack matched related or unrelated donors, somatic gene therapy is an attractive treatment option for WAS. The results of the first two of a total of 10 boys treated with gene therapy by transduction of $CD34^+$ selected peripheral blood stem cells using an MFG-based γ-retroviral vector after low-dose busulfan conditioning has recently been reported. These two patients achieved successful reconstitution of immune function, control of eczema, and rise in platelets. However, this treatment has been associated with insertional mutagenesis and development of leukemia. Therefore, efforts are underway to develop safer strategies, and trials using a lentiviral self-inactivating vector have been recently opened.

NEMO Deficiency

A rare syndrome in which boys were affected by hypohidrotic ectodermal dysplasia and immunodeficiency (EDA-ID) was described in 2002 to be attributable to hypomorphic mutations in the *IKGBG* gene. The *IKGBG* gene encodes for the protein nuclear factor kappa-B (NFκB) essential modulator (NEMO), also known as IKK-γ, the regulatory subunit of the IκB kinase complex. This disorder was the first example of an immunodeficiency caused by defects in the NFκB signaling pathway in humans.

The NFκB signaling pathway is ubiquitous to all tissues and stages of development, playing critical roles in cell proliferation, oncogenesis, cell survival, and inflammatory responses. All described patients have partial expression of NEMO. Complete lack of NEMO expression is embryonically lethal in males; females who are heterozygous for null NEMO mutations have incontinentia pigmenti.

Phenotypic manifestations of EDA-ID are largely restricted to epithelial tissues and the immune system, with sparse hair, shiny skin, lack of sweat glands and other appendages, and rare conical shaped teeth. There is often frontal bossing and a characteristic facies. Typical infections are due to bacteria, including sepsis and meningitis, especially *Streptococcus pneumoniae, Staphylococcus* spp. and *Haemophilus influenzae;* DNA viral infections such as CMV and HSV; and atypical mycobacterial infection. Pneumocystis and other opportunistic infections can occur but less frequently. Other manifestations of the disease that are present in some, but not all, patients include inflammatory colitis, lymphedema, and osteopetrosis. Furthermore, some patients do not have prominent features of ectodermal dysplasia, adding to phenotypic heterogeneity.

T- and B-cell numbers in general are normal, but variable defects in T-cell proliferation to mitogen and antigens are seen. Hypogammaglobulinemia with normal or high IgM and defective antibody production (especially against polysaccharides) are common. Defects in NK cell cytotoxicity have been reported. Finally, monocytes from patients with NEMO fail to elaborate inflammatory cytokines such as tumor necrosis factor-α (TNF-α) in response to stimulation by a variety of TLR ligands.

The prognosis and natural history of NEMO mutation is not well known, but these patients have an increased risk of sepsis, mycobacterial disease, and inflammatory complications. Aside from supportive therapy with intravenous immunoglobulin (IVIG) replacement, antibiotic prophylaxis, and treatment of infections, HCT has been used to treat patients with severe cases of NEMO deficiency with variable results. Because of the expression of NEMO in nonhematopoietic tissues, certain manifestations such as colitis may not be immediately ameliorated by HCT.

DISORDERS WITH T CELL-MEDIATED IMMUNE DYSREGULATION

Along with generation of a diversified repertoire of T and B lymphocytes, purging of self-reactive cells is essential to maintain immune homeostasis and prevent autoimmune diseases. We have already reported how autoimmune manifestations are common in severe forms of immunodeficiency characterized by oligoclonal expansion of T lymphocytes (e.g., Omenn syndrome, complete atypical DGS) or by defective intracellular signaling (e.g., calcium flux defects). Here we describe other forms of PID with faulty control of central or peripheral T-cell tolerance.

Autoimmune Polyendocrinopathy Candidiasis Ectodermal Dystrophy Syndrome

Also known as autoimmune polyglandular syndrome type 1 (APS1), autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) is an autosomal recessive disorder characterized by autoimmune endocrine manifestations (hypoparathyroidism, Addison disease), candidiasis, and nail dystrophy. The disease is caused by mutations of the autoimmune regulator *(AIRE)* gene, which encodes for a transcription factor expressed by medullary thymic epithelial cells (mTECs), where it regulates expression of tissue-specific antigens that are presented to nascent T cells, thereby promoting clonal deletion of self-reactive T lymphocytes or their conversion to natural regulatory T cells (nTreg cells).

In patients with APECED, mucocutaneous candidiasis usually develops first (in infancy or early childhood) followed by autoimmune hypoparathyroidism with hypocalcemia and adrenal failure. Around 15% to 20% of the patients may develop insulin-dependent diabetes. Other autoimmune manifestations (hepatitis, ovarian failure) are also common. Hyposplenism has been reported in one study. Candidiasis may reflect elevated levels of antibodies to IL-17 and IL-22 that play an important role in the defense against *Candida* spp.

Management of patients with APECED is based on regular follow-up and search for autoantibodies, which should be repeated every 6 months. Hormone replacement therapy is indicated for the endocrinopathies. Aggressive management and prevention of candidiasis is important to avoid persistent or recurrent infections that may favor development of squamous cell carcinoma.

Immune Dysregulation Polyendocrinopathy Enteropathy X-linked Syndrome

Immune dysregulation polyendocrinopathy enteropathy X-linked (IPEX) syndrome is an X-linked disorder of systemic autoimmunity. Males with IPEX present early in life with skin rash, intractable watery diarrhea, insulin-dependent diabetes mellitus, lymphadenopathy, splenomegaly, and failure to thrive. Other autoimmune manifestations include thyroid disease, nephropathy, cytopenias, and vasculitis. In addition, patients with IPEX show elevated levels of IgE.

IPEX is caused by mutations of the *FOXP3* gene that encodes for a transcription factor that plays a critical role in the development and function of Treg lymphocytes. These cells have suppressive functions; they have a distinctive phenotype ($CD4^+$ $CD25^{hi}$ $FOXP3^+$) and normally represent 5% to 15% of $CD4^+$ circulating lymphocytes. Most patients with IPEX lack Treg cells; activated self-reactive T lymphocytes infiltrate target tissues and secrete cytokines, causing tissue damage.

IPEX has a severe prognosis. Death often occurs within the first few years of life because of severe malabsorption, failure to thrive, metabolic derangement, or severe infections secondary to immune suppression. Use of immunosuppressive drugs (steroids, sirolimus, tacrolimus, rituximab) is necessary to treat the disease. However, the only definitive treatment is allogeneic HCT. Mixed chimerism is sufficient to control the disease; therefore, reduced-intensity conditioning has been used with good results.

CD25 Deficiency

IL-2 plays an important role in T-lymphocyte proliferation and in immune homeostasis by increasing expression of FOXP3 and enhancing the suppressive activity of Treg cells. Autosomal recessive mutations of the *IL2RA (CD25)* gene that encodes for the α chain of the IL-2 receptor cause a disease that associated IPEX-like manifestations (lymphadenopathy, hepatosplenomegaly, autoimmune cytopenias, inflammatory bowel disease) and increased susceptibility to severe viral infections. The number of circulating T cells may be normal or slightly reduced, and in vitro proliferative response to mitogens is decreased. The patients' T cells produce reduced amounts of the immunosuppressive cytokine IL-10 upon in vitro activation. HCT represents the only definitive treatment.

Autoimmune Lymphoproliferative Syndrome

Interaction between FAS (CD95) on activated T and B lymphocytes and FAS ligand (FAS-LG) on activated T cells triggers the extrinsic pathway to activation of the caspase cascade, culminating in apoptosis. In addition, cellular stress (including cytokine deprivation) may activate the intrinsic pathway of apoptosis, leading to disruption of mitochondrial membrane permeability, release of cytochrome c, activation of caspase 9, and apoptosis. Defects of FAS- or mitochondrial-dependent apoptosis are responsible for the autoimmune lymphoproliferative syndrome (ALPS, also known as Canale-Smith syndrome), characterized by early-onset, chronic (>6 months), nonmalignant lymphoproliferation; autoimmunity; and an increased risk of lymphoma.

The majority of patients with ALPS carry heterozygous dominant-negative mutations in the *FAS (CD95, TNFRSF6)* gene (ALPS-FAS). Somatic mutations of the *FAS* gene are the second most common cause of the disease (ALPS-sFAS). More rarely, ALPS is caused by mutations of the *FASLG* gene (ALPS-FASLG), of caspase 8, caspase 10, Fas-associated death domain (FADD) protein, or somatic activating mutations of N-RAS or K-RAS. Both caspase 8 and caspase 10 deficiency are inherited as autosomal dominant traits.

Lymphoproliferation, manifesting as lymphadenopathy, splenomegaly, or hepatomegaly, is the most common clinical manifestation, with a trend toward progressive remission in adulthood. More than 70% of ALPS patients develop autoimmune disease, most commonly immune cytopenias and less frequently organ-specific autoimmunity. There is an increased risk of malignancies, especially EBV-associated NHL.

An immunologic signature of ALPS is the increased number of DN circulating T lymphocytes that express the αβ form of the TCR but do not express CD4 or CD8 molecules. There is defective in vitro apoptosis of lymphocytes through FAS-mediated or intrinsic pathway (depending on the genetic variant). Elevated levels of soluble FAS ligand, vitamin B_{12}, and IL-10, hypergammaglobulinemia, and antiphospholipid antibodies are often present in patients with ALPS-FAS. Patients with caspase 8 deficiency and with FADD deficiency have recurrent infections, and the latter have functional hyposplenism. The number of DN T cells may be normal in patients with *NRAS* or *KRAS* mutations.

Treatment is based on immunosuppression (with steroids, rituximab, mycophenolate mofetil, or sirolimus) and surveillance against lymphoma. Splenectomy may improve cytopenias; however, relapse of autoimmunity has been observed in 50% of splenectomized patients. Furthermore, severe, invasive bacterial infections have been reported in 30% of splenectomized patients, and the mortality rate for invasive bacterial infection after splenectomy is as high as 13.3%.

DEFECTS OF CELL-MEDIATED CYTOTOXICITY

Mechanisms of immune defense against viral infections are largely dependent on responses mediated by $CD8^+$ cytotoxic T lymphocytes (CTLs) and NK lymphocytes. Multimers of perforin, a protein contained in cytolytic granules, form pores through which CTL and NK cells release cytotoxic proteins (granzyme B, granulolysin) into virus-infected target cells, causing activation of caspases and apoptosis. In resting CTL and NK lymphocytes, cytotoxic proteins are contained in endosomal secretory lytic granules. After interaction of CTL or NK cells with the target cell, lytic granules are transported, dock, and fuse with the cell membrane, permitting release of cytotoxic proteins into the target cells.

Defects along this process are responsible for various forms of familial hemophagocytic lymphohistiocytosis (FHL). Defective cell-mediated cytotoxicity is also observed in Chédiak-Higashi syndrome (CHS). Finally, selective susceptibility to EBV infection is at the basis of various forms of lymphoproliferative syndrome.

Chédiak-Higashi Syndrome

Chédiak-Higashi syndrome is an autosomal recessive disease caused by mutations of the *LYST* gene, which encodes for a protein involved in the sorting of proteins to secretory endosomes. This defect affects not only cytotoxic lymphocytes (accounting for FHL-like clinical features) but also melanocytes (that are unable to transfer melanin to keratinocytes and other epithelial cells) and peripheral neurons. Clinical features of CHS include partial albinism (with silvery hair), progressive peripheral neuropathy, recurrent bacterial infections, and

a mild tendency to bleeding. Patients with CHS are prone to accelerated phases of hemophagocytic lymphohistiocytosis (HLH) because of uncontrolled macrophage activation in response to viral infections. Neutropenia is often present and may cause bacterial infections. Giant lysosomes can be identified in circulating leukocytes.

Treatment is based on prophylactic antibiotics and aggressive treatment of infections. HCT may restore hematologic and immunologic abnormalities; however, progressive neurologic dysfunction is not affected by treatment.

X-Linked Lymphoproliferative Disease

In normal individuals, primary infection with the EBV causes infectious mononucleosis, a self-limiting disease. EBV establishes latency in B lymphocytes, salivary glands, and some epithelial cells and is maintained under control by $CD8^+$ CTL and NK lymphocytes. Males with X-linked lymphoproliferative disease type 1 (XLP1) are uniquely susceptible to life-threatening complications of EBV infections. XLP1 is caused by mutations of the *SH2D1A* gene that encodes for a small adaptor molecule, signaling lymphocyte activation molecule (SLAM)-associated protein (SAP). In the absence of SAP, cytotoxic responses to EBV-infected cells are markedly reduced. Persistence of EBV triggers continuous activation of $CD8^+$ CTLs that hyperproliferate and release high amounts of interferon-γ. Ultimately, this condition ensues in a macrophage activation syndrome. After EBV infection, patients with XLP1 are also at high risk of B-cell lymphoma. SAP is also important for the function of follicular helper T cells (T_{FH}) that promote maturation of antibody responses. Consistent with this, males with XLP1 often develop hypogammaglobulinemia with a lack of memory B lymphocytes. Finally, XLP1 is also associated with impaired development of NK T lymphocytes. Flow-cytometric analysis of SAP expression and mutation analysis at the *SH2D1A* locus confirm the diagnosis.

A minority of patients with XLP carry defects in another gene *(BIRC4)* that encodes for the X-linked inhibitor of apoptosis (XIAP). Consistent with this, lymphocytes from patients with this disease (XLP2) show increased susceptibility to activation-induced apoptosis. Compared with XLP1, patients with XLP2 have a higher incidence of HLH (with or without EBV infection) but do not show an increased risk of lymphoma. Hypogammaglobulinemia is often present. Flow cytometric analysis of XIAP expression and mutation analysis at the *BIRC4* locus are used to confirm the diagnosis.

Both XLP1 and XLP2 are life-threatening disorders. Administration of immunoglobulins may be beneficial, but the only curative approach is HCT.

Diagnostic and Therapeutic Approach to Cytotoxicity Defects

- PID with defects of cell-mediated cytotoxicity includes a heterogeneous group of disorders characterized by increased susceptibility to severe viral infections.
- Typical clinical features include high fever, liver and spleen enlargement, lymphadenopathy, coagulation defects, abnormalities of liver function, and cytopenias after viral infections.
- Two major groups of cell-mediated cytotoxicity defects include familial forms of hemophagocytic lymphohistiocytosis (fHLH) and X-linked lymphoproliferative disease. In the former, diagnosis is based on demonstration of abnormal cytotoxic function of T and NK lymphocytes. Defective expression of CD107a on activated lymphocytes or reduced expression of perforin may help define the nature of the underlying disorder causing fHLH.
- Prompt recognition and treatment of the underlying infection is essential. Immunosuppression is also required to block exaggerated inflammatory responses. However, the only curative approach to defects of cell-mediated cytotoxicity is represented by HCT. Mixed chimerism is sufficient to allow immune reconstitution. This goal can be achieved with reduced-intensity conditioning, with a lower risk of treatment-related toxicity.

DEFECTS OF B-CELL DEVELOPMENT AND FUNCTION

The previous section covered defects that predominantly affect T lymphocytes' development and/or function. This section covers PIDs in which abnormalities of B cell development or function are the main feature (Figs. 49-2 and 49-3).

X-linked Agammaglobulinemia

X-linked agammaglobulinemia (XLA), also known as Bruton agammaglobulinemia, is the most common monogenic cause of failure of B-cell development and affects approximately one in 390,000 individuals in central Europe. Males with XLA lack circulating B cells because of mutations of the Bruton tyrosine kinase or *BTK* gene, which encodes for a tyrosine kinase involved in signaling through various receptors, including the pre–B-cell receptor (BCR) and the BCR. Impaired signaling through the pre-BCR causes a severe, but incomplete, block at the pre–B cell stage in the bone marrow (see Fig. 49-2).

Approximately 1000 mutations have been reported in the BTKbase (http://bioinf.uta.fi/BTKbase). Milder mutations that are permissive for BTK protein expression are associated in vivo with higher levels of serum IgM and later age at diagnosis.

Clinical manifestations of XLA include recurrent sinopulmonary infections (pneumonia, bronchitis, sinusitis, otitis), particularly with encapsulated organisms such as pneumococcus and *H influenza;* bacterial skin infections (cellulitis, impetigo, pyoderma gangrenosum, perirectal abscess); and sepsis with *Pseudomonas* spp. or staphylococcus. Symptoms typically begin after 3 to 6 months of age when maternally derived antibodies disappear. The proportion of circulating B cells is markedly reduced (typically 0.05%–0.3% of lymphocytes), and there is profound deficiency of all immunoglobulin isotypes. Neutropenia, secondary to severe infections, is observed in approximately 10% to 25% of patients; typically, it resolves with antibiotics and immunoglobulin replacement therapy.

In addition to bacterial infections, patients with XLA are uniquely susceptible to enteroviral infections (including chronic meningoencephalitis) caused by poliovirus, Coxsackie, and others; infections with *Mycoplasma* and *Ureaplasma* spp. affecting joints, the prostate, or lungs; and *Giardia lamblia* infection, causing protracted diarrhea and malabsorption. Increased incidences of lymphoma, colorectal cancer, and gastric adenocarcinoma have been reported in patients with XLA.

Therapy is based on lifelong regular administration of immunoglobulins intravenously or subcutaneously and on prompt and aggressive treatment of infections. With this regimen, survival approaches that of the general population. Antibiotic prophylaxis may be beneficial, but its role has not been firmly established. Treatment of enteroviral meningoencephalitis is more problematic; some success has been reported with high-dose immunoglobulins and the antiviral agent pleconaril. Patients on immunoglobulin replacement therapy should be monitored for side effects and adverse reactions and for liver and renal function.

Autosomal Recessive Agammaglobulinemia

Although the majority of agammaglobulinemia cases are caused by the X-linked form, about 15% of cases are presumed to be autosomal recessive (see Fig. 49-2). Mutations of the immunoglobulin μ heavy chain gene *(IGHM)* are the second most common cause of agammaglobulinemia. Other cases are caused by defects in other

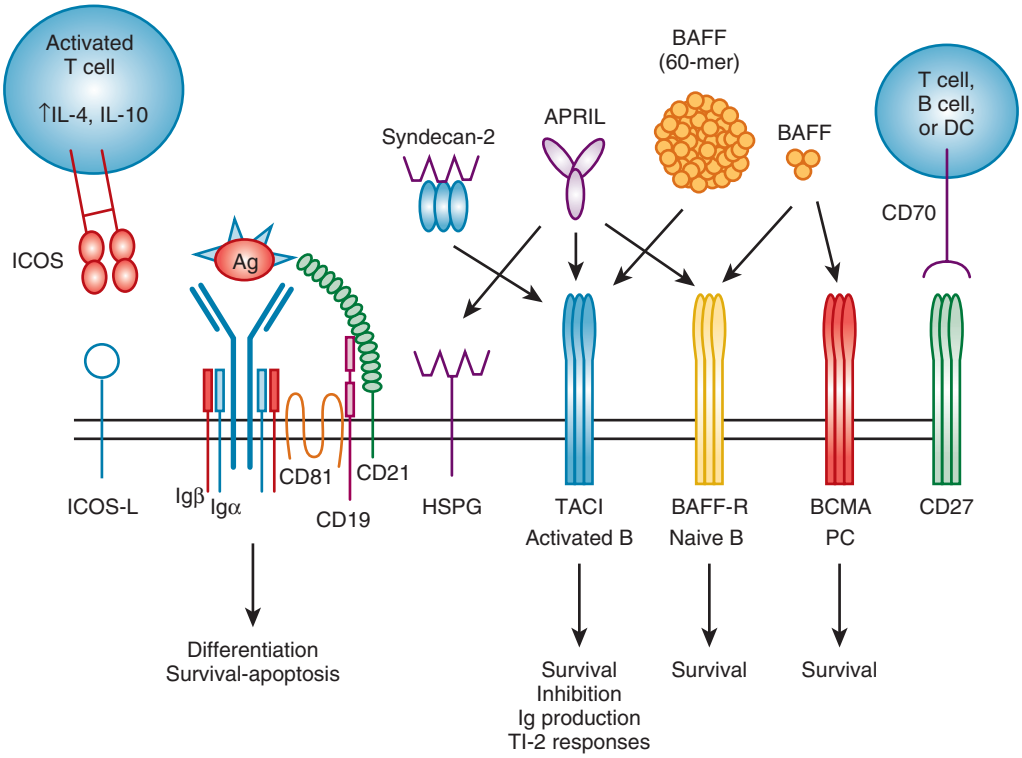

Figure 49-3 GENETIC DEFECTS ASSOCIATED WITH COMMON VARIABLE IMMUNODEFICIENCY (CVID). Schematic of cell surface molecules expressed on B cells and their ligands, highlighting those in which defects have been shown to be associated with CVID. *Ag,* Antigen; *APRIL,* a proliferation-inducing ligand; *BAFF,* B-cell activating factor; *BAFFR,* B-cell activating factor receptor; *BCMA,* B-cell maturation antigen; *DC,* dendritic cell; *HSPG,* heparin sulfate proteoglycan; *ICOS,* inducible T-cell costimulator; *ICOS-L,* inducible T-cell costimulator ligand; *IL,* interleukin; *PC,* plasma cell; *TACI,* transmembrane activator and calcium modulator and cyclophilin ligand interactor; *TI-2,* T-cell independent type 2.

components of the pre-BCR–BCR complex, including the signaling moieties Igα (CD79A), Igβ (CD79B), and λ5 (IGLL1), the surrogate light chain that pairs with Vpre-B. Finally, mutation in the scaffold protein B cell linker (BLNK), which brings BTK into the signaling complex, was reported in a single patient. Aside from the genetics, the clinical phenotype and treatment of all of these patients is similar to XLA.

Common Variable Immunodeficiency

Common variable immunodeficiency (CVID) is the most common PID severe enough to require treatment, with a prevalence estimated to be one in 25,000 to 30,000 whites and accounting for approximately 10% to 20% of humoral immunodeficiencies. Although a growing number of genetic defects have been found to be associated with a CVID phenotype, these defects account for a minority of cases. The "variable" nature of the clinical manifestations of CVID patients could reflect genetic heterogeneity but also refers to distinct clinical and immunologic features that distinguish subgroups of CVID patients. However, the most common genetic variant described to date (mutations in *TACI*) can be found in asymptomatic individuals and more likely represents a predisposition to CVIDs than primary cause. Thus the genetic causes of the majority of cases of CVIDs remain obscure and are not clearly monogenic in nature.

Diagnostic criteria for CVIDs were established in 1999 by consensus of European and Pan-American societies and include the presence of hypogammaglobulinemia (<2 standard deviations below the mean for age of IgG, IgA, or IgM) and lack of specific antibody responses in individuals with onset of symptoms after 2 years of age for whom other causes of humoral immunodeficiency have been ruled out. The number of circulating B cells detected is variable. Specific antibody responses should be assessed to more than one antigen. Because an increasing number of gene defects causing hypogammaglobulinemia early in life have been identified, many experts would recommend limiting the diagnosis of CVID to patients in whom symptoms appeared after 4 years of age.

Consistent with the antibody deficiency, CVID patients have recurrent bacterial infections of the respiratory tract; sepsis with encapsulated organisms; and infections from *Ureaplasma urealyticum, Giardia* spp., and enteroviruses. However, variable derangement of T-cell numbers and function often results in noninfectious manifestations, including autoimmunity, lymphoid infiltration or proliferation, and malignancy. In one survey, only 26% of CVID patients had infections as the only manifestation of disease. Autoimmune cytopenias are quite common (≈12%) and may be the presenting feature. Other autoimmune complications include rheumatoid arthritis, systemic lupus erythematosus, hypothyroidism, vitiligo, psoriasis, diabetes, and autoimmune gastritis with pernicious anemia. Polyclonal lymphocytic granulomatous infiltrates are common and may involve the lungs, liver, or gut (causing enteropathy that is resistant to gluten withdrawal). Finally, both lymphoid (NHL, chronic lymphocytic leukemia) and nonlymphoid (gastric cancer) malignancies are more frequent in patients with CVID, although the latter may be related to *Helicobacter* pylori infection.

Replacement of immunoglobulins and treatment and prevention of infection remain the mainstays of management of CVID. Immunosuppression may be needed for inflammatory and autoimmune manifestations. Analysis of the European CVID registry containing 334 patients observed over 25 years revealed that disease manifestations such as autoimmunity, polyclonal lymphocytic infiltrative disease, enteropathy, and malignancy have differential and increasing

impact on survival (relative risk of death 2.5, 3.0, 4.0, and 5.5, respectively), but patients with solely infectious manifestations have equivalent survival to the general population. Treatment with HCT has been performed with limited success and often in the context of consolidative treatment for lymphoproliferation.

Immunophenotyping, genotyping, and recently genome-wide association studies have been performed in an attempt to subcategorize the heterogeneous group of CVIDs into pathobiologically relevant groups. In large part, the associations have not been sufficiently robust to direct diagnosis or clinical management and underscore the genetic heterogeneity of the disease. B-cell subphenotypes most common among CVID patients include a severe reduction in switched memory B cells ($CD19^+$ $CD27^+$ IgD^-); some patients manifest expansion of transitional B cells ($CD19^+$ $CD24^{hi}$ $CD38^{hi}$), expansion of $CD21^{lo}$ B cells, or reduction in CD4 T-cell number.

Genetic Variants Associated With Common Variable Immunodeficiency

A few genes have been reported to be associated with CVID, including transmembrane activator and CAML interactor (TACI, *TNFRSF13B*), *CD19, ICOS,* and B-cell activating factor receptor (BAFF-R, *TNFRSF13C*) (see Fig. 49-3). TACI is a TNF receptor superfamily member, which is expressed at high levels on activated B cells and marginal zone B cells, and binds two ligands, B cell activating factor belonging to the TNF family (BAFF) and a proliferation-inducing ligand (APRIL). Similar to other TNF receptor superfamily members, TACI assembles as a trimer or higher order multimer. Heterozygous and homozygous mutations in TACI have been documented in 10% to 15% of CVID patients; however, they are also found at lower frequency in the general population. Thus the presence of TACI mutations is considered to be a predisposing factor to CVID rather than a disease-causing factor.

Mutations of CD19, CD81, and CD21, which are all components of the B-cell coreceptor, have been reported in few individuals. These defects do not affect B-cell development but impair signaling, causing hypogammaglobulinemia, a low number of switched memory B cells, and poor antibody response to T-independent antigens.

Mutations of inducible T cell co-stimulator (ICOS), a molecule expressed by activated T cells, account for rare cases of CVID. Most patients present during early adulthood with increased rates of respiratory infections. Autoimmune phenomena and lymphoproliferative disorders have been described.

One family with two affected older adult members exhibited homozygous mutation in BAFFR, with a 24–base pair deletion in the transmembrane region. One sibling was diagnosed at age 57 years with CVID; the other was 80 years old and essentially asymptomatic. Both exhibited hypogammaglobulinemia and normal response to T-dependent antigen but defective response to carbohydrate antigen. Peripheral B-cell numbers and percentage of memory B cells were low.

Finally, mutations of CD27, a molecule expressed by T, B, and NK lymphocytes, and an important costimulator of plasma cell differentiation, were identified in two individuals with hypogammaglobulinemia, defective antibody response to T-dependent antigens, and persistent EBV viremia (see Fig. 49-3).

Diagnostic and Therapeutic Approach to Defects in Humoral Immunity

- Defects in humoral immunity may be attributable to intrinsic defects in B-cell development and function or combined immunodeficiency disorders in which a lack of T-cell help is the primary cause of B-cell dysfunction.
- Age-specific norms must be used for children. IgG levels at birth reflect the maternally transferred antibody, which nadir between 2 to 6 months and then progressively rise with age. IgA and IgM levels rise continually with age until the teenage years.
- Based on enumeration of T, B, and NK cells, XLA (absence of B cells) can be rapidly ruled out.
- The finding of hyper-IgM with low IgG should prompt a workup for CD40L deficiency, CD40 deficiency, AID, and UNG. The likelihood of each of these is, of course, different depending on gender and family history. It is important to note that CD40L deficiency may present with a normal IgM.
- The diagnosis of CVID should only be made after other causes have been ruled out and should be made with caution, if at all, in children younger than 4 years of age. Disorders such as XLA, autosomal recessive agammaglobulinemia, various hyper-IgM syndromes, and XLP should be specifically considered and ruled out. Other diseases that may masquerade as CVID include other combined immunodeficiencies, cystic fibrosis, HIV, and conditions leading to immunoglobulin loss such as protein-losing enteropathy. Medications may cause a picture that looks like CVID. Finally, in adults, hypogammaglobulinemia may herald the development of thymoma or lymphoid malignancies and therefore may be secondary to evolving neoplasia.
- Treatment of patients with XLA and the hyper-IgM syndromes other than CD40L deficiency is long-term IVIG replacement, which is very effective.
- Experts disagree on whether patients with CD40L deficiency should be treated with early HCT, and currently, there are no clear predictors to determine who is likely to experience opportunistic infections. A patient with CD40L deficiency who has developed *Cryptosporidium* infection and sclerosing cholangitis generally has a much worse outlook with HCT.
- Treatment of patients with CVID with HCT is generally reserved for those with an alternate reason for allogeneic transplant such as lymphoid malignancy or lymphoproliferation that requires continual immunosuppression.

B-CELL–INTRINSIC DEFECTS OF CLASS SWITCH RECOMBINATION: DEFECTS OF ACTIVATION-INDUCED CYTIDINE DEAMINASE AND URACIL-N-GLYCOSYLASE

Maturation of the antibody response is associated with class switch recombination (CSR), whereby the μ heavy chain is replaced by other immunoglobulin heavy chains and somatic hypermutation (SHM), with introduction of mutations in the immunoglobulin variable region that allow affinity maturation. After CD40LG–CD40 interaction and activation of the NFκB signaling pathway, expression of activation-induced cytidine deaminase (AID) and of uracil-DNA-glycosylase (UNG) occurs in germinal center B lymphocytes (see Fig. 49-3). AID acts on the DNA of immunoglobulin heavy chain switch regions and converts cytidine to uridine, which is recognized and removed by UNG. The abasic sites are cleaved by a DNA endonuclease. DNA repair then brings together two different switch regions allowing CSR.

Mutations of AID and of UNG are inherited as autosomal recessive traits. Patients have recurrent bacterial infections. Autoimmune manifestations have been observed in several patients. Circulating B cells are present, but there is a severe reduction of all immunoglobulin isotypes with the exception of IgM, which are often elevated. Lymphadenopathy is common and is associated with expansion of germinal centers. SHM is severely compromised in patients with AID deficiency and follows an abnormal pattern in patients with UNG deficiency.

Treatment is based on regular administration of immunoglobulins and prompt recognition and therapy of infections.

CHAPTER 50

HISTIOCYTIC DISORDERS

Michael B. Jordan and Alexandra Hult Filipovich

The histiocytic disorders comprise a broad grouping of hematologic diseases united by the observation that monocyte/macrophages or dendritic cells appear to be the principal pathologic protagonists. The term *histiocyte* refers to phagocytic cells, historically identified on tissue sections but now more precisely defined as cells of the monocyte/macrophage lineage (Fig. 50-1). The ontogeny of these cells continues to be actively studied and debated, and their role(s) in pathogenesis is an active area of investigation. The characteristic cells seen in various histiocytic lesions can, in general, be differentiated by a variety of functional and phenotypic markers. The modern classification of the histiocytoses mirrors this biology (Table 50-1). Although malignant disorders involving monocyte/macrophages or dendritic cells were originally included in this classification, this chapter focuses solely on nonmalignant disorders in this category.

Of the dendritic cell–related histiocytoses, the most clinically prominent and common is Langerhans cell histiocytosis (LCH). This chapter also briefly discusses other dendritic cell–related histiocytic disorders, including juvenile xanthogranuloma (JXG); Erdheim-Chester disease (ECD); and sinus histiocytosis with massive lymphadenopathy (SHML), also referred to as Rosai-Dorfman disease.

The prominent monocyte/macrophage–related histiocytic disorder, hemophagocytic lymphohistiocytosis (HLH), is discussed in detail later in this chapter. In HLH, activated macrophages, activated T cells, and defective natural killer (NK) cells are the dysfunctional interactive partners.

Table 50-1 lists a currently accepted classification of histiocytic disorders. These disorders are a diverse grouping, ranging from benign skin lesions to rapidly life-threatening systemic disorders. Tables 50-2 and 50-3 list clinical features and commonly used pathological markers or features that may be used to help distinguish some of these disorders. The clinical diversity of histiocytic disorders is underscored by recent discoveries related to their pathogenesis. Studies dating to the late 1990s have demonstrated that HLH (at least in its familial form) is a primary immune deficiency, albeit a very unique one. Demonstrations of clonality as well as genetic abnormalities of B-Raf now suggest that LCH is a benign neoplasm despite its variable clinical phenotype. The pathogeneses of less common dendritic cell– and macrophage-related histiocytic disorders are still unknown.

LANGERHANS CELL HISTIOCYTOSIS

Langerhans cell histiocytosis is the most common of the histiocytoses. The central cell of LCH, the Langerhans dendritic cell, was first described in 1868 by 21-year-old Paul Langerhans. Between 1893 and 1920, Hand, Schüller, and Christian described the various nonfatal presentations of LCH, which include bony lesions, skin rash, and diabetes insipidus (DI). Letterer and Siwe (1924 and 1933, respectively) added to the list of clinical presentations by describing cases with liver and spleen involvement in infants and toddlers. These disorders were later grouped under the term *histiocytosis X* (denoting the uncertainty about disease pathogenesis) by Lichtenstein. It was eventually theorized by Nezelof (1973) that histiocytosis X is due to a proliferation of pathologic Langerhans cells. At present, the term *LCH* has been adopted to refer to all of the varied manifestations of this protean disorder. It is now well recognized that LCH can present at any time in life from the neonatal period to old age. LCH lesions may spontaneously regress or repeatedly "reactivate," contributing to long-term disabilities such as DI or a neurodegenerative disease. Life-threatening forms of LCH, previously referred to as Letterer-Siwe disease, typically present in infancy and clearly require intensive therapy and sometimes salvage treatment such as allogeneic bone marrow transplantation (BMT) to cure the children.

Epidemiology

The incidence of LCH has been estimated to be between five and 15 cases per million children, per year. The incidence of LCH in adults is believed to be lower than in children but is likely underestimated because of a lack of recognition of LCH in adult medicine. Notably, LCH does not appear to have significant geographic or ethnic predilections. Although families with multiple cases of LCH have been reported, these kindreds are extremely rare. One notable clinical or epidemiologic association reported thus far involves an unexplained coincidence of both LCH and leukemia (of various subtypes) in rare patients.

Pathobiology

The understanding of the pathobiology of LCH is currently undergoing significant evolution driven by new insights into both normal and disease-associated Langerhans cells. Over the years, LCH has been classified as a neoplasm, a reactive disorder, or an aberrant immune response. LCH cells are pathologic in that they bear heterogeneous characteristics not normally identified in healthy Langerhans cells that are typically resident in the skin. The granulomatous lesions of LCH, which can be found in nearly any organ, represent an accumulation of normal inflammatory cells, including eosinophils, lymphocytes (especially T cells), and macrophages, in addition to the LCH cells. The clinically benign behavior of most cases, including spontaneous remissions and lack of aggressive disease evolution with recurrences, as well as the benign histopathologic appearance of lesions, have suggested a nonmalignant etiology. The failure of many laboratories to culture pathologic Langerhans cells has reinforced this impression. Thus LCH has been hypothesized to be a reactive or immunologic disorder by many. On the other hand, lesional Langerhans cells have been demonstrated by several investigators to be clonal. This observation, combined with the clinical utility of antineoplastic drugs, has bolstered the opinion that LCH may be a neoplastic disorder.

A recent report (which has been independently confirmed) of highly prevalent B-Raf mutations in lesional Langerhans cells has again shifted thinking and strongly supports a neoplastic etiology. The mutation in question (B-Raf, V600E) is well described in both malignant melanomas and in benign nevi, among other neoplasms. This mutation leads to activation of the extracellular signal-related kinase (ERK) pathway. Along with these disease-specific findings, understanding of the biology of normal Langerhans cells has advanced. Cutaneous Langerhans dendritic cells have been shown to arise from in situ precursors, but during inflammation or stress, to arise from circulating myeloid precursors. Therefore, a picture is emerging in

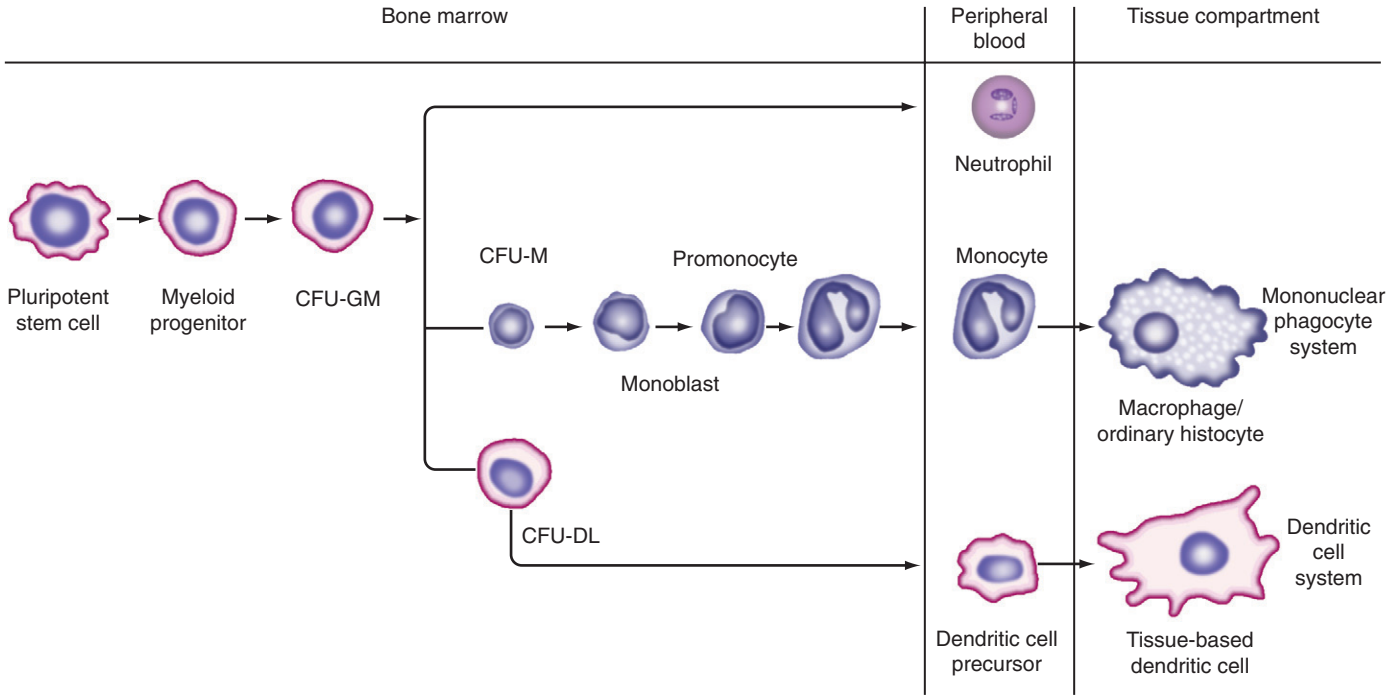

Figure 50-1 DEVELOPMENT OF CELLS OF THE MONOCYTE/MACROPHAGE LINEAGE. *CFU-DL,* Colony-forming unit–dendritic Langerhans cell; *CFU-GM,* colony-forming unit–granulocyte-macrophage; *CFU-M,* colony-forming unit–macrophage.

Table 50-1 Classification of Histiocytic Disorders: Benign Disorders of Varying Biologic Behavior

A. Dendritic cell related
Langerhans cell histiocytosis
Juvenile xanthogranuloma and related disorders including:
- Erdheim-Chester disease
- Solitary histiocytomas with juvenile xanthogranuloma phenotype
- Secondary dendritic cell disorders

B. Monocyte/macrophage-related
Hemophagocytic lymphohistiocytosis: familial and sporadic
Secondary hemophagocytic syndromes
- Infection-associated
- Malignancy-associated
- Autoimmune-associated

Sinus histiocytosis with massive lymphadenopathy (Rosai-Dorfman disease)
Solitary histiocytoma of macrophage phenotype

which the acquisition of mutation(s), such as B-Raf V600E, in myeloid precursors may cause a neoplastic proliferation of a terminally differentiated clone that colonizes a distinct anatomic location. Similar to a cutaneous nevus, this neoplasm is a benign one because lesional cells are not fully transformed. Thus recent findings support the hypothesis that LCH is a benign hematopoietic neoplasm, or a hematopoietic "mole." Thus far, there has been no compelling insight into why LCH has such diverse manifestations, ranging from solitary to widely disseminated disease.

Clinical Manifestations

Clinical involvement with LCH can be highly variable but most often involves bony lesions (present in ≈80% of cases), which may be painful or painless; the latter is common with skull lesions. Skin involvement, typically papulosquamous lesions, often affecting the scalp (and frequently mistaken for cradle cap, seborrhea) is reported in 30% to 60% of patient series. Soft tissue swelling, often in proximity to bony lesions, external ear drainage, enlargement of lymph nodes and thymus, and gum hypertrophy with premature eruption of baby teeth are also well-recognized manifestations. More serious systemic involvement occurs when there is hepatosplenomegaly, liver dysfunction, lung scarring, and hematopoietic failure with or without intestinal involvement. The latter findings are more typical of the widely disseminated form of LCH seen in young infants, which carries a high mortality rate.

Bony Involvement

Solitary or multifocal bony lesions are found predominantly in older children and young adults, usually within the first 3 decades of life. Such lytic bone lesions are commonly referred to as *eosinophilic granuloma* because of their pathologic appearance. The incidence of bone lesions peaks between 5 and 10 years of age. Solitary or multifocal eosinophilic granuloma (with or without involvement of other organ systems) represents approximately 60% to 80% of all instances of LCH. Patients with systemic involvement frequently have bone lesions in addition to other manifestations of disease. Patients often cannot bear weight and may have tender swelling caused by tissue infiltrates overlying the bone lesions. Radiographically, the lesions are sharply marginated, round, or oval and usually have a beveled edge on radiography that gives the appearance of depth. Hand-Schüller-Christian disease, referring to the triad of bony involvement, skin lesions, and DI, is most commonly described in younger children, ages 2 to 5 years. It represents 15% to 40% of these patients, although this type of involvement can be observed in patients of all ages. Signs and symptoms include bony defects with exophthalmos, with a tumor mass in the orbital cavity being characteristic. This condition usually occurs from involvement of the roof and lateral wall of the orbital bones. In addition, teeth are often lost because of gum infiltration or mandibular involvement (Fig. 50-2).

The most frequent sites of skeletal involvement include the flat bones of the skull, ribs, pelvis, and scapula. There may be extensive involvement of the skull, with irregularly-shaped, lucent lesions giving rise to the so-called geographic skull. Long bones and lumbosacral vertebrae, usually the anterior portion of the vertebral body, are involved less frequently. Involvement of the vertebral bodies may lead to collapse *(vertebra plana)* as the principal or only presenting

Table 50-2 Clinical Features of the Non–Langerhans Cell Histiocytosis, Non–Hemophagocytic Lymphohistiocytosis Histiocytoses

Diagnosis	Ages	No. of Lesions	Appearance	Common Sites	Natural History
JXG	0-18 yr (median, 2 yr)	Single : multiple 9 : 1 (disseminated in <6 mo)	Reddish progressing to yellow brown	Head and neck	Gradual involution
Giant JXG	Young	Single	>2 cm	Upper extremity or back	Involution
Systemic JXG (4% of JXG)	(3 mo*)	Single, multiple	Almost 50% have no skin lesions	Subcutis, liver, spleen, lung, CNS, iris	May involute (4%-10% fatal)
Adult XG	18-80 (35 yr*)	Single	Same as JXG	Upper body	No involution
BCH	Young child	Few, multiple	Reddish-tan papules	Head and neck	Involution or progression to XG
GEH	Young adult	Disseminated	Reddish-tan papules in crops	Face, trunk, arms	Involution or progression
XD	Young adult	Disseminated	Yellow/reddish-brown plaques and nodules	Eyelids, mucosae, viscerae, CNS	Slow involution or progression
PNH	40-60 yr	Disseminated	Xanthoma, nodules	Skin, subcutis	Progression to disfigurement
MRH	40 yr+	Multiple	Pink/reddish-brown or yellow	Head, extremities with erosive polyarthritis	Progression
SHML	Wide age range (20 yr*)	Mainly systemic	Firm indurated papules	Cervical adenopathy, 80% "B" symptoms, extranodal (43%)	Exacerbations and remissions (5%-11% fatal)
ECD	7-84 yr (53 yr*)	Mainly systemic	Xanthelasma, xanthoma	Long bone sclerosis, retroperitoneal fibrosis	Highly fatal

manifestation. In such cases, the diagnosis may be problematic, although biopsy is typically not advisable unless a soft tissue mass is present. In long bones, growth of lesions in the medullary cavity leads to pressure that may result in erosion through the cortex, stimulating the formation of periosteal new bone accompanied by soft tissue extension. The differential diagnosis includes Ewing and osteogenic sarcoma, bone lymphoma, benign bone tumor and cyst, and infection. Involvement of the wrists, hands, knees, feet, or cervical vertebrae is less common. Orbital involvement may result in vision loss or strabismus caused by optic nerve or orbital muscle involvement, respectively, and may mimic preseptal cellulitis. Oral involvement commonly affects the gums, palate, or both. Erosion of the lamina dura gives rise to the characteristic "floating tooth" seen on dental radiographs. The entire mandible may be involved (see Fig. 50-2), with loss of bone leading to diminished height of the mandibular rami. Erosion of gingival tissue causes premature eruption, decay, and tooth loss. Parents of affected children, particularly infants, frequently report precocious eruption of teeth when, in fact, the gums are receding leading to exposure of immature dentition. Chronic otitis media caused by involvement of the mastoid and petrous portion of the temporal bone, leading to otitis externa is common.

Cutaneous Involvement

Cutaneous involvement by LCH is both common (occurring in 20%-40% of patients) and highly variable. The rash is typically a scaly seborrheic, eczematoid, sometimes purpuric rash involving the scalp, ear canals, abdomen, and intertriginous areas of the neck, face, trunk and groin (Fig. 50-3). The rash may be maculopapular or nodulopapular. Ulceration may result, especially in intertriginous areas, and may be painful. Mild, isolated cutaneous involvement is

relatively common in young infants. Rarely, LCH may present as deep subcutaneous skin nodules only (formerly described as Hashimoto-Pritzker syndrome), typically in young infants.

Involvement of Other Organ Systems

A subset of infants and toddlers with LCH have involvement of the spleen, liver, or bone marrow (BM), usually in addition to prominent skin involvement and variable bony disease. This clinical phenotype, previously referred to as Letterer-Siwe disease, is the most severe manifestation of LCH and the only form that is likely to be life threatening. Involvement of the BM, usually as evidenced by cytopenias, is an especially poor prognostic factor. Of note, unlike with other tissues, biopsy of the BM in these patients does not typically reveal an obvious infiltrate with $CD1a^+$ cells but rather tends to have a dysplastic appearance. Liver involvement may be severe, leading to significant cholestasis, hypoproteinemia, and diminished synthesis of clotting factors.

Langerhans cell histiocytosis can have a strictly nodal presentation, not to be confused with SHML, also known as Rosai-Dorfman disease. This presentation is characterized by significant enlargement of multiple lymph node groups with little or no other signs of disease. Thymic involvement is relatively common in children with multisystem involvement. Pancreatic and thyroid involvement have also been reported. Gastrointestinal tract disease has rarely been identified. It is sometimes associated with severe symptoms of diarrhea, malabsorption, and hypoproteinemia.

Isolated pulmonary involvement usually is seen in young adults in their third or fourth decades of life and occasionally in adolescents. It may follow a severe and often chronic debilitating course; patients may present with pneumothorax. Cigarette smoking has been strongly implicated in primary pulmonary histiocytosis. In contrast, pulmonary involvement in younger patients with systemic disease frequently is mild, although fulminant pulmonary disease may occur. Findings on chest radiographs vary from a diffuse infiltrate consistent with bilateral interstitial pneumonia to a "honeycomb lung" appearance (Fig. 50-4).

Figure 50-2 COMPUTED TOMOGRAPHIC SCAN OF A DESTRUCTIVE LANGERHANS CELL HISTIOCYTOSIS MANDIBULAR LESION IN A CHILD.

Other Clinical Features

Diabetes insipidus affects 5% to 40% of patients with LCH, depending on the report. Most instances of DI occur in children who present with systemic disease and involvement of the orbit and skull. Fewer than one-third of children who ultimately develop DI have polydipsia and polyuria as presenting symptoms of LCH. Most cases of DI present within 4 years of diagnosis. DI is caused by infiltration by Langerhans cells and macrophages into the hypothalamus with or without involvement of the posterior pituitary gland (Fig. 50-5). DI may occur at any time during the course of LCH. Patients should be instructed to report signs of DI as soon as they develop because dehydration and electrolyte imbalance may be quite serious. In addition, definitive documentation of DI with measurement of serum and urine electrolytes and osmolality before and after a several-hour water deprivation period should be performed. Vasopressin levels can be measured to document a deficiency. The effectiveness of LCH treatment for reversal of new-onset DI is controversial.

Short stature has been found in up to 40% of children with systemic LCH. Chronic illness and steroid therapy are believed to play an important role in this phenomenon. However, short stature also may be a consequence of anterior pituitary involvement and growth hormone deficiency, which can occur in up to half of patients with initial anterior pituitary dysfunction. Other endocrine manifestations include hyperprolactinemia and hypogonadism caused by hypothalamic infiltration.

A severe complication or manifestation of LCH is the development of a delayed central nervous system (CNS) neurodegenerative syndrome. This CNS involvement is typically seen in children who had classic lytic bony involvement or soft tissue mass lesions in or

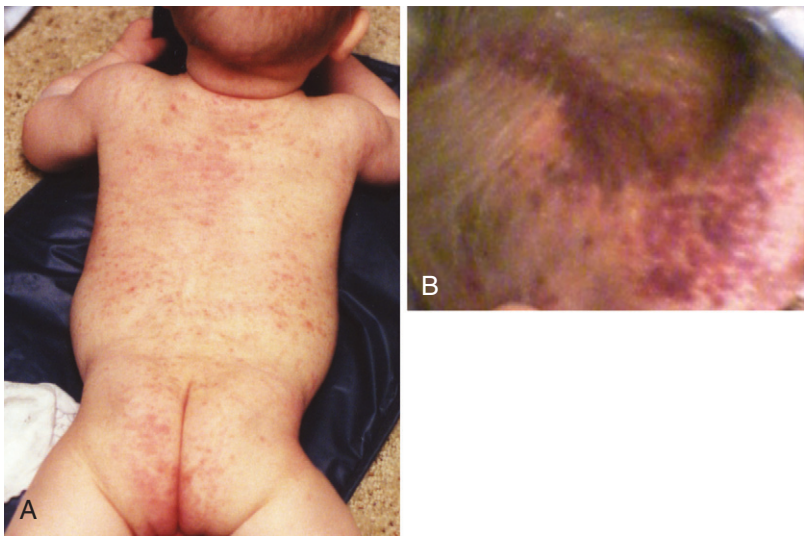

Figure 50-3 SKIN INVOLVEMENT IN LANGERHANS CELL HISTIOCYTOSIS. **A,** Diffuse maculopapular rash. **B,** Hemorrhagic scalp rash.

around the CNS years earlier. Delayed CNS involvement is typically diagnosed after a prolonged, sometimes insidious, decrease in school function. Magnetic resonance imaging (MRI) reveals diffuse or polymorphic lesions involving the white matter of the cerebellum, pons, and cerebral hemispheres. Limited biopsy studies have revealed an inflammatory infiltrate, predominated by $CD8^+$ T cells. Such findings suggest that this form of CNS involvement is analogous to a paraneoplastic syndrome. However, the timing (usually years after disease resolution) and the lack of concurrently active LCH in most patients are unique to this syndrome. Currently, there are no agreed upon diagnostic criteria for CNS LCH, but neurologic involvement (as evidenced by neuropsychiatric testing) with or without MRI findings is essential. Of note, although abnormal MRI findings (with white matter lesions) may precede clinical manifestations, such findings do not always correlate with clinical disease (even in retrospect). Lesions involving the CNS itself or bony lesions of the skull base and facial bones (but not the calvarium or mandible) are thought to confer the greatest risk for subsequent development of this complication.

Laboratory Manifestations

Langerhans cell histiocytosis is the most common and prominent of numerous dendritic cell–related histiocytic disorders. Tables 50-2 and 50-3 list the clinical and pathologic features that help to describe and distinguish LCH from other, much rarer, histiocytic disorders (as well as SHML and HLH, discussed in the next section). The typical histologic appearance of LCH varies with the age of the lesion examined (Fig. 50-6). The Langerhans cell is the essential diagnostic feature in the histology of LCH. Early lesions often are locally destructive, with proliferation and accumulation of phenotypically and functionally immature Langerhans cells. Mitoses usually are not present in great numbers but when found are of no known prognostic significance. Multinucleated giant cells are commonly noted. Other inflammatory cells, such as granulocytes, eosinophils, macrophages, and lymphocytes, are also present. Giant cells and macrophages may be phagocytic and, over time, may accumulate cholesterol. As lesions mature or show signs of regression, fewer Langerhans cells are present, and development of fibrotic reaction is less. The diagnosis of LCH relies on the immunohistochemical identification of the presence of Langerhans cells by cell surface CD1a or by the presence of Birbeck granules by electron microscopy in biopsied lesions. Pathologic criteria for the diagnosis of LCH have been established and were formalized by the Histiocyte Society in 1987. With the availability of antibodies to CD1a for use in routinely processed paraffin-embedded specimens, electron microscopy is rarely needed. Of note, $CD1a^+$ Langerhans cells are known to accumulate at the sites of inflammation and may be seen at the margins of malignant lesions. Thus care should be taken that an adequate biopsy specimen has been obtained to observe the full context of a putative lesion.

Unlike with many malignancies, there are no predictive pathologic features that may define "favorable" or "unfavorable" histology. Although patients are grouped based on their organ system involvement, untreated patients generally do not progress to a different grouping. Within a few months after presentation, it will become apparent that the lesions seen initially are limited to the skeleton or were the "heralding lesion(s)" of diffuse systemic involvement. When cutaneous involvement is the only obvious presenting sign, several months may be required to determine the ultimate extent of disease.

Patients who are suspected to have LCH or who have a new biopsy-proven diagnosis of LCH should have a screening positron emission tomography (or plain radiography and bone scan, although this has been demonstrated to be less sensitive) to help determine the extent of disease involvement. All patients should be evaluated with a complete blood count, chemistries including liver function tests, coagulation workup, and urine osmolality. Dental examination and radiographs should also be considered. The occurrence of cytopenias, particularly thrombocytopenia, in the presence of liver or spleen involvement may be diagnostic of BM involvement.

Differential Diagnosis

The differential diagnosis of LCH depends on the clinical presentation and is typically clarified with a tissue biopsy. Skin involvement frequently mimics seborrheic dermatitis, albeit with a severe or refractory course. Immunodeficiency syndromes or viral infection must be considered as well. The differential diagnosis of bony lesions, although typically quite distinctive, may include bone cyst, lymphoma, sarcoma, or metastatic solid tumor. Chronically draining ears from

Sometimes these histiocytes show more vacuolization or xanthomatization. **H,** Scattered Touton-type giant cells are present.

temporal bone involvement is often diagnosed as chronic otitis media. Liver and spleen involvement must be distinguished from leukemia and storage diseases.

Prognosis

The prognosis of patients with LCH is largely determined by the nature of their disease presentation and their response to initial therapies. In general, the only patient population with significant mortality rates are those with visceral, or so-called "risk organ," involvement (e.g., liver, spleen, or BM). Furthermore, the international Histiocyte Society conducted a clinical trial (LCH-II) that identified the response after an initial 6 weeks of therapy with weekly vinblastine and daily prednisolone as the single most important factor in predicting mortality in patients with risk organ involvement. Of the approximately 79% of patients who responded to initial therapy, 94% were alive at 5 years, but only 11% of the nonresponders survived. These important data suggest that alternative therapies should be tested early during the course of therapy for patients with poor early responses. Based on early clinical trials, a staging system was developed for the LCH-III trial that will be further modified in the upcoming LCH-IV trial.

Therapy

A generally accepted standard for initial treatment of patients with LCH is use of an appropriate amount of the least toxic therapy to treat the disease. In patients with potentially morbid or life-threatening disease at presentation or in those who develop morbid or life-threatening disease during the course of treatment, alternative and sometimes more aggressive treatment should be implemented. This approach emphasizes the need for treatment protocols based on careful prognosis-based risk stratification. Whether more intense upfront therapy in lower risk patients can reduce disease sequelae such as DI, CNS degeneration, sclerosing cholangitis, or disease recurrence is currently under evaluation. For the majority of patients with localized or limited systemic disease, the goal of therapy should be minimizing loss of function and preventing cosmetic deformity. Seborrhea-like dermatitis of the scalp may improve with use of a selenium- or phenol-based shampoo. Topical steroids can be effective, but prolonged exposure or use on the face should be avoided. Topical nitrogen mustard has been used for problematic focal skin lesions. In patients with particularly refractory and extensive skin involvement, psoralen ultraviolet A (PUVA) can be effective. These topical therapies have not been studied in clinical trials.

Surgery and Radiotherapy

Patients with disease involving a single bone usually can be managed with local therapy. This most often involves surgical curettage for patients whose lesions are in easily accessible, noncritical locations. Complete "cancer operation" resections are not considered necessary and should be avoided to reduce cosmetic and orthopedic deformities as well as loss of function. Local soft tissue disease (e.g., scalp, thymus, lymph nodes) generally recurs despite surgery; thus additional treatment with antiinflammatory or cytoreductive drugs is usually required. Because of concerns about the development of secondary malignancies, systemic therapy usually is favored over radiation. However, local radiotherapy is indicated under certain circumstances, for example, when patients are at risk for visual or hearing loss, skeletal deformity, spinal cord injury, or severe pain when systemic therapy is not rapidly effective.

Chemotherapy

Historically, drugs used in therapy for classic malignant diseases have been used for the systemic or local treatment of LCH. A variety of drugs, including vinblastine, vincristine, cytarabine, nitrogen mustard, cyclophosphamide, procarbazine, chlorambucil, etoposide, methotrexate, corticosteroids, and 6-mercaptopurine (6-MP), have been used, alone or in combination, with variable success. Therapeutic advances for LCH in recent years have largely come from international cooperative trials conducted by the Histiocyte Society. The Histiocyte Society is currently developing the next international trial, LCH-IV, which has strata allowing for the enrollment of all patients with LCH, either as a treatment or as a registry study. For patients not enrolled on LCH-IV, detailed treatment recommendations are available on the Histiocyte Society's website (http://www.histio.org).

A reasonable therapeutic approach to systemic therapy is to observe patients with limited, single-system disease who respond to local (i.e., surgery, radiation) or nonsystemic (i.e., topical steroids) therapy and look for signs of disease resolution. If persistent symptomatic lesions or evidence of progressive disease is seen, systemic treatment should be pursued. Patients with disease that is localized to skin, bone, and lymph nodes (defined as "non-risk" organs) generally have a good prognosis and may require only minimal treatment. Extensive refractory skin disease may warrant systemic therapy with low-dose oral methotrexate, vinblastine–prednisone, or low-dose cytarabine or with topical therapy such as nitrogen mustard.

Multisystem disease or multifocal bony disease usually warrants treatment with systemic chemotherapy. The current standard of care is a risk-adapted approach, largely using vinblastine, prednisone, and 6-MP, based on the LCH-III trial. This approach has evolved in a stepwise fashion from previous multicenter trials conducted by international groups (DAL-HX 83/90 protocols [Austria, Germany, Switzerland, Netherlands], LCH-I, and LCH-II). All of these protocols were risk adapted and were based on different combinations of prednisone, vinblastine, etoposide, methotrexate, and 6-MP. The Histiocyte Society has stratified patients with LCH into "low-" (LR) and "high-" (HR) risk groups based on outcomes related to the extent and location of the LCH lesions. LR patients include patients with skin, bone, lymph node, and pituitary involvement. Patients with liver, spleen, or BM involvement usually have a worse prognosis and are considered higher risk. Children with lung LCH, without involvement of other HR organs, are generally not considered to be HR. Additionally, LR patients believed to have lesions that may increase their future risks of CNS degenerative disease (lesions within the CNS, skull base, or facial bones) are designated as "CNS risk."

Alternative treatment has not been standardized for patients with recurrent or refractory disease. Patients with recurrent disease (i.e., disease that reappears after a period of remission) often respond well to the drugs with which they initially were treated. Several studies, including an international phase II trial, have demonstrated significant activity of 2-chlorodeoxyadenosine (2-CdA) against recurrent and refractory LCH. In addition, the combination of 2-CdA and high-dose cytarabine has been used in refractory, high-risk patients. BMT for high-risk or refractory patients warrants further evaluation in the context of a controlled clinical trial.

Long-Term Follow-Up

Retrospective analysis of "CNS risk" patients treated with only surgery, steroid injection, radiation therapy, or a single chemotherapy drug have a 40% incidence of DI. If they receive vinblastine and prednisone for 6 months the incidence of DI is 20%. Complications of developing DI include a significant incidence of anterior pituitary hormone deficiencies or neurodegenerative syndrome. Patients with neurodegenerative syndrome may have ataxia, dysarthria, dysmetria, and learning and behavior difficulties. The diagnosis may be aided by brain MRI, in which T2 hyperintense signals in the cerebellum, basal ganglia, or pons may be present, but such abnormalities do not always correlate with clinical disease or vice versa. Treatment with intravenous immunoglobulin (IVIG) or low-dose cytarabine has anecdotally resulted in stabilization of these symptoms.

A retrospective analysis by Willis et al of 71 patients from a single institution followed for a median of 8.1 years from diagnosis revealed the presence of significant late sequelae in 64% of patients followed for more than 3 years. Skeletal defects were found in 42%, dental problems in 30%, DI in 25%, growth failure in 20%, sex hormone deficiency in 16%, hypothyroidism in 14%, hearing loss in 16%, and CNS dysfunction in 14%. The risk of malignancy in patients with LCH undergoing radiation and chemotherapy is well documented. Thus judicious use of radiotherapy, avoidance of potentially carcinogenic chemotherapeutic agents, and good supportive care are recommended. Leukemia in LCH patients treated with etoposide as a single agent and in combination with other agents has been reported. Because etoposide was not shown to be any more effective than vinblastine in both the LCH-I and LCH-II trials for patients without risk organ involvement, there does not appear to be reason to include this leukemogenic agent in the treatment of these patients with newly diagnosed LCH.

Another serious late effect of LCH is sclerosing cholangitis, which may lead to secondary biliary cirrhosis and liver failure. Sclerosing cholangitis may develop years after successful therapy for LCH and does not typically signify disease recurrence. The only successful treatment of sclerosing cholangitis has been liver transplantation. Other late complications of LCH are pulmonary cyst formation, fibrosis, and chronic pneumothoraces. No effective treatment is available, and progression to cor pulmonale and respiratory failure may occur. Lung transplantation has been used for treatment of such patients. Thus all patients with LCH require long-term follow up. In addition to late malignancies, patients should be monitored for signs of long-term disabilities, including cosmetic, orthopedic, and cutaneous deformities that may lead to loss of function and emotional disorders, loss of permanent dentition, endocrinologic disorders and growth failure, hearing impairment, CNS abnormalities and neurocognitive function, sclerosing cholangitis with biliary cirrhosis, and pulmonary fibrosis and cor pulmonale.

Future Directions

The treatment of LCH has undergone significant refinement over the past decade. However, therapy remains empirically defined. With the recent insights into the pathophysiology of LCH, such as B-Raf mutations, new possibilities for more intelligently designed, targeted therapies are conceivable. Future clinical trials for such targeted therapies will likely focus on patients with therapy-resistant risk organ involvement because these children have the least satisfactory outcomes.

JUVENILE XANTHOGRANULOMATOUS DISEASE

Juvenile xanthogranuloma (or more broadly, the full spectrum of juvenile xanthogranulomatous diseases) is a dendritic cell–related histiocytic disorder. JXG most commonly affects infants and young children and presents as a solitary or a few "fleshy nodules." These red-yellowish, benign-appearing lesions are sometimes mistaken for molluscum. However, when biopsied, these lesions reveal a distinctive pathology (see Fig. 50-6). Multinucleated, Touton giant cells are usually found, and lesional histiocytes are positive for CD14, CD68, CD163, factor XIIIa, and fascin, suggesting that they are dermal dendrocytes. The cells are usually negative for CD1a, S100, and the plasmacytoid monocyte antigen CD123.

Juvenile xanthogranuloma most commonly presents as a single skin lesion in infants and young children. The lesions are nodular and usually yellowish to reddish purple. Lesions may vary significantly in size and number but often are several millimeters to 1 cm in size and solitary. However, in some patients, the lesions become widespread and quite disfiguring (Fig. 50-7). Furthermore, JXG may

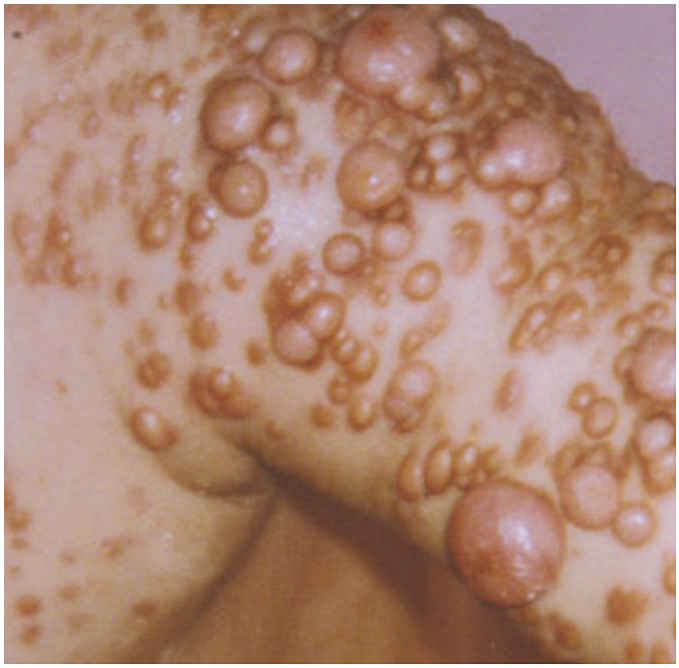

Figure 50-7 EXTENSIVE JUVENILE XANTHOGRANULOMATOUS DISEASE IN AN INFANT.

become systemic, involving multiple organs, including the liver, lungs, heart, and CNS. CNS involvement can present with seizures, hemiplegia, and increased intracranial pressure. Patients diagnosed with JXG, particularly multifocal JXG, may benefit from screening CT scans to rule out disseminated involvement, particularly if clinical history suggests this. However, regardless of clinical symptoms, all patients with JXG should have ophthalmologic examination to rule out anterior chamber involvement and prevent potentially blinding complications.

Cutaneous JXG lesions usually resolve over several months and require no treatment. Of note, residual pigmented areas may persist indefinitely even after lesions have regressed. In patients in whom JXG becomes systemic and involves multiple organs, systemic chemotherapy similar to that for patients with LCH has been used. In patients who do not respond to initial treatment with vinblastine and steroids, use of other agents, such as methotrexate, steroids, and 2-CdA, has led to responses, according to anecdotal reports.

ERDHEIM-CHESTER DISEASE

Erdheim-Chester disease is a rare, non-Langerhans form of histiocytosis first described in 1930 with a wide range of manifestations. The number of new cases has dramatically increased over the past 10 years because of the better recognition of this condition. The natural evolution is variable, but the prognosis in the absence of effective therapy is poor.

Erdheim-Chester disease is seen most commonly in patients 50 years or older. It usually presents with xanthoma-like skin nodules and bilateral lower limb bone pain. Patients with more disseminated disease may have cardiopulmonary insufficiency; renal failure caused by characteristic retroperitoneal and perinephric infiltrative or constrictive changes; and CNS involvement manifested by ataxia, DI, and altered mental status. They may also have periorbital involvement with exophthalmos and impingement on the optic nerves. The disease may be progressive and fatal. The pathophysiology of ECD remains a mystery, although a plasma cytokine profile consisting of elevated interferon-α (IFN-α), interleukin-12 (IL-12), monocyte chemotactic protein-1 (MCP-1), IL-4, and IL-7 in these patients suggests a systemic immune perturbation.

Table 50-4 Diagnostic Criteria for Hemophagocytic Lymphohistiocytosis, Established for the Conduct of the Hemophagocytic Lymphohistiocytosis-2004 Trial

The diagnosis of HLH may be established by:*

A. A molecular diagnosis consistent with HLH: Pathologic mutations of *PRF1, UNC13D, Munc18-2, Rab27a, STX11, SH2D1A,* or *BIRC4*
 or
B. Five of the eight criteria listed below are fulfilled:
 1. Fever ≥38.3° C
 2. Splenomegaly
 3. Cytopenias (affecting at least two of three lineages in the peripheral blood)
 4. Hemoglobin <9 g/dL (in infants <4 weeks: hemoglobin <10 g/dL)
 Platelets <100 × 10^3/mL
 Neutrophils <1 × 10^3/mL
 5. Hypertriglyceridemia (fasting >265 mg/dL) or hypofibrinogenemia (<150 mg/dL)
 6. Hemophagocytosis in BM, spleen, lymph nodes, or liver
 7. Low or absent NK cell activity
 8. Ferritin >500 ng/mL
 9. Elevated soluble CD25 (soluble IL-2 receptor α)

BM, Bone marrow; *HLH,* hemophagocytic lymphohistiocytosis; *IL-2,* interleukin-2; *NK,* natural killer.
*Additionally, in the case of familial HLH, no evidence of malignancy should be apparent.

First-line treatment for ECD consists of IFN-α. Other effective treatments have been limited, although responses have been observed with steroids, vinblastine plus steroids, methotrexate, 2-CdA, and bisphosphonates, in addition to IFN-α. Autologous hematopoietic BMT has been reported as a therapeutic modality.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS

In the broad classification of histiocytic disorders (see Table 50-1), HLH is categorized as a monocyte/macrophage–related histiocytic disorder. HLH derives its name from its sometimes distinctive pathology (hemophagocytosis) in which macrophages appear to be widely infiltrating tissues and engulfing blood and BM cells in a nonspecific fashion. However, HLH is best conceptualized as an immune regulatory disorder, which is characterized by clinical signs and symptoms of extreme inflammation and the development of cytopenias, hepatitis, and CNS dysfunction which are severe and life threatening.

Hemophagocytic lymphohistiocytosis was first described as a familial disease by Farquhar and Claireux in 1952, which they named *familial haemophagocytic reticulosis*. Through the years, the syndrome of HLH has been recognized as both a sporadic and familial disorder and in various clinical contexts. Although we prefer to lump each of these clinical variations into a single syndrome (HLH), the medical literature has used a plethora of names: familial erythrophagocytic lymphohistiocytosis (FEL), viral-associated hemophagocytic syndrome (VAHS), and malignancy-associated hemophagocytic syndrome (MAHS), among others. Furthermore, macrophage activation syndrome (MAS), the systemic inflammatory syndrome observed in association with rheumatologic disorders, is likely a variant of the HLH syndrome because both "classic" HLH and MAS have similar clinical phenotypes and appear to share some underlying mechanisms. The International Histiocyte Society formally adopted the name of HLH in 1998 and defined criteria for its diagnosis, which were updated in 2004 (Table 50-4).

Epidemiology

The true incidence and prevalence of HLH are unknown and remain difficult to ascertain accurately. The diagnosis of HLH is challenging

because of its variable presentation and the many nonspecific clinical features it shares with other disease processes. HLH is considered to be rare, but increasing awareness and recognition of the syndrome is leading to more frequent diagnoses. Currently, it is estimated that the autosomal recessive forms of familial HLH have a prevalence of one in 50,000 live births. A recent report estimated the incidence of HLH in tertiary care pediatric hospitals at one case of HLH per 3000 inpatient admissions. Because of the typically autosomal recessive nature of familial HLH, this disorder is reported to occur more frequently in isolated populations or kindreds with consanguinuity.

Pathobiology

The immunologic basis of HLH was long suspected because of its inflammatory nature and the finding of cytotoxic deficiencies and other immune abnormalities in patients with HLH. The first confirmation that HLH is an immunodeficiency came in 1999 with the discovery of perforin mutations in affected patients. However, unlike other immunodeficiencies, the principal clinical characteristic of HLH is one of intense, prolonged, systemic inflammation rather than unusual or severe infections. Although this inflammation may be triggered by infection or vaccination, the inflammation itself (and not apparently the sometimes benign or transient infection) appears to drive the clinical features of HLH. Thus familial HLH appears to be a deficiency of immune regulation. Animal studies have begun to detail how this immune regulation functions and how deficiencies may lead to HLH. In brief, cytotoxic lymphocytes kill not only infected cells but also antigen-presenting cells (APCs). These APCs promote T-cell activation during infection. This persistence of activating signals leads to excessive or prolonged acute T-cell activation. Abnormal T-cell activation, in turn, leads to activation of macrophages and the development of disease pathology. In animal models, INF-γ appears to be the critical nexus between T-cell activation and disease development. In several published series, INF-γ appears to be elevated in patients with HLH. However, clinical data appear mixed, and it remains uncertain whether INF-γ is critical for HLH development in all patients. An underlying lesion of immune regulation and the associated pathophysiology is less clear in apparently sporadic cases of HLH, sometimes referred to as *secondary HLH*. However, the traditional dichotomy between primary (familial) HLH and secondary HLH (associated with infections, malignancy, or autoimmunity) is becoming increasingly murky.

Hemophagocytic lymphohistiocytosis may present in a variety of clinical contexts and with a variety of etiologic associations. Patients are often categorized as having either "primary" or "secondary" HLH. Patients in the primary HLH category are those with clear familial inheritance or genetic causes, are usually infants or younger children, and are thought to have fixed defects of cytotoxic function (although this is not always the case). These patients have a clear risk of HLH recurrence and will not survive long term without hematopoietic cell transplantation (HCT). Although HLH in these patients can be associated with infections (e.g., cytomegalovirus [CMV] or Epstein-Barr virus [EBV]) or vaccination, the immunologic trigger is often not apparent. The term *secondary HLH* generally refers to older children (or adults) who present without a family history or known genetic cause for their HLH. These patients typically have concurrent infections or medical conditions that appear to trigger their HLH, such as EBV infection, malignancy, or rheumatologic disorders. The list of triggering stimuli for both familial and apparently nonfamilial HLH is extensive. Patients with presumed secondary HLH are sometimes reported as having immune studies that normalize with disease resolution, although in the authors' experience, this is variable or unclear. Although the mortality rate from HLH may be significant, the risk of recurrence in cases of secondary HLH is poorly defined. Recurrence of HLH in the absence of autoimmune disease or malignancy is generally considered to be good evidence that a patient has primary HLH, regardless of the other clinical features. Absent a known genetic defect or family history, it is often not possible to make an initial diagnosis of "primary" or "secondary" HLH. Further obscuring this dichotomy, a recent report by Zhang et al described a large series of adults with HLH who were found to have genetic mutations typically seen in children with familial HLH.

A variety of genetic causes of familial HLH have been identified, all either autosomal recessive or X-linked (Table 50-5). Most of these genetic lesions affect a biologic pathway referred to as *granule-dependent,* or *perforin-dependent, cytotoxicity* (Fig. 50-8). This pathway is used by T cells and NK cells to kill target cells, typically those infected by viruses. When triggered, specialized lysosomal granules containing perforin, granzymes, and other proteins are released, leading to apoptotic death of target cells. The first genetic lesions

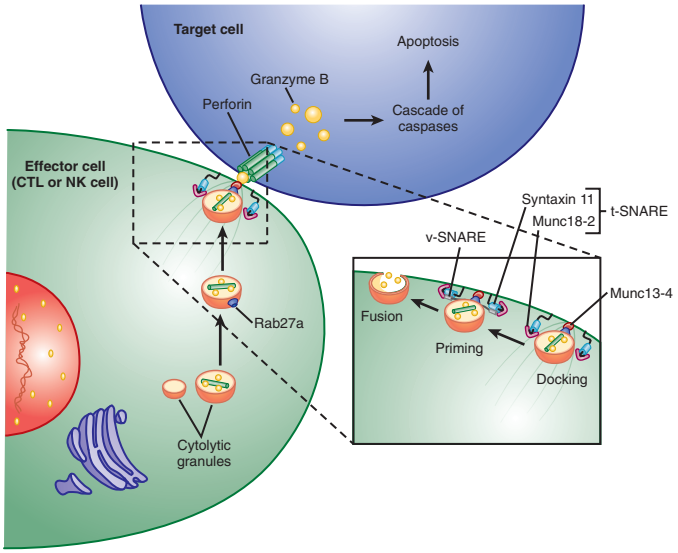

Figure 50-8 MECHANICS OF CYTOTOXIC FUNCTION REVEALED BY HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH)–ASSOCIATED GENE MUTATIONS. HLH-associated genetic abnormalities (in the indicated genes) may affect granule-dependent lymphocyte cytotoxicity by impairing trafficking, docking, priming for exocytosis, or membrane fusion of cytolytic granules. The function of this pathway may also be severely impaired by loss of functional perforin, the key delivery molecule for pro-apoptotic granzymes. Diverse mutations in this pathway all give rise to similar clinical phenotypes (albeit of variable severity). Lyst (the gene affected in Chédiak-Higashi syndrome) is not portrayed because its function is not entirely clear, although it appears to play an important role in the maintenance of normally-sized (and functional) cytolytic granules. *(Adapted from Jordan MB, Allen CE, Weitzman S, Filipovich AH, McClain KL: How I treat hemophagocytic lymphohistiocytosis.* Blood *118:4041, 2011.)*

identified in patients with HLH were mutations in *prf1,* the gene encoding the protein perforin. *Prf1* mutations account for about 15% to 20% of HLH in certain geographic areas and are known as familial HLH 2 (FHL2). FHL2 has mild and severe phenotypes that correlate with the degree of mature perforin protein that is produced. Abnormalities of granule formation, mobilization, and extrusion are also identified as causes of HLH. MUNC 13-4, a protein essential to the exocytotic process, is mutated in FHL3. FHL3 has a worldwide distribution and accounts for 15% to 20% of all hereditable HLH. However, recent discoveries of previously unappreciated intronic mutations in this gene may expand the proportion of patients with FHL3. FHL4 is caused by mutations in the protein syntaxin 11, a member of the SNARE (soluble N-ethylmaleimide-sensitive fusion attachment receptor protein) family of proteins, which is necessary for the fusion of cytotoxic vesicles with the plasma membrane to release their granules. Mutations in the syntaxin-binding protein 2, also important for this process, have been designated FHL5. The genetic defect responsible for FHL1 has not been identified, and no mutations in granzyme proteins have been associated with HLH.

Two X-linked causes of HLH are known. The first, called X-linked lymphoproliferative syndrome 1 (or XLP1), is caused by defects in SH2D1A or SAP. This disorder is a complex one characterized by lymphoproliferation, hypogammaglobulinemia, excess risk of lymphoma, and development of HLH. It appears to share some of the pathophysiology with classic familial HLH, although other abnormalities (of B cells and other cells) make this disorder distinctive. The second X-linked cause of HLH, sometimes called XLP2 (although this is disputed), are abnormalities of a gene/protein called BIRC4 (baculoviral inhibitor of apoptosis protein repeat-containing protein 4)/XIAP (X-linked inhibitor of apoptosis protein). The apparently unique pathophysiology of HLH caused by XIAP deficiency is not understood. Other immunodeficiency syndromes caused by defects in lysosomal trafficking have been linked to life-threatening episodes of HLH. These include Chédiak-Higashi syndrome; Griscelli syndrome; and Hermansky-Pudlak syndrome, type II.

Taken together, the nine genetic disorders described above still account for fewer than half of the diagnosed cases of HLH in children, including many familial cases still awaiting molecular definition. Until recently, it was widely believed that symptoms of HLH caused by genetic causes arose during infancy and early childhood. With the more widespread availability of genetic testing, it is apparent that the first significant episode of HLH can occur throughout life from prenatal presentations through the seventh decade of life. Distinctions between primary (genetically determined) and secondary (acquired) forms of HLH become increasingly blurred together as new genetic causes are identified and patients who develop HLH beyond early childhood or in the contexts of EBV infection or autoimmune disease are being found to share some of the same genetic etiologies.

Clinical Manifestations

The classic presentation of HLH consists of prolonged, hectic fevers (usually present for 1-2 weeks before diagnosis), hepatosplenomegaly, and cytopenias. Neurologic symptoms are common and distinctive features of these patients; these include symptoms of irritability, ataxia, hypo- or hypertonia, evidence of increased intracranial pressure, meningismus, depressed mental status, cranial nerve palsies, and seizures. Standard diagnostic criteria have been defined by the Histiocyte Society for the conduct of the now closed HLH2004 trial (see Table 50-4). Although imperfect, these criteria are widely accepted for the diagnosis of HLH. However, because HLH is a clinical syndrome, it may present in many forms, including fever of unknown origin (FUO); hepatitis or acute liver failure; and sepsis-like, Kawasaki-like, and primary neurologic abnormalities. Not all of the HLH diagnostic criteria may be present initially, so it is important to follow clinical signs and laboratory markers of pathologic inflammation repeatedly to identify the trends. Typical clinical features seen in patients with HLH, grouped by organ system, are described below.

Prolonged Fever

Fever of unknown origin is a very common diagnosis on general pediatric wards, and differentiating HLH from other causes of FUO may be challenging. In one series, patients ultimately diagnosed with HLH presented with fevers above 102° F for a median of 19 days (range, 4-41 days). In patients with FUO, cytopenias, highly elevated ferritin (>3000 g/dL), or sCD25 significantly above age-adjusted normal ranges generally suggest that a complete HLH diagnostic evaluation should be pursued.

Liver Disease and Coagulopathy

Most patients with HLH have variable evidence of hepatitis at presentation. HLH should be considered in the differential diagnosis of acute liver failure, especially if lymphocytic infiltrates are noted on biopsy. Autopsy evaluation of the liver has shown chronic persistent hepatitis with periportal lymphocytic infiltration in the majority of patients. Neonates with HLH may present with hydrops fetalis and liver failure. Most patients have evidence of disseminated intravascular coagulation (DIC) and are at high risk for acute bleeding. Furthermore, patients with HLH caused by degranulation defects may have intrinsic platelet dysfunction.

Bone Marrow Failure

Anemia and thrombocytopenia occur in more than 80% of patients at the time of presentation with HLH. The cellularity of BM aspirates varies from normocellular to hypo- or hypercellular. The prevalence of hemophagocytosis in association with HLH diagnosis ranges from 25% to 100%. Although hemophagocytosis in BM is associated with HLH, the morphologic phenomenon may also be induced by more common events, including blood transfusions, infection, autoimmune disease, and other forms of BM failure or causes of red blood cell destruction. Despite the nomenclature of HLH, diagnosis of HLH should never be made or excluded solely on the presence or absence of hemophagocytosis. Infiltration of BM or liver by CD^{163+} macrophages, along with global clinical evaluation, may distinguish HLH from other causes of hemophagocytosis.

Skin Manifestations

Patients may have a variety of skin manifestations, including generalized maculopapular erythematous rashes, generalized erythroderma, edema, panniculitis, inflamed papular lesions, petechiae, and purpura. The incidence of skin manifestations ranges from 6% to 65% in published series with highly pleomorphic presentations. Some patients may present with features suggestive of Kawasaki disease, including erythematous rashes, conjunctivitis, red lips, and enlarged cervical lymph nodes. Rashes may correlate with lymphocyte infiltration on skin biopsy, and hemophagocytosis may also be found.

Pulmonary Dysfunction

Patients may develop pulmonary dysfunction that leads to urgent admission to the intensive care unit. In a review of the radiographic abnormalities in 25 patients, 17 had acute respiratory failure with alveolar or interstitial opacities, with fatal outcomes in 88% of those cases.

Brain, Ophthalmic, and Neuromuscular Symptoms

More than one-third of patients present with neurologic symptoms, including seizures, meningismus, decreased level of consciousness,

cranial nerve palsy, psychomotor retardation, ataxia, irritability, or hypotonia. The cerebrospinal fluid (CSF) is abnormal in more than 50% of HLH patients with findings of pleocytosis, elevated protein, or hemophagocytosis. MRI findings are highly variable and include discrete lesions, leptomeningeal enhancement, or global edema, and images correlate with neurologic symptoms. Retinal hemorrhages, swelling of the optic nerve, and infiltration of the choroid have been reported in infants with HLH. Diffuse peripheral neuropathy with pain and weakness secondary to myelin destruction by macrophages may also occur.

Laboratory Manifestations

Laboratory manifestations are a critical component of diagnosing HLH. Biochemical abnormalities noted on clinical laboratory assessment include anemia, thrombocytopenia, neutropenia, elevated liver transaminases, hyperbilirubinemia, hypofibrinogenemia, coagulation abnormalities, hypoalbuminemia, hyponatremia, hypertriglyceridemia, elevated soluble CD163, elevated soluble CD25 (sCD25, also called soluble IL-2 receptor), and hyperferritinemia. Specialized immunologic testing may reveal low or absent NK cell or CTL function (although this is not always seen), low levels of perforin or other disease-associated proteins (e.g., SAP or XIAP), and decreased degranulation (observed with mutations affecting granule trafficking). Additionally, pathologic examination of BM biopsy, liver biopsy, CSF, spleen or lymph node, or even occasionally peripheral blood may reveal hemophagocytosis and infiltration with CD^{163+} macrophages and activated T cells (Fig. 50-9). Examination of CSF reveals pleocytosis, elevated protein, and elevated neopterin levels with CNS involvement. Brain MRI often reveals polymorphic white or grey matter abnormalities in such cases.

Elevations in sCD25 are a particularly useful and notable laboratory feature of HLH. In the authors' experience, this marker is dynamically associated with "active" HLH, and patients with active HLH rarely, if ever, have normal levels of sCD25. Of note, the interpretation of soluble IL-2 receptor levels must be undertaken with care because normal levels change with age and the method of analysis. Despite a few small reports of increased soluble IL-2 receptor levels in sepsis, significant elevations of this marker are rarely observed outside the context of HLH. However, the clinical utility of sCD25 is often compromised by delays because most institutions must send patient samples to referral laboratories. Because of its ready availability in most hospitals, the serum ferritin level can serve as an important adjunct to the decision-making process. The HLH diagnostic guidelines define a cutoff at greater than 500 μg/L, which may be observed in sepsis or other hyperinflammatory conditions. Ferritin levels in HLH are usually dramatically higher, with some series finding mean levels near 45,000 μg/L. A recent review of elevated ferritin values at a large pediatric academic tertiary care hospital demonstrated that a ferritin level greater than 10,000 was 90% sensitive and 96% specific for HLH.

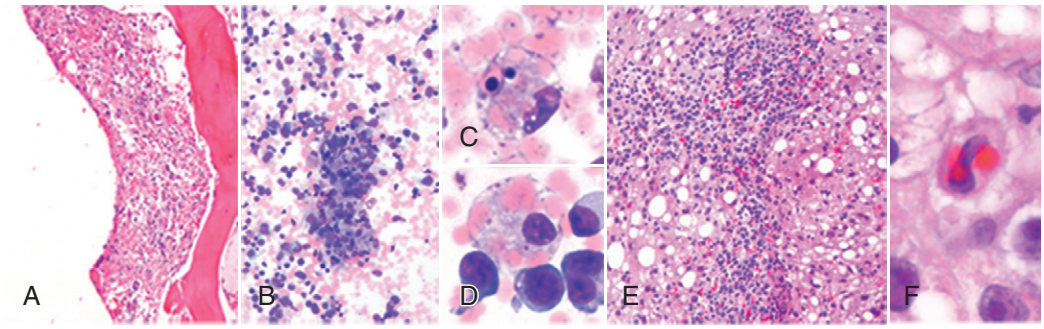

Figure 50-9 A to **F,** FAMILIAL HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS. Illustrations from a 3-month-old girl who presented with diarrhea, pancytopenia, hepatomegaly, and liver failure. Bone marrow (**A** and **B**) showed left-shifted granulopoiesis and increased histiocytes, which at high power (**C** and **D**) were undergoing prominent phagocytosis of erythrocytes, platelets, and other cells. Liver biopsy sample **(E)** showed a lymphohistiocytic infiltrate also associated with hemophagocytosis **(F).** The patient was shown to harbor a mutation of the perforin gene in exon 2.

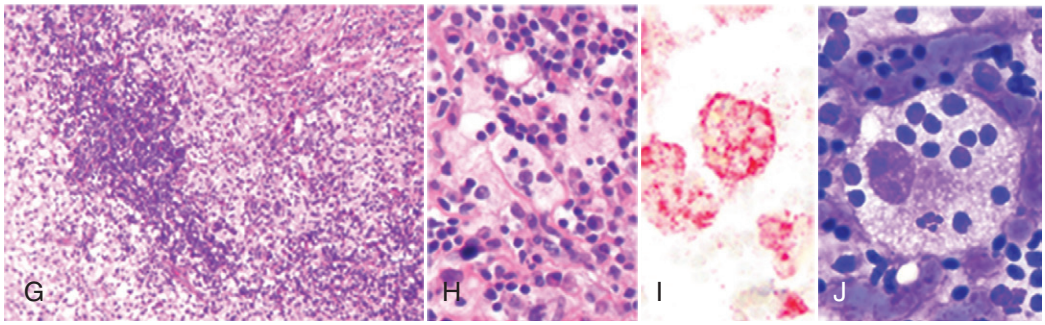

Figure 50-9, cont'd G to **J,** SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY (ROSAI-DORFMAN DISEASE). Low-power magnification of the biopsy sample **(G)** shows a mottled appearance of the lesion caused by dark areas containing small lymphocytes and lighter areas containing histiocytes. At higher magnification **(H),** the histiocytes have abundant pale cytoplasm with scattered cells within. This is emperipolesis, a process of cells traveling through the cytoplasm but not apparently becoming phagocytized or degraded. Note the plasma cells in the background. The emperipolesis can be better visualized with a CD68 stain for histiocytes **(I).** This process delineates the cell boundary and the cells within the histiocyte cytoplasm. The emperipolesis can also be seen on a Wright-stained touch preparation **(J).**

Differential Diagnosis of Hemophagocytic Lymphohistiocytosis

Because HLH presents as an inflammatory syndrome, the differential diagnosis of this disorder is a broad one. Infection must be considered as either a mimic of HLH or as an underlying trigger of the disorder. The list of infections reported as associated with HLH is extensive. If the patient presents with acute multiorgan failure, then sepsis is generally considered first before a diagnosis of HLH is considered. Viral infections, including EBV, CMV, dengue, severe influenza, and so on, should always be considered and treated. Protozoan infections, including malaria, toxoplasmosis, and leishmaniasis, may be a consideration in endemic areas. Visceral leishmaniasis, in particular, may be clinically indistinguishable from primary HLH. In addition to infectious disorders, rheumatologic disorders, including systemic onset juvenile idiopathic arthritis (soJIA) and Kawasaki syndrome, should be considered. Finally, as either a mimic or trigger, malignancy should be considered, particularly lymphoma and leukemia.

Diagnosis

Because of the severe nature of this disorder and the existence of disease-altering therapies, it is crucial to identify patients early in their course. The Histiocyte Society established diagnostic criteria for the HLH-2004 trial, which is widely used for patients not treated on this trial, using both clinical and laboratory findings (see Table 50-4). Laboratory verification of a known genetic defect confirms the diagnosis independent of the presence or absence of any clinical signs or symptoms. However, genetic diagnosis is not usually available in a timely fashion for patients with acute clinical presentations. In the absence of a genetic diagnosis, five of the eight clinical criteria must be met to make a diagnosis. It is important to note that NK cell dysfunction is only present in about 50% of patients with HLH. Additionally, hemophagocytosis may not be present early in the HLH disease process; therefore, serial assessments may be required if that diagnostic criterion is to be met.

Therapy

Without therapy, survival of patients with active familial HLH is historically reported to be approximately 2 months. The first international treatment protocol for HLH was organized by the Histiocyte Society in 1994 and led to reported survival of 55%, with a median follow-up of 3.1 years. The HLH-94 protocol, as illustrated in Fig. 50-10, included an 8-week induction therapy with dexamethasone, etoposide, and intrathecal methotrexate. The principal goal of induction therapy is to suppress the life-threatening inflammatory process that underlies HLH. At the end of 8 weeks, patients are either weaned off of therapy or transitioned to continuation therapy, which is intended only as a bridge to transplantation.

The Histiocyte Society opened a new trial in 2004, HLH-2004, which is now closed. The major modifications from HLH-94 were to move cyclosporine dosing to the beginning of induction and add hydrocortisone to intrathecal therapy. Results of this trial are not reported at this time. An alternative approach to etoposide-based regimens with comparable survival was published as a single center retrospective experience over 14 years in which all patients were treated with corticosteroids and antithymocyte globulin (ATG) followed (rapidly) by HCT. Until this immunotherapy approach can be compared with etoposide–dexamethasone in the setting of a clinical trial and until the results of the HLH-2004 study are published, the standard of care therapy for patients not enrolled in a clinical trial should be based on HLH-94.

Often, the principal challenge for treating patients with HLH is making a timely and accurate diagnosis. It is critical to search for and treat underlying triggers of HLH and institute specific antimicrobial therapy. Rituximab is often helpful in controlling EBV infection. IVIG is an appropriate adjunct for most viral infections. If the patient is stable and not severely ill, consideration can be given to treating the underlying trigger with disease-specific therapy with or without corticosteroids and close follow-up. However, in most cases, an aggressive therapeutic approach is warranted and may reasonably be initiated before obtaining final results for all diagnostic studies. Specifically, HLH therapy should not be withheld while awaiting results of genetic testing because our understanding of HLH-associated gene defects remains incomplete and testing typically takes weeks to complete. With the exception of autoimmune disease and malignancy, initial therapy for patients with suspected familial or reactive HLH does not differ.

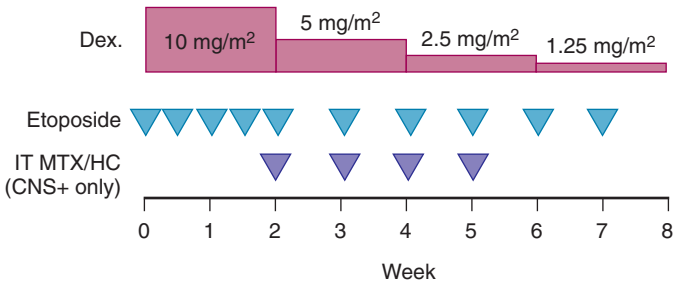

Figure 50-10 INDUCTION THERAPY FOR HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS (HLH). Based on the HLH-94 study, this approach should be considered standard of care for all patients not enrolled in clinical trials based on published evidence of efficacy. Etoposide is dosed as 150 mg/m^2 per dose. Alternatively, for patients weighing less than 10 kg, consideration may be given to dosing etoposide as 5 mg/kg per dose. Dexamethasone (Dex.) is dosed as indicated and may be given orally or intravenously, although the latter is preferred at therapy initiation. Intrathecal methotrexate and hydrocortisone (IT MTX/HC) should be given to patients with evidence of central nervous system (CNS) involvement as early as lumbar puncutre (LP) may be safely performed (which may vary from the diagram) and dosed as follows: age younger than 1 year, 6/8 mg (MTX/HC); age 1 to 2 years, 8/10 mg; age 2 to 3 years, 10/12 mg; and age older than 3 years, 12/15 mg. Weekly intrathecal therapy is generally continued until at least 1 week after resolution of CNS involvement (both clinical and cerebrospinal fluid indices). *(Adapted from Jordan MB, Allen CE, Weitzman S, Filipovich AH, McClain KL: How I treat hemophagocytic lymphohistiocytosis.* Blood *118:4041, 2011.)*

Induction Therapy

The current standard of care consists of a decrescendo course of etoposide and dexamethasone with or without intrathecal therapy (see Fig. 50-10). Ideally, critically ill patients should be treated at facilities familiar with care of cancer and BMT patients. It is important to initiate therapy promptly even in the face of unresolved infections, cytopenias, or organ dysfunction. After starting therapy, patients should be monitored closely for signs of improvement as well as potential complications and toxicities, and therapy may need to be customized. For patients who respond well, with resolution of symptoms and normalization of inflammatory markers, therapy may be weaned per protocol. However, dexamethasone doses and etoposide frequency may need to be increased in response to disease reactivation (see Salvage Therapy below). Deterioration of liver function and blood counts as well as steady increases in serum ferritin, sCD25, and sCD163 tests may signal relapse of HLH disease activity. If patients do not display at least a partial response within 2 to 3 weeks of therapy initiation, salvage therapy should be considered. Recurrence of fever and increased inflammatory markers after an apparent response should also prompt a careful search for opportunistic infection.

Central Nervous System Disease

Patients may present with CNS involvement or may have recurrent disease as treatment doses are being tapered. All patients should

receive a careful neurologic examination, lumbar puncture, and brain MRI, even if they are asymptomatic, as soon as they can be safely performed. Changes in mental status at any time during therapy should be investigated urgently. Patients with proven CNS involvement should be treated with weekly intrathecal methotrexate and hydrocortisone until CSF abnormalities and symptoms normalize. Risk of posterior reversible encephalopathy syndrome (PRES) appears to be significant during induction therapy. Although the etiology of PRES is incompletely understood, it is more frequent in settings of hypertension and is also associated with cyclosporine use. Blood pressure should be aggressively managed during induction. Because CNS involvement suggests a familial etiology and because this disease feature is associated with substantial risks for long-term morbidity, HCT should be considered for patients with this complication.

Supportive Care

Supportive care guidelines for patients on therapy for HLH should be similar to standard practice for patients undergoing HCT, including acute care nursing, *Pneumocystis jiroveci* prophylaxis, fungal prophylaxis, IVIG supplementation, and neutropenic precautions. Any new fever should be evaluated for HLH reactivation, as well as opportunistic infection, and empiric broad-spectrum antibiotic therapy should be initiated. Because of inflammation, consumptive coagulopathy, and intrinsic platelet defects in some patients, they are at very high risk of spontaneous bleeding. The authors aim to maintain platelet count greater than 50×10^9/L and do not recommend prophylactic heparin, which is sometimes used in acutely ill patients. Platelets, fresh-frozen plasma, cryoprecipitate, and occasionally activated factor VII are required for acute bleeding.

Continuation Therapy

Patients who can be weaned off of dexamethasone and etoposide without recurrence, recover normal immune function, and have no identified HLH-associated gene defects may stop therapy after the 8-week induction course. HCT is generally recommended in patients with age younger than 2 years, CNS involvement, recurrent or refractory disease, persistent NK cell dysfunction, or proven familial or genetic disease. Continuation according to HLH-94 consists of pulses of dexamethasone and etoposide (etoposide, 150 mg/m^2 every 2 weeks alternating with dexamethasone 10 mg/m^2/day for 3 days every 2 weeks). Cyclosporine may be added in patients with stable blood pressure and adequate liver and kidney function. Patients on continuation therapy should proceed to HCT as quickly as possible because of the ongoing risks of infection, disease reactivation, or leukemia or myelodysplastic syndrome related to prolonged use of etoposide.

Salvage Therapy

A significant number of patients with HLH either fail to respond adequately to current therapies or relapse before HCT. Approximately 50% of patients treated in the HLH-94 study experienced a complete resolution of HLH, 30% experienced a partial resolution, and approximately 20% died before HCT. Notably, most deaths occurred during the first few weeks of treatment and may reflect either preexisting morbidities or primary refractory disease. Although it is hoped that some patients will fare better with more prompt diagnosis of HLH, others remain unresponsive to standard therapy. Initial treatment with ATG (thymoglobulin, rabbit ATG) has been reported to give higher complete response rates, but partly because of higher relapse rates, long-term outcomes do not appear superior. Although current therapy is effective, there is a need for new treatments for patients with refractory HLH. At present, there are few data regarding potential second-line therapies. Case reports exist describing the use of infliximab, daclizumab, alemtuzumab, anakinra, vincristine, and other agents as salvage therapies for HLH. A recent report found that alemtuzumab has significant activity against refractory HLH in a larger series of patients. Although refractory HLH appears to have a dismal prognosis, approximately 70% of patients in this series survived. Because of its immunoablative qualities, alemtuzumab should be used with caution and by those with experience caring for profoundly immune compromised patients. CMV reactivation and adenoviremia were frequent complications of this therapy. In contrast to refractory patients, those patients who initially respond well to standard therapy but then relapse as treatment is tapered or withdrawn often respond to reintensification of therapy with standard agents. Because of the variability in patient responses, a critical aspect of initial or salvage therapy is close monitoring of the patients for improvement and potential toxicities such as BM suppression or infection.

Hematopoietic Cell Transplantation

Because the time to transplant is a factor in morbidity and mortality from the disease, a donor search should begin at the time of diagnosis even though the precise etiology of HLH (e.g., genetic defect) has not yet been defined. Generally, HCT is recommended in cases of documented familial HLH, recurrent or progressive disease despite intensive therapy, and CNS involvement. Long-term disease-free survival after HCT was approximately 50% to 65% before 2000, regardless of whether a matched sibling or closely matched unrelated donor was used. Most patients transplanted during that era succumbed to "transplant-related" complications during the first 100 days after infusion. A significant proportion of fatal complications involved inflammatory conditions termed acute respiratory distress syndrome, veno occlusive disease (VOD), and multisystem organ failure, unspecified. In rare cases, residual HLH was identified at autopsy despite the use of myeloablative conditioning therapy.

During the past decade, the use of reduced-intensity conditioning (RIC) regimens before HCT has been investigated after encouraging results from an institutional series. Most cases of RIC pretreatment have included alemtuzumab and demonstrated superior early posttransplant survival. In a single-center analysis directly comparing HCT outcomes after myeloablative conditioning versus RIC, a statistically significant improvement was observed after RIC conditioning, with all patients surviving at 6 months after transplant. At present, published data regarding outcome of RIC transplants using umbilical cord blood is not sufficient to draw conclusions regarding safety or efficacy. Donor choice should also take into account the possibility of an occult predisposition to HLH in siblings of patients without identified gene defects. Much remains to be learned and refined regarding the optimal application of alemtuzumab as well as other agents used before HCT. The timing of pretransplant alemtuzumab impacts the probability of graft-versus-host disease; mixed chimerism; and in rare cases, rejection. Other factors, such as donor source, human leukocyte antigen match, cell dose, and patient condition with regard to HLH disease activity at time of conditioning, may all play roles in determining the likelihood of success after RIC HCT.

Patients with CNS HLH need close posttransplant follow-up. The authors recommend examination of CSF within 100 days of HCT even in asymptomatic patients. Follow-up MRIs are recommended if pretransplant abnormalities were present. In some patients with mixed or full hematopoietic donor chimerism, HLH disease activity in the CSF can be effectively treated with intrathecal therapy during the early posttransplant months. CNS disease is subsequently controlled as donor immune reconstitution progresses.

Prognosis

Significant strides have been made in the treatment of HLH with survival now generally ranging from 50% to 70%. In children with nonfamilial HLH, overall survival has been reported at 72%, but only

20% of the patients did not require HCT. Survival is increased in children, irrespective of genetic status, who receive HSCT from matched rather than unmatched donors. RIC pretransplant regimens appear to further decrease mortality. The best outcomes in HSCT are seen in children who have a rapid and complete response to pretransplant therapies and who do not exhibit significant neurologic involvement. Prompt initiation of HSCT in familial patients after disease remission is obtained is also likely to increase survival. Patients with significant neurologic involvement may experience severe and permanent sequelae even if they survive.

MACROPHAGE ACTIVATION SYNDROME

Macrophage activation syndrome is the name commonly given to a severe, potentially fatal, inflammatory condition seen in the context of rheumatologic disorders such as soJIA or systemic lupus erythematosus (SLE). The syndrome of MAS shares many similarities with classic HLH, and many investigators view it as a special form of HLH. The main manifestations of MAS include fever, hepatosplenomegaly, lymphadenopathy, severe cytopenias, serious liver disease, and coagulopathy consistent with DIC. Hemophagocytosis is often seen in the BM of patients with MAS. The true incidence of MAS may be underestimated because relatively mild cases of MAS often remained unrecognized. Recent evidence suggests that mild subclinical MAS occurs in as many as one-third of patients with active soJIA and may be the first manifestation of soJIA. Infections or change in medications may precede the diagnosis of MAS; in most patients, MAS is triggered by a flare-up of the underlying rheumatologic disease. Published observations suggest that as in HLH, MAS patients have profoundly depressed NK cell function, sometimes associated with abnormal perforin expression, and these abnormalities are associated with specific perforin and MUNC13-4 polymorphisms.

Diagnosis and Treatment

There are no validated diagnostic criteria for MAS, and early diagnosis is often difficult. Thus, in a patient with persistently active underlying rheumatologic disease, a fall in the erythrocyte sedimentation rate (ESR) and platelet count, particularly in combination with persistently high C-reactive protein and increasing levels of ferritin, should raise a suspicion of impending MAS. The diagnosis of MAS is usually confirmed by the demonstration of hemophagocytosis in the BM. Assessment of the levels of sCD25 and sCD163 in serum may help with the timely diagnosis of MAS. Although mild elevation of sCD25 has been reported in many rheumatic diseases, including JIA and SLE, a several-fold increase in the levels of sIL2Rα in these diseases is highly suggestive of MAS. The application of the HLH diagnostic criteria to systemic JIA patients with suspected MAS is problematic. Some of the HLH markers, such as lymphadenopathy, splenomegaly, and hyperferritinemia, are common features of active systemic JIA itself and therefore do not distinguish MAS from a conventional systemic JIA flare. Patients with systemic JIA often have increased white blood cell and platelet counts as well as serum levels of fibrinogen as a part of the inflammatory response seen in this disease. Therefore, when they develop MAS, they reach the degree of cytopenias and hypofibrinogenemia seen in HLH only at the late stages of the syndrome when medical management becomes challenging. This is even more problematic for the diagnosis of MAS in patients with SLE in whom autoimmune cytopenias are common and difficult to distinguish from those caused by MAS.

Early recognition of this syndrome and immediate therapeutic intervention to produce a rapid response are critical. Prompt administration of more aggressive treatment in these patients may, in fact, prevent development of the full-blown syndrome. To achieve rapid reversal of coagulation abnormalities and cytopenias, most clinicians start with intravenous methylprednisolone pulse therapy (30 mg/kg for 3 consecutive days) followed by 2 to 3 mg/kg/day divided in four doses. After normalization of hematologic abnormalities and resolution of coagulopathy, steroids are tapered slowly to avoid relapses of MAS. Commonly, however, MAS appears to be corticosteroid resistant, with deaths being reported even among patients treated with massive doses of steroids. Parenteral administration of cyclosporine A has been shown to be highly effective in patients with corticosteroid-resistant MAS. The utility of biologic drugs in MAS treatment remains unclear. Although tumor necrosis factor–inhibiting agents, biologics that neutralize IL-1 and IL-6, have been reported to be effective in occasional MAS patients, other reports describe patients in whom MAS occurred while they were receiving these agents. Based on some success with IVIG administration in virus-associated HLH, this treatment might be effective in MAS triggered by viral infection. If MAS, however, is driven by EBV infection, rituximab, a monoclonal antibody that depletes B lymphocytes (the main type of cells harboring the EBV virus) may be considered.

Future Directions

As an alternative approach to etoposide-based approaches, ATG–prednisone has been used for a number of years in some centers. These two approaches appear to have unique strengths and weaknesses. Although a significant number of patients fail to respond adequately or completely to etoposide-based regimens, ATG-based regimens are complicated by relatively frequent and early relapse (median time to relapse reported by Ouachee-Chardin et al, 5.5 weeks). Thus a rational combination of these approaches may improve outcomes by increasing initial responses and maintaining them until HCT can be obtained. Currently, a multicenter clinical trial, called *hybrid immunotherapy for HLH* (HIT-HLH) is underway in North America testing the potential of this idea. A sister trial is being conducted in Europe. In this approach, ATG and etoposide are incorporated into one regimen, but the etoposide dose intensity is decreased to minimize potential myelosuppression. No data are available yet regarding the usefulness of this approach. Alternative strategies using anticytokine antibodies for induction therapy are also being developed.

Although HLH appears to be a disease of excessive immune activation, the ideal form of immune suppression and antiinflammatory therapy remains unknown. Although somewhat responsive to corticosteroids and clearly responsive to anti–T-cell serotherapy, such as ATG or alemtuzumab, HLH remains difficult to treat. In the foreseeable future, a variety of new, rationally designed immunosuppressive agents are likely to come into clinical use for transplantation and autoimmune disorders. Future studies will likely focus on defining which sort of immune suppression displays the best balance of safety and efficacy.

SINUS HISTIOCYTOSIS WITH MASSIVE LYMPHADENOPATHY OR ROSAI-DORFMAN DISEASE

First described in 1969, sinus histiocytosis with massive lymphadenopathy, or Rosai-Dorfman disease, is clinically characterized as a benign, frequently chronic, painless massive lymphadenopathy usually involving cervical lymph nodes and, less frequently, axillary, hilar, peritracheal, and inguinal nodes. Extranodal disease is present in approximately 30% of patients. The upper respiratory mucosa is involved in 20% of patients, bone in 25%, and orbit or eyelid in 10%. Occasionally, there is involvement of skin, CNS (meninges), lung, liver, and kidney. Ocular manifestations, such as uveitis, have been observed. Although SHML is a histologically reactive and molecularly polyclonal disorder, significant morbidity and death have been associated with massive tissue invasion of the liver, kidney, lung, brain, and other critical structures. In these instances, the disease may have a rapid downhill course.

Eighty percent of patients are diagnosed in the first or second decade of life; however, the disorder also can affect elderly adults. Typically, patients are of African descent; the incidence of SHML is greatest in Africa and the West Indies. Males and females are equally affected.

Laboratory evaluation frequently reveals an elevated ESR, moderate polyclonal hypergammaglobulinemia, anemia, and granulocytosis. Subtle abnormalities of immune indices may also be seen. Involved lymph nodes (see Fig. 50-9) show marked sinusoidal dilation with proliferation of foamy histiocytes within the sinuses. Eosinophils usually are low in number, but plasma cells are abundant. A characteristic finding, referred to as *emperipolesis,* demonstrates lymphocytes surrounded by the membranes of histiocytes as observed best by electron microscopy. The proliferating histiocytes appear to be macrophages. These large, pale cells show variable expression of S100. They can be distinguished from Langerhans cells found in the lymph nodes of patients with classic LCH by the absence of Birbeck granules, the presence of α1-antichymotrypsin, and the absence of CD1a expression.

The etiology of Rosai-Dorfman disease is unknown, but disordered immune regulation has been proposed as a significant contributor. It was originally thought that Rosai-Dorfman disease represented an unusual response to herpesviruses, but this has not been confirmed. Although patients frequently are febrile, infectious agents are not commonly implicated, and the fever is presumed to be a manifestation of systemic disease.

Disease manifestations can subside over several months to years. Of 215 cases in a patient registry, 21% had complete resolution of disease. However, 14 patients died. Five died of "immunologic" causes, such as severe hemolysis; three died of infections; and six probably died as a direct consequence of disease infiltration. As the disease resolves, extranodal disease regresses before nodal disease. Corticosteroids, vinblastine, and low-dose cyclophosphamide are sometimes effective; however, the results with these agents have been inconsistent. Attempts at treatment should be reserved for special circumstances, such as tracheal or epidural compression or invasion of other vital structures, as well as for significant cosmetic disfigurement. Local excision may be useful in selected patients, although the lesions may reappear.

CHAPTER 51

LYSOSOMAL STORAGE DISEASES: PERSPECTIVES AND PRINCIPLES

Edward H. Schuchman and Melissa P. Wasserstein

The lysosomal storage diseases (LSDs) are a diverse group of inherited disorders caused by the defective function of specific lysosomal proteins (Table 51-1). Originally described by DeDuve and colleagues,[1] lysosomes are ubiquitous organelles required to metabolize macromolecules. This includes molecules internalized by cells through the process of endocytosis, as well as those produced during the natural turnover of endogenous cell components (autophagocytosis). More than 50 hydrolytic enzymes have been found within the lysosome, as well as several membrane-embedded transport proteins, ion pumps, and other specialized components. Unique to the lysosome is a highly acidic pH, and the enzymes and proteins found within this organelle have evolved to optimally function within this unique environment. Hers[2] was the first to describe enlarged and abnormally shaped lysosomes in a patient with Pompe disease (α-glucosidase deficiency), thus delineating the first LSD. To date, more than 50 disorders have been attributed to defective lysosomal proteins. Most are inherited as autosomal recessive traits, although two are X-linked (Fabry disease and mucopolysaccharidosis [MPS] type II [Hunter disease]). In general, LSDs are categorized according to the type of macromolecule(s) that accumulate (e.g., lipidoses, mucopolysaccharidoses). The pathophysiology of these diseases is directly related to these accumulating material(s), although as the diseases progress many secondary abnormalities also occur and contribute to the disease pathology. There is also considerable cell and organ specificity related to the location and function of the specific macromolecules affected.

PATHOBIOLOGY OF LYSOSOMAL STORAGE DISEASES

Biology of the Lysosome and Lysosomal Enzymes: Basic Principles

Lysosomes are formed through the fusion of enzyme-containing vesicles produced in the trans-Golgi network (TGN) with other vesicles such as endosomes or autophagosomes. Central to the formation of a mature lysosome is the establishment of an acidic pH. Mature lysosomes have a pH below 5, which is maintained by a proton pump found within the lysosomal membrane. Acidification of the compartment is required for proper activation of the hydrolytic enzymes and the release of macromolecules from their membrane receptors, providing access to the fully active hydrolytic enzymes. Although lysosomes have been historically considered discrete organelles, it is now known that the lysosomal system is highly dynamic and consists of a series of digestive vesicles with varying pH, hydrolytic enzyme activities, and cellular location.[3]

Key to the formation of the lysosome is the delivery of the hydrolytic enzymes to the acidified vesicles in the TGN. This is accomplished through a series of specific targeting mechanisms unique to these proteins[4] (see box on Lysosomal Protein Biosynthesis and Sorting). All lysosomal enzymes are glycoproteins that are synthesized in the rough endoplasmic reticulum (ER) with typical amino-terminal hydrophobic leader or signal peptides. Within the ER, they are glycosylated on select *N*-glycosylation sequences through the en block transfer of a core mannosyl oligosaccharide chain from a lipid intermediate, dolichophosphate.

After the completion of their synthesis and *N*-glycosylation, the lysosomal enzymes in the ER generally undergo additional proteolytic processing and are assembled into transport vesicles for delivery and further processing in the cis-Golgi apparatus. At this stage, all proteins destined for the lysosomes contain only branched mannosyl oligosaccharide chains that terminate with short-chain α-glucosyl moieites. During transport through the Golgi apparatus, they acquire additional, complex oligosaccharide modifications that result in their sorting to lysosomes. A series of glycosyl hydrolases and transferases within specific regions of the cis-, mid-, and trans-Golgi participate in these sequential modifications. For example, in the cis-Golgi, α-glucosidase and α-mannosidases remove terminal glucose and mannose residues to produce mannose-terminated core oligosaccharides. Within the mid-Golgi, additional sugars are added, including β-*N*-acetylglucosamine and β-galactoside. The addition of terminal sialic acid residues occurs in the trans-Golgi.

Coincident with the addition of the β-*N*-acetylglucosamine moiety is the addition of a phosphate group to this sugar by the enzyme *N*-acetylglucosaminyl-1-phosphotransferase. This modification is essential for lysosomal targeting, and mutations in the gene encoding this enzyme lead to a severe LSD (I-cell disease) characterized by the abnormal targeting and secretion of many lysosomal enzymes.[5] The glucosaminyl residues are subsequently cleaved, exposing terminal mannose-6-phosphate residues (M6P) on the

Lysosomal Protein Biosynthesis and Sorting

More than 50 distinct LSDs have been described that are caused by the deficient function of specific lysosomal enzymes or transport proteins. All lysosomal enzymes are cotranslationally *N*-glycosylated in the rough ER through en block transfer of the carbohydrate chain from a lipid intermediate (dolichol). In the Golgi apparatus, the carbohydrate chains are modified to acquire M6P residues, allowing sorting of these proteins to newly formed lysosomes by interaction with M6P receptors embedded in the membrane. Interaction of the M6P-containing proteins with the receptors occurs in the trans-Golgi, where the newly formed vesicles bud from the Golgi membrane and undergo sequential acidification to become mature lysosomes. These vesicles also may fuse with endosomal vesicles that deliver materials from the cell surface. Most lysosomal proteins undergo this sorting mechanism, although a small number are delivered to lysosomes by non–M6P-mediated pathways. Two enzymes localized in the Golgi are responsible for the creation of the M6P residues, and a deficiency of one can lead to a rare inherited disorder (I-cell disease) in which many of the lysosomal proteins are abnormally sorted and secreted from cells. Within the mature acidified lysosomes, additional proteolytic and carbohydrate modifications may occur, leading to full activity of the proteins. Acidification also triggers the release of the M6P-containing proteins from the receptors. In addition, within lysosomes, the active and mature proteins may associate into higher order molecular scaffolds that function to degrade the macromolecules.

Table 51-1 Examples of Lysosomal Storage Diseases

Category	Disease	Protein Abnormalities
Lipidoses	Fabry	α-Galactosidase A
	Farber	acid ceramidase
	Gaucher (types 1, 2, and 3)	β-Glucosidase
	GM_1 gangliosidosis	β-Galactosidase
	GM_2 Gangliosidosis	β-Hexosaminidase A
	Tay-Sachs	β-Hexosaminidase A and B
	Sandhoff	
	Metachromatic leukodystrophy	Arylsulfatase A
	Niemann-Pick	
	Types A and B	Acid sphingomyelinase
	Type C	
	Type 1	NPC1
	Type 2	NPC2/HE1
	Wolman disease (cholesterol ester storage disease)	Acid lipase
Mucopolysaccharidoses	MPS I (Hurler and Scheie)	α-Iduronidase
	MPS II (Hunter)	Iduronidase sulfatase
	MPS III (Sanfilippo)	
	Type A	Heparan *N*-sulfatase
	Type B	*N*-Acetyl-α-D-glucosaminidase
	Type C	Acetyl-CoA-α-glucosaminide acetyltransferase
	Type D	*N*-Acetylglucosamine-G-sulfate sulfatase
	MPS IV (Morquio)	
	Type A	Galactosamine-6-sulfatase
	Type B	β-Galactosidase
	MPS VI (Maroteaux-Lamy)	*N*-Acetylgalactosamine-4-sulfatase (arylsulfatase B)
	MPS VII (Sly)	β-Glucuronidase
	MPS IX	Hyaluronidase
Others	Aspartylglycosaminuria	Aspartylglycosaminidase
	Cystinosis (Fanconi syndrome)	Cystinosin
	Fucosidosis	Fucosidase
	I-cell disease (MLII)	*N*-Acetylglucosamine-I-phosphotransferase
	Pompe	α-Glucosidase
	Mannosidosis	α-Mannosidase
	Schindler disease	α-Galactosidase B

oligosaccharides. Importantly, for any given lysosomal enzyme, the oligosaccharide chains may be highly heterogeneous, containing varying amounts of M6P, sialic acid, and glucosaminyl sugars.

In addition to targeting the lysosomal enzymes to the organelle, the oligosaccharide side chains also participate in the tertiary structure and folding of the proteins and are in many cases necessary for their activity. Proteolytic processing within the lysosome is also sometimes required for activity, as well as assembly into macromolecular "scaffolds" that may include protector proteins, activators, and so on. These events may be driven, at least in part, by pH. Finally, although most lysosomal enzymes use the M6P targeting system, it is also important to recognize that non-M6P targeting systems have been described and may function alone or in combination with M6P.[6] For example, the lysosomal membrane proteins (LIMPs or LAMPs) are sorted to the lysosomal membrane through tyrosine residues located near the carboxyl-terminal end of the proteins.

Pathogenesis of Lysosomal Storage Diseases: General Concepts

The majority of LSDs result from mutations in genes encoding individual lysosomal enzymes, leading to the intralysosomal accumulation of the enzyme's substrate. A small number of the diseases also result from mutations in genes encoding defective transport proteins that reside within the lysosomal membrane or other nonhydrolytic enzymes required for lysosomal enzyme biosynthesis (e.g., I-cell disease). Two main categories of LSDs are distinguished by the type of primary macromolecules that accumulate: those that accumulate mucopolysaccharides (i.e., the mucopolysaccharidoses; MPS diseases), and those that accumulate lipids (i.e., the lipidoses) (see Schulze et al[7] and Giugliani et al[8] for reviews). With only a few exceptions (e.g., Wolman disease), the lipid substrates stored in the lipidoses share a common structure that includes a ceramide backbone (2-*N*-acylsphingosine, i.e., the sphingolipids). More than 100 sphingolipids are known, and because many of these molecules are essential components of cell membranes,[9] their abnormal metabolism and accumulation in the LSDs results in a wide range of physiologic and morphologic alterations, as well as characteristic clinical manifestations. For example, progressive lysosomal accumulation of glycosphingolipids in the central nervous system leads to neurodegeneration, and storage in visceral cells can lead to organomegaly, skeletal abnormalities, pulmonary infiltration, and other manifestations.

For the MPS diseases, the mucopolysaccharides (also known as glycosaminoglycans [GAGs]) are the primary accumulating macromolecules and are found predominately within connective tissues. The accumulation of these materials results in severe cartilage and bone abnormalities that affect the skeletal system, trachea, and other organs, which are characteristic of the disorders. In some cases, the brain also may be affected.

In general, the storage of a substrate in a specific tissue of an LSD patient is dependent on its normal distribution in the body, and this tissue-specific storage pattern is responsible for the organ-specific pathology. For example, in Hurler syndrome (MPS type I), two GAGs, dermatan and heparan sulfate, accumulate, resulting in severe skeletal and neurologic manifestations. In contrast, in Maroteaux-Lamy disease (MPS type VI), only dermatan sulfate accumulates. Because this GAG is not normally found in the brain, neurologic disease does not occur in MPS VI. Similarly, in Tay-Sachs and Sandhoff diseases, the deficiencies of β-hexosaminidase A, or β-hexosaminidases A and B, respectively, results either in primary CNS disease or in combined CNS and visceral disease caused by the different accumulated substrates. Whereas β-hexosaminidase A cleaves the glycosphingolipid (ganglioside) GM2, which is very abundant in the brain, β-hexosaminidase B cleaves primarily sialic acid containing gangliosides and globosides. Globosides, in particular, are synthesized in visceral tissues, resulting in visceral storage in Sandhoff disease.

Although the primary pathogenic mechanisms leading to most LSDs is clear (i.e., a single genetic lesion results in a primary protein defect and the resultant accumulation of a specific substrate or substrates), in recent years, the complexity of these diseases has been recognized. For example, in the MPS diseases, although GAGs are the primary accumulating macromolecules, other compounds, including the neural-specific gangliosides, also accumulate, contributing to disease pathogenesis. In addition, in Niemann-Pick disease (NPD) type C, the primary protein abnormalities affect cholesterol transport, although sphingolipids also accumulate and are responsible, in part, the cellular dysfunction and death. In fact, an approved therapy for NPD type C, Miglustat (see below), is based on the principle of reducing ganglioside storage in the brain rather than correcting the primary cholesterol transport defect. Similarly, in NPD types A and B, the sphingolipid sphingomyelin is the primary accumulating substrate, although cholesterol storage also is a major contributory factor.

Indeed, for any individual LSD, the pattern of macromolecule accumulation may be extremely heterogeneous and, importantly, also may be tissue and cell specific.[10] Although the mechanism(s) leading to this heterogenous storage pattern is not always known, it presumably relates to a global dysfunction of the lysosomal system, providing a connection between seemingly distinct metabolic pathways. For example, the accumulation of cholesterol in NPD type C is known to have a secondary, inhibitory effect on acid sphingomyelinase (ASM) activity. The resultant loss of functional ASM leads to the secondary accumulation of sphingomyelin, which has a major impact on cell function. Recovery of ASM activity in type C NPD cells also leads to a reduction in cholesterol storage and restoration of normal cellular function. In addition, because most lysosomal enzymes are likely assembled in higher order molecular scaffolds in which their activities are tightly and coordinately controlled, this also likely contributes to the multiple effects of the single enzyme deficiencies.

As the macromolecules accumulate, the lysosomes become distended and destabilized and eventually may fail to carry out their normal functions related to phago- and autophagocytosis. In turn, this may result in cell senescence or death or at the very least cell dysfunction. In addition, because of the progressive cell and organ disease that occurs in the LSDs, inflammatory pathways are frequently activated in an attempt to repair the damage. However, because the inflammatory cells themselves are dysfunctional, the diseases progress, and the inflammatory changes may become chronic. Inflammation is therefore also an important contributory factor to the pathogenesis of LSDs. For example, in the MPS diseases, GAG storage is known to activate the Toll-like receptor 4 signaling pathway, leading to the release of tumor necrosis factor-α (TNF-α) and other inflammatory cytokines.[11] TNF-α, in turn, causes the elevation of the toxic lipid ceramide within cartilage cells (chondrocytes), contributing to the cell death. Treatment of animal models of MPS with anti-TNF-α drugs alone has resulted in the reduction of chondrocyte death, and the combination of enzyme replacement and anti–TNF-α therapies can have substantial clinical benefits in animal models.

GENETICS AND DIAGNOSIS OF LYSOSOMAL STORAGE DISEASES

All LSDs except for two, Fabry disease and MPS type II (Hunter disease), are inherited as autosomal recessive traits. Fabry and Hunter diseases are inherited as X-linked recessive traits. Most mutations causing individual LSDs result in single amino acid changes in the enzyme's polypeptide chain, resulting in absent or defective function. The genes encoding most lysosomal proteins have been cloned, and there is no obvious clustering of these genes within the genome. In some cases, nonfunctional pseudogenes also have been described, which may or may not be transcribed or translated into a nonfunctional protein. Although there is no clustering of the lysosomal genes, it has recently been shown that most of these genes exhibit coordinated transcriptional behavior and are regulated by the transcription factor EB (TFEB).[12] In LSDs, TFEB is translocated from the cytoplasm to the nucleus to "turn on" expression of other lysosomal proteins and enhance lysosomal biogenesis. However, because the newly formed lysosomes in these diseases will retain the same primary metabolic defect, this may lead to amplification of the disease pathology.

In some cases, mutations in a lysosomal gene may lead to abnormal biosynthesis of the enzymes or delivery to lysosomes or may affect the individual gene's expression or mRNA stability. The mutant proteins in LSD patients may be stable and delivered to lysosomes, but with reduced function, or may be unstable with only partial or absent delivery to lysosomes. The effect of these individual mutations also may be cell and tissue specific. In general, heterozygous "carriers" of single mutations in a lysosomal gene do not develop clinical symptoms of the disorder, except in the X-linked disorders (Fabry and Hunter diseases), where X-inactivation patterns can lead to clusters of cells without enzyme activity that develop disease related pathology.[13] In addition, one lysosomal gene, *SMPD1,* encoding ASM, is known to be "paternally imprinted" (i.e., preferentially expressed from the maternal chromosome), suggesting that type A and B NPD individuals who inherit "severe" *SMPD1* mutations on the maternal chromosome may be more severely affected than those who inherit the same mutations from the paternal chromosome.[14] This also suggests that some NPD carrier individuals (with maternally-derived mutations) might exhibit clinical or laboratory manifestations of the disorder, and there is at least one report documenting very low serum high-density lipoprotein levels in such carrier individuals.

Although all LSDs are caused by DNA abnormalities in the genes encoding lysosomal proteins, as already noted, the disease pathogenesis is more directly related to the individual effect of these mutations on the proteins themselves and the resultant biology of the accumulating macromolecules. Diagnostic assays for patients suspected of having an LSD generally rely on the measurement of specific enzymatic activities in isolated leukocytes or cultured fibroblasts. For some disorders, carrier identification and prenatal diagnosis are available as well. However, because the detection of individual enzyme activities in these cell sources must use in vitro assay conditions and non-natural substrate analogues (e.g., fluorescently conjugated), the enzymatic confirmation of suspected cases should be carried out in specialized laboratories experienced in these methods. In addition, because in most LSDs, leukocytes and skin fibroblasts are not clinically relevant cell types, these assay methods are at best indirect measures of the defective lysosomal protein's function at the pathological sites. For this reason, predicting the clinical outcome from these analyses is generally not reliable.[15] For example, cells from patients with the infantile, neurologic form of ASM deficient NPD (type A) and the later-onset, non-neurologic form (type B) often have similar residual enzymatic activities, although their clinical course is markedly different. This likely reflects the function of the individual mutant ASM polypeptides in the brain.

As already noted, many genetic abnormalities have been identified as causing individual LSDs. For most diseases, multiple mutations have been found, and the majority of these are unique (i.e., private) to individual families. However, for some LSDs, there are specific

populations that may have recurrent mutations caused by founder effects or consanguinity, facilitating the use of DNA-based screening methods for the detection of the LSD. This has been most effectively translated into clinical use in the Ashkenazi Jewish population, in which relatively small number(s) of mutations account for several LSDs (and several other genetic disorders).[16] This has led to the establishment of a DNA-based "Jewish Genetic Disease" screening panel and the population-based identification of carrier individuals for the same disorder. Such individuals are referred for genetic counseling to assist with family planning and pregnancy outcome choices. The implication of such screening has led to a dramatic reduction in the incidence of some diseases within this population (e.g., infantile Tay-Sachs disease), and will likely lead to the prevention of other disorders as well. The rapid evolution of cost-effective, high-throughput sequencing methods is also likely to open other populations and disorders to these DNA-based approaches.[17] However, it is important to note that the functional consequences of most DNA abnormalities on the protein function have not been confirmed, and thus DNA-based methods alone should not be used to predict clinical outcome unless the biochemical consequences of these abnormalities is fully established. In general, confirmation of a suspected LSD case should be confirmed by both enzymatic and DNA-based studies, and in only rare cases can the laboratory results be used to predict clinical outcomes.

THERAPY OF LYSOSOMAL STORAGE DISEASES: AN OVERVIEW

Since the first recognition that LSDs resulted from the defective function of lysosomal proteins, the concept of simply "replacing" the missing protein in individual patients was put forward[18] (see box on Treatment of Lysosomal Storage Diseases). This concept was further strengthened in the 1970s by the identification of the M6P targeting system for lysosomal enzymes and the finding that the secreted forms of many lysosomal enzymes could be rapidly internalized, or "taken up," by cell surface M6P receptors and delivered into the lysosomal system.[19]

Initial attempts at replacing the normal protein in LSD patients were accomplished by cell and organ transplantation. The premise of this approach is that transplanted cells expressing the normal lysosomal proteins would release some of these proteins into the circulation and locally at the sites of pathology and that these proteins would be taken up by the diseased cells, leading to metabolic "cross-correction." "Proof-of-principle" for this approach was documented by Neufeld,[20] who showed that metabolic cross-correction of MPS cells could be achieved by co-culture of these cells with normal cells or by replacing the media in MPS cells with "conditioned" media obtained from the normal cells. In addition to these proof-of-principle experiments, there also was an early recognition that very low levels of residual enzymatic activities in the individual LSDs could have an important impact on the clinical presentation of the individual patients. This suggested that low levels of enzyme release and re-uptake were likely required to achieve metabolic cross-correction in vivo.

The majority of the clinical experience using cell-based therapy in LSDs comes from bone marrow transplantation (BMT).[21] Bone marrow has several advantages as a cell source, including the fact that it contains multiple stem and progenitor cell lineages that can lead to repopulation of various organs and tissues. Thousands of individual LSD patients have received BMTs over the past 3 decades, and the results have been mixed. First, aggressive immunosuppressive preconditioning is required to achieve effective engraftment in the transplanted patients, leading to high morbidity and, in some cases, mortality. In addition, graft-versus-host disease may occur. These deleterious effects can be severe and may lead to clinical complications in patients that are worse than the disorders themselves. The availability of cord blood repositories and improved transplant methods have reduced these risks, but the possibility of high morbidity remains.

In patients who have successfully undergone BMT and achieved a high level of engraftment, the clinical results have been variable. A number of factors account for this. First, repopulation after BMT is not uniform throughout the body, and depending on the organ systems affected in the patients, clinical improvement may or may not occur. For example, the hematopoietic system is particularly amenable to BMT repopulation, but the skeletal system (cartilage and bone) is not. In the nervous system, some bone marrow–derived cells may cross the blood–brain barrier and repopulate the microglial population, but the number of these cells is small and the repopulation efficiency low.[22] A second factor accounting for the variable clinical results after BMT is the age at which the transplant is undertaken. Many of the disease manifestations that occur in LSDs lead to permanent tissue damage (e.g., fibrosis, apoptosis) and are not reversible. Thus, not only must efficient engraftment be achieved after transplantation, but the procedure must also be undertaken before irreversible damage sets in.

Other than BMT, liver transplantation also has been undertaken in various LSDs, also with variable success (e.g., see Ayto et al[23]). Because the liver is a natural secretory organ, the concept underlying liver transplantation is that even partial repopulation of this organ with healthy cells will lead to secretion of these proteins into the circulation and widespread metabolic cross-correction. As with BMT, however, the uptake and distribution of the secreted enzymes will be limited by physiologic barriers (e.g., blood–brain barrier) and dependent on the vascular supply to the tissue. Unlike BMT, there also will no circulating stem cells available for organ engraftment other than in the liver. It is also of interest that early attempts at cell therapy for LSDs used amniotic cells for transplantation. Although the engraftment of these cells was extremely low and the clinical outcomes poor, these studies represented the first embryonic stem cell–based approach for these disorders.

Simultaneous with the development of cell and organ transplantation for LSDs, investigators also began to isolate and study the normal lysosomal proteins involved in the individual disorders and

Treatment of Lysosomal Storage Diseases

The principle underlying the treatment of most LSDs is replacement of the missing or defective protein. This can be accomplished by stem cell transplantation, protein replacement therapy, or gene therapy. In some cases, treatments also have been developed that are either aimed at slowing the accumulation of undegraded materials (substrate reduction therapy) or enhancement of the mutant protein function (chaperone therapy). BMT has been undertaken in more than 1000 LSD patients with varying results. The premise of this approach is that stem cells in the bone marrow will repopulate in the transplanted individual and provide a source of secreted and normal lysosomal proteins that can be taken up by neighboring cells for metabolic correction (cross-correction). This approach is most effective for soluble lysosomal proteins and diseases in which cells of the monocyte–macrophage system are primary sites of pathology. However, despite the availability of cord blood registries, such cell transplantation is still limited by a high morbidity and the lack of suitable donors. Enzyme replacement therapy is also available for six LSDs and under development for several others. This approach, although effective, requires lifelong weekly or biweekly infusions of the recombinant proteins, and the costs are very high. Gene therapy approaches have been evaluated in numerous LSD animal models but are not yet available for patients. This approach, however, has also proven very effective in some disease models and could be evaluated in the clinic during the upcoming years. In general, the efficacy of any of these approaches is dependent on the cellular and tissue sites of pathology and the ability of the therapeutic proteins, stem cells, or gene therapy vectors to access these sites.

to explore the idea of protein (enzyme) replacement therapy (ERT). Because this work originated before the development of recombinant DNA technology, it relied on discarded human materials as the enzyme source, usually urine or placentas. The first short-term experience with ERT in human patients took place in the early 1970s by Brady,[18] Desnick, and others, and revealed (1) that the enzymes were generally well tolerated, (2) that the half-life of the enzymes in the circulation was short lived, and (3) that the sugar moieties on the enzymes had an important influence on their clearance from the circulation. In general, enzymes with terminal sialic acid residues had longer half-lives in the circulation than those with exposed mannose or M6P residues.

Despite these early successes, the further development of ERT was limited by the inability of the academic-based research laboratories to produce enough of the enzymes for long-term treatment. In the 1980s, a small biotechnology company took on this challenge and began to commercially prepare β-glucocerebrosidase, the enzyme deficient in Gaucher disease, from human placentas. This led to the first long-term experience with ERT in patients with non-neurologic (type 1) Gaucher disease.[24] Importantly, the purified enzyme was chemically modified to expose terminal mannose residues, leading to preferential uptake by macrophages, the major cellular site of pathology in this disease.

The results of ERT in type 1 Gaucher disease were life changing and led to remarkably reduced organomegaly and improved hematologic findings. Although the therapy required biweekly intravenous infusions, it led to substantially improved quality of life and was approved by the international regulatory authorities. By the early 1990s, DNA technologies had evolved to the point where human recombinant β-glucocerebrosidase could be produced (in overexpressing Chinese hamster ovary cells), and this eventually replaced the use of placental enzyme.

In addition, based on the outstanding success in Gaucher disease, several other ERTs began to be developed, including therapies for Fabry disease (α-galactosidase), Pompe disease (α-glucosidase), and several of the MPS disorders. ERT is now commercially available for Fabry, Pompe, and three MPS diseases (MPS I, II, and VI) and under development for others. With these developments came the recognition that the effects of ERT were disease specific and could be complicated by immune reactions to the infused recombinant proteins. In addition, the costs of these therapies were extremely high, placing a very high burden on the reimbursement systems.

These realizations have led researchers to explore other therapies as well, and this research has been greatly aided by the use of DNA technologies to develop animal models for most of the LSDs. Considerable effort has been directed towards gene therapies, which have been extensively evaluated in the animal models.[25] Clinical and pathological improvements have been obtained, although the translation of these technologies into the clinic has been slow because of safety concerns and issues with large-scale vector production. Recently, the first gene therapy clinical trials for LSDs have been approved in Europe, and over the next decade, results should be forthcoming regarding the efficacy of these approaches.

Other investigators have sought alternative therapeutic approaches for these diseases, focusing on inhibiting the production of substrate in order to reduce glycosphingolipid production and accumulation (substrate reduction therapy [SRT]). Miglustat (OGT 918, *N*-butyldeoxynojirimycin; trade name, Zavesca) is a low–molecular-weight compound that inhibits glucosylceramide synthase, which catalyzes the first step in the biosynthesis of glucosylceramide and other glycosphingolipids. Miglustat is an oral compound that has been shown to effectively decrease organ volume and improve hematologic parameters in patients with type 1 Gaucher disease. However, gastrointestinal side effects are fairly common, so the use of Miglustat is limited to Gaucher disease patients for whom ERT is not suitable. Miglustat has also been used in patients with type C NPD, which causes progressive and severe neurologic disease. Most patients with type C NPD have mutations in an integral membrane protein involved in cholesterol transport (NPC1). However, because the deficiency in NPC is a nonsoluble transporter, protein replacement therapy is not a therapeutic option at the present time. Using animal models, investigators showed that the neurologic pathology in type C NPD was associated with the secondary accumulation of a particular glycolipid, GM_2 ganglioside. Based on this finding, studies were carried out in the type C NPD animal models using SRT to inhibit glycolipid biosynthesis, resulting in reduction of GM_2 storage and partial neurologic improvements. Clinical trials of Miglustat in type C NPD patients revealed stabilization or improvement of some clinical markers.

Another small molecule approach under development for the LSDs is based on the use of enzyme-specific inhibitors that can act as "chaperones" of the corresponding mutant proteins, thereby facilitating their delivery to lysosomes and enhancing their residual enzymatic activities. Such "chaperone" therapy is currently being evaluated in clinical trials for several LSDs. Numerous other approaches also have been or are being evaluated in the various LSD animal models, including targeting of inflammatory pathways and stem cell–based therapies, and in the future, patients should have access to various therapeutic choices. As with ERT, the effects of these individual therapies are likely to be disease and organ specific, and it is expected that in the future effective treatment of LSD patients will require a combination of these approaches.

HEMATOLOGIC MANIFESTATIONS OF LYSOSOMAL STORAGE DISEASES

Hematologic findings are associated with several LSDs, but in two, Gaucher disease and types A and B NPD, hematologic abnormalities are among the common presenting features. Hematologic findings should be considered in the differential diagnosis of both disorders, and patients with Gaucher disease or NPD may be seen by hematologists to manage their symptoms. In the section below, the hematologic features of these disorders are discussed, as well as several other relevant issues related to hematologic manifestations and LSDs.

Gaucher Disease: β-Glucosidase Deficiency

Cells of the monocyte–macrophage system are the primary sites of pathology in this disorder. In general, these cells are enriched for lysosomes and highly active in phagocytosis. As such, disruption of lysosomal function may have a profound effect on their function. An important diagnostic hallmark of Gaucher disease is the presence in a variety of tissues of lipid-filled cells derived from the monocyte–macrophage system, referred to as *Gaucher cells*. These cells are readily evident in the bone marrow but also can be seen in blood smears and histologically in other tissues, including liver, spleen, lung, and others. As the disease progresses, the deposition of Gaucher cells in these organs increases.

Bleeding is a common presenting symptom of patients with Gaucher disease and is primarily caused by thrombocytopenia. The major sites of bleeding are mucocutaneous, including epistaxis, easy bruising, and gingival hemorrhage. Thrombocytopenia in Gaucher disease is generally thought to be caused by splenic sequestration of platelets. Spleen enlargement is present in all symptomatic patients and is a common presenting sign of the disease. Splenic enlargement in Gaucher disease may be massive, up to 75-fold normal.[26]

Some patients with type 1 Gaucher disease have excessive bleeding that is disproportionate to their platelet counts and coagulation profiles. Abnormal platelet function has been described in patients with type 1 Gaucher disease with abnormal bleeding tendencies.[27] These defects have been attributed to defects in platelet adhesion as well as aggregation. Coagulation deficiencies, particularly low factor levels of factor XI, also have been described.[28] Because both factor XI deficiency and type 1 Gaucher disease are relatively common in the Ashkenazi Jewish population, this finding may reflect concurrence of the two disorders. However, a report describing Egyptian type 1 Gaucher disease patients with deficiencies in factors II, V, VII, VIII, X, XI, and XII supports the concept that the coagulopathy is not

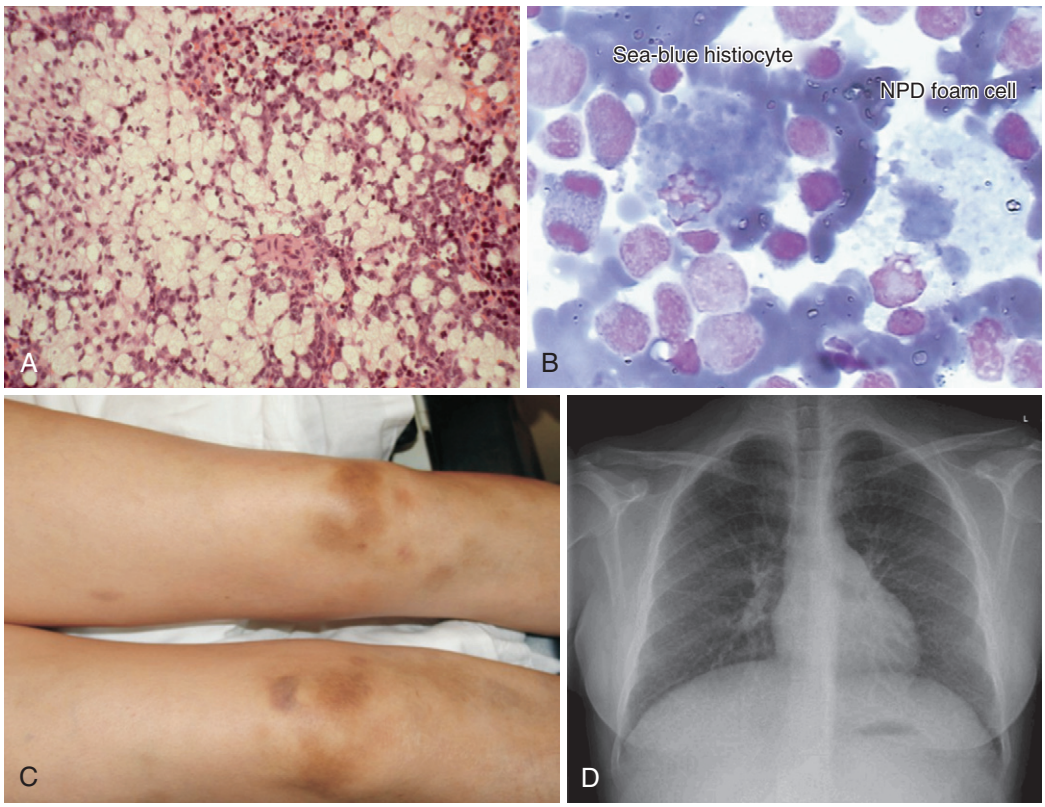

Figure 51-1 **A,** Typical histopathology (hematoxylin and eosin E staining) of a liver section from a patient with type B Niemann-Pick disease (NPD). Note the lipid-filled macrophages (Niemann-Pick cells) that are characteristic of this disorder. **B,** Micrograph of the bone marrow from the same patient with type B NPD showing the presence of an NPD cell, as well as a sea-blue histocyte. Both cells may be characteristically found in the bone marrow of these patients. **C,** Bruising that may be seen in type B NPD and is associated with thrombocytopenia. **D,** Chest radiograph of a patient with type B NPD showing the diffuse reticulonodular interstitial changes in this disorder.

limited to Ashkenazi Jewish patients and may have a distinct pathophysiology.[29] In fact, many patients with Gaucher disease have significant deficiencies (<50%) of multiple coagulation factors.[28] This is associated with elevations of coagulation activators, suggesting ongoing activation of the coagulation cascade with a resultant consumption of coagulation factors.[28]

Anemia in patients with Gaucher disease is usually mild but occasionally may be severe and can be associated with leukopenia. These findings are also probably attributable to sequestration of cells in the spleen, as well as dysfunctional bone marrow production of cells as the disease progresses. The mainstay of treatment for the hematologic abnormalities in Gaucher disease is ERT. ERT typically produces a remarkable improvement in the platelet count, hemoglobin, and white blood cell count, as well as a reduction in spleen size.[24] ERT may also partially improve the coagulation profile.[28]

In patients with massive splenomegaly, splenectomy is often approached as a treatment option with the expectation that it will improve the platelet count and reduce the risk of splenic rupture. However, the spleen is an important reservoir for storage material, and its removal can displace lipid deposition to other organs, accelerating the rate and severity of disease.

Types A and B Niemann-Pick Disease: Acid Sphingomyelinase Deficiency

The hematologic findings in types A and B NPD are similar to those in Gaucher disease and may include thrombocytopenia and anemia. Splenic enlargement is also a common presenting feature of this disorder, and sequestration of cells in the spleen is thought to be the underlying cause of the low platelets, low hemoglobin, or leukopenia (Fig. 51-1, *A* and *B*). Some patients with type B NPD have excessive bleeding without significant thrombocytopenia or coagulopathy. Frequent and prolonged epistaxis can be particularly problematic and in some extreme cases may require cauterization, packing, and blood transfusions.

As with Gaucher disease, a primary cellular site of pathology in types A and B NPD is the monocyte–macrophage system, and the characteristic pathological cells are referred to as *Niemann-Pick cells*. These can be distinguished from Gaucher cells by an experienced pathologist but are frequently missed, leading to misdiagnosis. They are also readily evident in blood smears, bone marrow, and other organs and increase as the disease progresses. As noted earlier, there is another form of NPD (type C) that is caused by primary defects in cholesterol transport. These patients also may present with mild hematologic findings and an enlarged spleen, although in general, the hematologic findings are less severe than in patients with types A and B NPD (Fig. 51-1, *C* and *D*)

Fabry Disease: α-Galactosidase Deficiency

Unlike Gaucher and NPD diseases, in Fabry disease, the monocyte–macrophage system is not primarily affected. In this disorder, the primary site of accumulation of glycolipids occurs in the vascular endothelial and smooth muscle cells that surround blood vessels. As such, constriction of blood vessels occurs, leading to skin lesions, strokes, and kidney dysfunction. It is noteworthy that several of the accumulating glycolipids in Fabry disease also are blood group lipids. For example, a number of blood group B glycolipids may contain terminal α-galactosyl moieties, and as such, patients with Fabry disease who have blood groups B and AB will accumulate four

glycolipid substrates as opposed to those with A or O blood groups, who will only accumulate two. The clinical consequence of this differential accumulation of blood group lipids in Fabry disease is unknown.

Sea Blue Histiocytosis and Lysosomal Storage Diseases

Sea-blue histocytes are lipid-laden macrophages detectable by May-Giemsa staining of the bone marrow, blood cells, or other organs (Fig. 51-1, *B*). The appearance of these cells may be secondary in many disorders, but for the LSDs, they are principally associated with NPD, Gaucher, Fabry, or ceroid storage diseases. For NPD and Gaucher disease specifically, there are several reports in the literature of patients with these disorders being misdiagnosed with primary sea-blue histocytosis and only later being found to have the primary lysosomal enzyme defect. Thus, the appearance of sea-blue histocytes should be considered as part of the differential diagnosis of these disorders.

CONCLUSIONS AND FUTURE DIRECTIONS

The LSDs comprise a diverse group of genetic disorders that may present from infancy through adulthood. Most LSDs are caused by single enzyme deficiencies, but these single protein defects can result in a complex array of metabolic abnormalities, leading to a wide range of clinical presentations. The pathophysiology of individual LSDs depends on the specific cells and tissues in which these metabolic abnormalities occur. Phenotypic heterogeneity among patients may be caused by different mutations in the enzyme-encoding gene, resulting in varying levels of residual enzyme activity. Hematologic abnormalities occur in several LSDs, although two diseases, type 1 Gaucher disease and types A and B NPD, primarily affect cells of the monocyte–macrophage system, and hematologic complications can be common and severe in some cases. Several treatment options are available for some of the LSDs, including ERT, and in the case of Gaucher disease, ERT is very effective at correcting the hematologic findings. ERT is also under development for type B NPD. Other treatment options, including small molecule approaches, also are actively being developed for many LSDs, and in the future, most LSD patients are likely to be treated by a combination of these methods. These efforts, together with the development of population-wide enzyme and DNA-based screening for the LSDs, should lead to better medical management and improved quality of life for most patients.

CHAPTER 52

INFECTIOUS MONONUCLEOSIS AND OTHER EPSTEIN-BARR VIRUS–ASSOCIATED DISEASES

Carl Allen, Cliona M. Rooney, and Stephen Gottschalk

The initial clinical descriptions of primary Epstein-Barr virus (EBV) infections are credited to Filatov and Pfeiffer at the end of the 19th century. Pfeiffer coined the term *glandular fever,* which described an illness consisting of fever, malaise, sore throat, and lymphadenopathy. In 1920, Sprunt and Evans introduced the term *infectious mononucleosis (IM)* to describe a series of patients with fatigue, fever, lymphadenopathy, and prominent mononuclear lymphocytosis (Fig. 52-1). Serologic diagnosis of IM became available in the 1930s with the heterophile agglutination test developed by Paul and Bunnel and later modified by Davidson (see box on EBV-Associated Clinical Syndromes).

The identification of EBV as the causative agent of IM was impeded for many years by the inability to transmit the disease to animals or to grow the virus ex vivo. In 1958 Burkitt described a lymphoma in African children and investigators suspected an infectious etiology because the lymphoma's geographic distribution pattern coincided with the African mosquito belt.[1] In 1964 Epstein, Achong, and Barr described herpesvirus-like particles in tumor biopsies from Burkitt lymphoma patients. Werner and Gertrude Henle developed an indirect immunofluorescent antibody assay to this new virus, now called *Epstein-Barr virus,* and showed that Burkitt lymphoma patients, as well as 90% of American adults, had antibodies against EBV. In 1965 the Henles documented seroconversion to EBV of an individual who presented with clinical symptoms of IM. This initial observation was corroborated by larger studies confirming the association of EBV and IM.

Since then, EBV has been linked to a heterogeneous group of diseases.[2] EBV was the first human virus implicated in oncogenesis, and the biology of the virus has been studied extensively on a cellular and molecular level.[3] Because primary EBV infection is a self-limiting disease in almost all individuals, therapeutic strategies have focused on the treatment of rare, potentially fatal EBV-associated diseases. Over the last decade, successful immunotherapeutic approaches have been developed for EBV-associated lymphoproliferative disease, using either monoclonal antibodies or the adoptive transfer of EBV-specific T cells[4,5] (see box on EBV-Associated Clinical Syndromes).

BIOLOGY OF EBV

EBV belongs to the family of herpesviruses, which has almost 100 members. Membership is based on the architecture of the virion that is 120 to 300 nm in size and contains (a) a core of linear, double-stranded DNA, (b) an icosadeltahedral capsid with 162 capsomers, (c) an amorphous material between the capsid and envelope designated tegument, and (d) an envelope containing viral glycoproteins.

EBV-Associated Clinical Syndromes

- Infectious mononucleosis
- Chronic active EBV infection
- Hemophagocytic lymphohistiocytosis
- X-linked lymphoproliferative disease
- Oral hairy leukoplakia

Besides EBV, designated human herpesvirus 4, seven other herpesviruses have been isolated from humans: herpes simplex viruses 1 and 2, cytomegalovirus, varicella-zoster virus, human herpesvirus 6, human herpesvirus 7, and the Kaposi sarcoma–associated herpesvirus (KSHV, human herpesvirus 8). Herpesviruses are further divided into subfamilies to reflect evolutionary relatedness and similar biologic properties. EBV and KSHV belong to the human gamma herpesvirus subgroup and have a limited tissue tropism to B and T lymphocytes and certain types of epithelial cells. Several variants of EBV have been identified by genomic polymorphisms. Initially, two EBV types were distinguished by sequence changes in EBV nuclear antigens 2 and 3 (EBNA2 and EBNA3). However, using polymorphisms in the latent membrane protein 1 (LMP1), further subtypes have been described. EBV strains vary by geography and have not been linked to a particular EBV-associated disease.

PRIMARY EBV INFECTION

Primary EBV infection usually occurs through the oropharynx, where mucosal epithelial cells and/or B cells become productively infected (Fig. 52-2). Infection of B cells by EBV is initiated by binding of the dominant viral glycoprotein gp350/220 to CD21, the C3d complement receptor; subsequent cell entry is mediated by a complex of three viral glycoproteins, gH, gL, and gp42. Gp42 binds to HLA class II, which functions as a coreceptor, and gH is most likely involved in virus-cell fusion. The entry of EBV into epithelial cells may occur through multiple mechanisms because the majority of epithelial cells are CD21 negative. After viral entry, the capsid is dissolved and the EBV genome is transported into the nucleus, where it circularizes. Infection of epithelial cells results in lytic or abortive infection, and whereas B-cell infection results predominantly in latency, the lytic infection also occurs, resulting in the release of infectious virus into the saliva and other secretions. During primary infection, EBV establishes lifelong latency in B cells and it is estimated that 1 to 50 cells per 1×10^6 B cells in the peripheral circulation are infected with EBV. The number of latently infected B cells within a person remains stable over years; however, intermittent reactivation of EBV in B cells into the lytic cycle at mucosal sites is probably responsible for the observed shedding of infectious virus into the saliva of asymptomatic carriers (see Fig. 52-2).

Although EBV can infect any B cell and express the full spectrum of latency proteins, extensive studies by the group of Thorley-Lawson have suggested that only infection of naive B cells results in persistent infection (see Fig. 52-2). EBV infection pushes the naive B cell into a memory state independent of an antigen-dependent germinal center reaction by upregulation of cytosine deaminase, which induces both class switching and somatic hypermutation. The former also requires the expression of EBV-encoded LMP1, a constitutively activated CD40 molecule, or CD40 ligation, most likely provided by germinal center Th3 cells that can provide T-cell help for B-cell differentiation by provision of CD40 ligand, IL-4, and IL-10 while preventing antigen-dependent effector T cell–mediated B-cell elimination by expression of TGF-β. This reaction occurs within the lymph node and also involves downregulation of latency proteins and expression of latency type II. On exit from the lymph node,

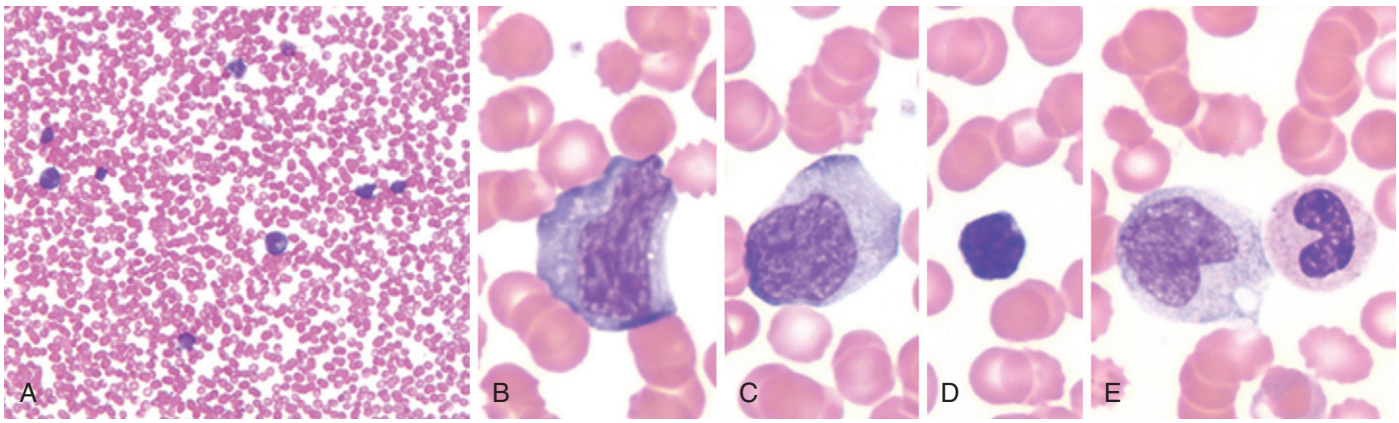

Figure 52-1 PROMINENT MONONUCLEAR LYMPHOCYTOSIS IN MONONUCLEOSIS. Low power **(A)** illustrates the leukocytosis, mainly due to activated lymphocytes (**B** and **C**), which are contrasted with a normal small lymphocyte **(D)** and a monocyte and granulocyte **(E)**. The large reactive lymphocytes are frequently confused with monocytes because of their morphologic resemblance and the term *mononucleosis*. Monocytes usually have a finer, lacy chromatin and a gray cytoplasm with small granules and vacuoles when compared with the large activated lymphocytes.

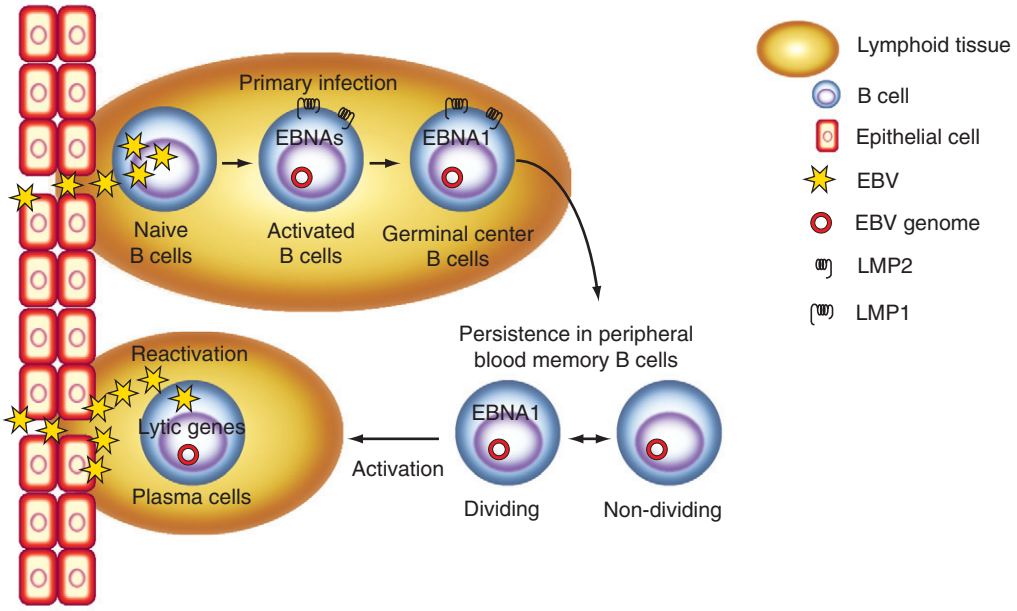

Figure 52-2 INFECTIOUS LIFE CYCLE OF EPSTEIN-BARR VIRUS.

expression of latency proteins is completely inhibited. In this way infected B cells can evade immune elimination. By contrast, primarily infected memory B cells enter and remain in latency type III and are rapidly eliminated by effector T cells and therefore do not contribute to virus persistence.

LATENT EBV INFECTION

During latent infection, EBV persists episomally in resting memory B cells. Initially, it was thought that EBNA1 and LMP2 were expressed in memory B cells; however, more recent studies indicate that the majority of infected cells do not express viral proteins and that of the almost 100 viral proteins, only EBNA1 is expressed during memory B-cell division (see Fig. 52-2).[3] This extremely limited expression of viral proteins allows EBV to persist long term despite a robust cellular EBV-specific immune response.

Three other distinct types of EBV latency have been characterized in a heterogeneous group of malignancies (Fig. 52-3). Latency type III, which can be readily produced by infecting B cells in vitro with EBV, is expressed in lymphoblastoid cell lines (LCL). These cells express the entire array of nine EBV latency proteins: EBNA1, -2, -3A, -3B, and -3C, EBNA leader protein (LP), and the two viral membrane proteins LMP1 and LMP2. This pattern of EBV gene expression characterizes the EBV-associated lymphoproliferative diseases (EBV-LPD) that occur in individuals severely immunocompromised by solid organ or hematopoietic stem cell transplantation, congenital immunodeficiency, or human immunodeficiency virus (HIV) infection. Latency type II is the hallmark of EBV-positive Hodgkin disease and non-Hodgkin lymphomas (NHL), as well as nasopharyngeal carcinomas (NPC). EBV proteins expressed in these malignancies are EBNA1, LMP1, and LMP2. In addition, BARF1 is expressed in subsets of latency type II associated malignancies. In latency type I, found in EBV-positive Burkitt lymphoma and gastric adenocarcinomas, only EBNA1 is expressed. However, variants in which all EBNAs are expressed in the absence of LMP1 have also been described.

The EBV proteins expressed during type III latency are involved in the transformation and growth of EBV-infected B cells. EBNA1 binds to the origin of replication of the latent viral genome and is responsible for the maintenance of the EBV episome in host B cells. EBNA2 upregulates the expression of the viral proteins LMP1 and LMP2 and cellular proteins that contribute to transformation.

EBNA3A and -3C are essential for EBV-induced B-cell transformation, and although EBNA3B is not essential for transformation, it is highly conserved and therefore must provide a survival function in vivo. EBNA-LP cooperates with EBNA2 in the induction of viral and cellular genes. LMP1, a viral oncogene, behaves like a constitutively activated CD40 molecule and is essential for EBV-mediated B-cell transformation. LMP2 mimics an activated B-cell receptor (BCR) allowing for long-term B-cell survival in the absence of antigen. In addition, it prevents the reactivation of EBV into the lytic phase of infection.

Besides EBV proteins, small nonpolyadenylated viral RNAs termed *EBERs 1* and *2* and the BamHI-A rightward transcripts (BARTS) are expressed in all forms of latency. In addition, the expression of at least 17 distinct EBV-derived microRNAs has been reported. The EBERs are the most abundant viral RNAs in latently infected cells. They enhance the oncogenic phenotype of EBV-transformed cells but are nonessential for EBV-mediated transformation. The expression pattern of the microRNAs depends on the latency type, and it is therefore likely that they play an important role during the life cycle of the virus.

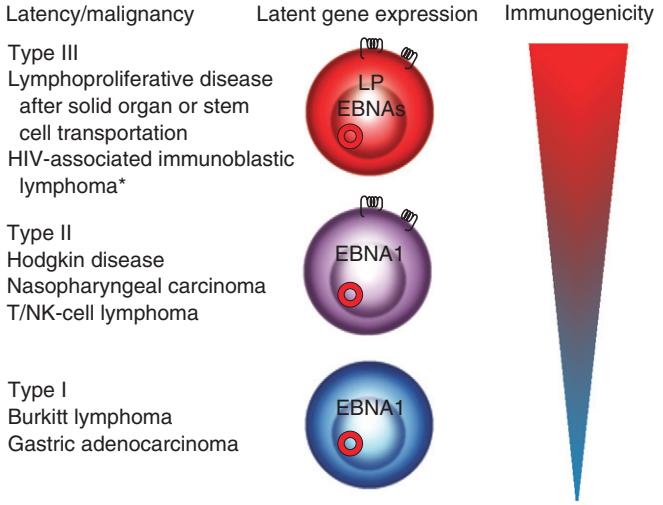

Figure 52-3 EBV-LATENT GENE EXPRESSION AND IMMUNOGENICITY OF COMMON EBV-ASSOCIATED MALIGNANCIES. *EBNA,* Epstein-Barr nuclear antigen; *LP,* leader protein. For an explanation of symbols, see Fig. 52-1. *Not all lymphomas are latency type III.

IMMUNE RESPONSE TO EBV

Healthy individuals mount vigorous humoral and cellular immune responses to primary EBV infection.[6] Although antibodies to the viral membrane proteins neutralize virus infectivity, the cellular immune response is essential for controlling virus-infected cells during both lytic and latent phases.

Humoral Immune Responses

Heterophile Antibodies

Heterophile antibodies, originally described by Paul and Bunnell, are present in 90% to 95% of EBV infections at some point during the illness. However, in infants and children under the age of 4 with primary EBV infection, heterophile antibody responses are often not detected. Heterophile antibodies are IgM antibodies, which agglutinate erythrocytes from different species, including bovine, camel, horse, goat, and sheep. EBV-induced heterophile antibodies have no reactivity against guinea pig kidney cells in contrast to naturally occurring antibodies (Forssman antibodies) or antibodies present in patients with serum sickness and other conditions.

In addition to heterophile antibodies, cold agglutinins directed preferentially against the anti-I antigen on red cell membranes are frequently detected in the sera of IM patients; however, hemolytic anemia is rare. Other antibodies (including anti-I, anti-N, Donath-Landsteiner antibodies, platelet antibodies, and anti–smooth muscle antibodies) have been described.

EBV-Specific Antibodies

EBV-specific antibody responses are detected with immunofluorescence assays developed in the first decades of EBV research. EBV antibodies are directed against (a) EBNA, (b) early antigen (EA), (c) the membrane antigen (MA) expressed on the surface of cells late in the lytic cycle, and (d) the viral capsid antigen (VCA) expressed within cells late in the lytic cycle. Each antigen is a composite of several distinct viral proteins, and attempts have been made to replace the aforementioned assays with tests using specific viral proteins; however, no single test has attracted widespread use.

VCA-IgM and -IgG antibodies are usually present at the onset of clinical symptoms because of the prolonged viral incubation period (Table 52-1). VCA-IgM antibodies are a good marker for an acute infection because they rapidly disappear within 4 to 8 weeks.

Table 52-1 Frequently Determined EBV-Specific Antibodies

Antibody Specificity	Positive in IM (%)	Time of Appearance in IM	Persistence	Comments
VIRAL CAPSID ANTIGEN				
VCA-IgM	100	At clinical presentation	4-8 weeks	Highly sensitive and specific; of major diagnostic utility
VCA-IgG	100	At clinical presentation	Lifelong	Useful for documentation of past EBV infection
EARLY ANTIGEN (EA)				
Anti-D	70	Peaks 3-4 weeks after onset	3-6 months	Correlates with disease severity; seen in NPC patients
Anti-R	Low	2 weeks to several months after onset	2 months to >3 years	Occasionally seen with unusually severe cases; seen in patients with African Burkitt lymphoma
EBNA	100	3-4 weeks after onset	Lifelong	Presence excludes primary EBV infection

Modified from Schooley RT: Epstein-Barr virus (infectious mononucleosis). In Mandell GL, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases,* Philadelphia, 2000, Churchill Livingstone, p 1599.

VCA-IgG antibodies persist for life and are commonly used to document prior EBV infection. IgG antibodies against EA are present at the onset of the clinical illness in approximately 70% of patients. EA antibodies are divided into methanol-sensitive (anti-D) and methanol-resistant (anti-R) antibodies, and the majority of EA antibodies detected are anti-D antibodies. The presence of anti-D antibodies is consistent with recent infection, because titers disappear after recovery. IgG antibodies to EBNA appear late in the course of almost all cases of EBV infection and persist throughout life; their presence early in a suspected case of primary EBV infection excludes the diagnosis. Aberrations in this pattern of serum reactivity are observed in many EBV-associated diseases and will be discussed under the specific disease sections. For example, the absence of EBNA antibodies despite previous EBV infection is one of the serologic markers suggestive for chronic active EBV infection (see CAEBV, later).

Cellular Immune Responses

In normal individuals, primary EBV infection often results in a massive expansion of activated, antigen-specific T cells. Using tetramer technology to enumerate antigen-specific T cells, it has been documented that the CD8 positive T-cell response may be dominated by T cells specific for a limited number of epitopes, as seen with T-cell responses against other herpesviruses. T cells specific for epitopes derived from immediate early and several early EBV proteins of the lytic cycle are dominant during the acute phase of IM, and long-term persistence of EBV-specific, CD8-positive T cells has been documented after primary EBV infection. As many as 5.5% of the circulating CD8-positive T cells in a healthy virus carrier may be positive for a single EBV epitope, illustrating how persistent EBV infection can influence the composition of the host's T-cell pool. Besides EBV-specific CD8-positive T cells, EBV-specific CD4-positive T cells play an important role in the control of EBV infections, and EBNA1-specific CD4-positive T cells have been implicated in the control of newly infected B cells. As for CD8-positive T-cell responses, there is a marked hierarchy of immunodominance, with the majority of CD4-positive T cells' responses directed against EBNA1 and to a lesser extent against EBNA3C.

EBV-Associated Malignancies

Malignancy	*EBV Frequency*
Hodgkin disease	≈40%
Non-Hodgkin lymphomas	
Burkitt lymphoma	20%-95%
Diffuse large B-cell lymphoma and CD30$^+$ Ki-1$^+$ anaplastic large cell lymphoma	10%-35%
Lymphomatoid granulomatosis	80%-95%
T cell–rich B-cell lymphoma	20%
Angioimmunoblastic lymphoma	>80%
T-cell, NK cell, and T/NK-cell lymphomas	30%-90%
Nasopharyngeal carcinoma	>95%
Gastric adenocarcinoma	5%-10%
Pyothorax-associated lymphoma	>95%
Leiomyosarcoma in immunocompromised patients	>95%

EBV VACCINE DEVELOPMENT

At present there is only limited experience with human EBV vaccines. In one study, nine seronegative children in Southern China were vaccinated with a recombinant vaccinia virus expressing the major EBV viral glycoprotein gp350. All nine patients developed neutralizing antibodies, and six patients remained EBV-negative over a 16-month period in contrast to none of the 10 controls. Another vaccine trial with a gp350 subunit vaccine has been completed, but efficacy data are not yet available. Although potentially ideal for preventing EBV-associated malignancies, vaccines providing life long immunity against primary EBV infection may not be feasible because the type of immunity required to avoid repeated infection through mucosal surfaces is not clearly defined. Moreover, a recent study suggests that the natural immune response to EBV is not sufficient to protect healthy EBV-positive individuals from repeated infections with different EBV strains.

Vaccine strategies for the immunotherapy of EBV-associated malignancies should seek to elicit or boost the EBV-specific cellular immune response against EBV latency. Individuals likely to benefit from this approach are EBV-seronegative patients scheduled to undergo solid organ transplantation or patients who have an EBV-associated malignancy with a low tumor burden or are in remission (see box on EBV-Associated Malignancies). Three vaccine studies have been conducted in EBV-positive NPC patients. In two studies patients with advanced disease were vaccinated with either dendritic cells (DCs) loaded with peptides derived from LMP2 or DCs transduced with an adenoviral vector encoding full-length LMP2 and an inactive form of LMP1. Administration of DC vaccines was safe, and a transient increase in the frequency of LMP2-specific T cells was observed on the DC/peptide vaccine trial. However, the clinical benefit in both studies was limited. Thus future studies should focus on DC vaccines with greater potency administered to subjects with less tumor burden. In another phase I clinical study, after frontline therapy, NPC patients were vaccinated with a vaccinia virus encoding the c-terminal portion of EBNA1 and LMP2. Induction of CD4- and CD8-positive antigen-specific T-cell responses was observed in the majority of patients after vaccination, and a Phase II clinical study is currently being planned.

In another trial, EBV-seronegative, HLA-B8 positive individuals were vaccinated with an MHC class I-restricted EBV peptide epitope derived from EBV latent viral protein EBNA3A; the peptide vaccine was well tolerated, but immunologic and virologic studies are pending.

In the past, EBV vaccine development was impeded by the lack of a suitable animal model. Most vaccination studies so far have been done in cottontop tamarins, a species of New World monkeys that develop B-cell lymphomas after intraperitoneal injection of EBV. This model lacks key features of human EBV disease such as oral transmission and long-term viral persistence, which are considered to be important for vaccine development. Since 1997 a rhesus monkey model for acute and persistent EBV infection is available that takes advantage of the rhesus lymphocryptovirus, which belongs to the same herpes virus subgroup as EBV. This animal model reproduces the salient features of human EBV infection, such as oral transmission, lymphadenopathy, atypical lymphocytosis, serologic responses to EBV proteins, and viral latency in B cells. In the future, this model has the potential to become a useful platform to test different vaccination strategies.

INFECTIOUS MONONUCLEOSIS

Epidemiology

EBV infections occur worldwide and in most populations 90% to 95% of adults have antibodies against EBV. Depending on geographic and socioeconomic factors, there is a wide variation in the age of primary EBV infections. Early, asymptomatic primary EBV infection occurs in individuals from lower socioeconomic groups and in third world countries. In higher socioeconomic groups in industrialized countries, the age of primary infection is often delayed until the second decade of life and clinically apparent IM is more prevalent.

Humans are the only source of EBV. EBV is present in the saliva of IM patients. A majority of EBV-positive adults shed virus into their saliva, and this percentage is increased in immunocompromised

patients such as solid organ transplant recipients. EBV is viable outside the body for 2 weeks at 4° C but is susceptible to drying; the virus has not been recovered from environmental sources, suggesting that close contact is needed for viral spread. The incubation period of IM is estimated to be 30 to 50 days.

Clinical Manifestations

Primary EBV infection in infants and young children either is asymptomatic or accompanied by mild, nonspecific symptoms and signs such as fever, upper respiratory tract infection, pharyngitis with or without tonsillitis, and cervical lymphadenopathy. In contrast, approximately 50% of adolescents and young adults present with the clinical picture of IM. Frequently, a prodrome consisting of fatigue, malaise, and low-grade fever is present for 1 to 2 weeks. Prominent pharyngitis with exudative tonsillitis is often the cardinal sign of IM; other signs and symptoms are listed in Table 52-2. The adenopathy in IM most commonly affects the posterior cervical lymph nodes, although diffuse adenopathy can occur. The enlarged lymph nodes are not fixed, may be tender to palpation, and lack overlying skin erythema. Hepatomegaly is uncommon; however, splenomegaly develops in more than 50% of patients and is more prominent in the second to fourth week of the illness. Skin manifestations include a faint, morbilliform rash reminiscent of rubella and less commonly erythema multiforme and erythema nodosum. Most patients with primary EBV infection have symptoms for 2 to 4 weeks and recover without significant complications or sequelae.

Complications of Primary EBV Infections

The incidence of complications associated with primary EBV infection is low, although any organ system can be affected.

Hematologic Complications

Patients with IM may present with a wide range of hematologic findings besides the atypical lymphocytosis (Fig. 52-4). These include anemia, neutropenia, thrombocytopenia, and rare cases of aplastic anemia.

Anemia

Autoimmune hemolytic anemia occurs in approximately 3% of patients with IM. It presents in the first 2 weeks of the illness, and the majority of patients recover within 1 to 2 months. Patients usually have a positive direct Coombs test. Most common anti-I antibodies are present; however, anti-I, anti-N, and Donath-Landsteiner antibodies have also been reported. In addition to hemolysis, IM-associated anemia can be caused by erythroblastopenia.

Neutropenia

Mild, self-limiting neutropenia is a common finding during the first 4 weeks of the disease. However, severe neutropenia associated with fatal bacterial infections has been reported.

Thrombocytopenia

Mild thrombocytopenia (50,000 to 150,000/mm^3) is a common finding in patients with IM. It usually occurs within the first 2 weeks of presentation and resolves within 2 months. Severe

Table 52-2 Clinical Manifestations of Infectious Mononucleosis

Manifestation	Percentage (Range)
SYMPTOMS	
Sore throat	82 (70-88)
Malaise	57 (43-76)
Headache	51 (37-55)
Anorexia	21 (10-27)
Myalgias	20 (12-22)
Chills	16 (9-18)
Abdominal discomfort	9 (2-14)
SIGNS	
Lymphadenopathy	94 (93-100)
Pharyngitis	84 (69-91)
Fever	76 (63-100)
Splenomegaly	52 (50-63)
Hepatomegaly	12 (6-14)
Palatal enanthem	11 (5-13)
Rash	10 (0-15)
Jaundice	9 (4-10)

Modified from Schooley RT: Epstein-Barr virus (infectious mononucleosis). In Mandell GL, Bennett JE, Dolin R, editors: *Principles and practice of infectious diseases*, Philadelphia, 2000, Churchill Livingstone, p 1599.

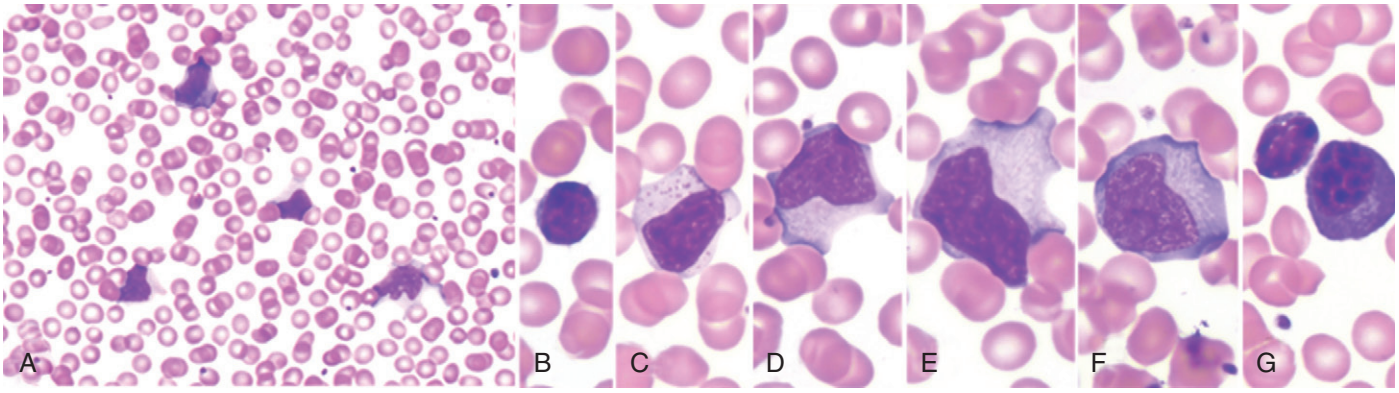

Figure 52-4 PERIPHERAL BLOOD SMEAR IN INFECTIOUS MONONUCLEOSIS. Low power **(A)** shows moderately high white blood cell count and high number of reactive, or "atypical" lymphocytes. Higher power **(B** to **G)** illustrates spectrum of lymphoid morphology, including small resting lymphocyte **(B)** for comparison, large granular lymphocyte **(C)**, atypical forms **(D** to **F)**, also referred to as "reactive" lymphs, and circulating plasma cell **(G)**.

thrombocytopenia with overt bleeding is rare; however, death from intracranial hemorrhage has been described. The etiology of the thrombocytopenia is not completely understood, and a variety of explanations have been suggested. Because bone marrow examination shows normal or increased numbers of megakaryocytes, peripheral platelet destruction is most likely due to the presence of antiplatelet antibodies or platelet pooling and destruction within an enlarged spleen.

Splenic Rupture

Splenic rupture (Fig. 52-5) occurs predominately in males, with an incidence of 1/1000 to 1/3000. The incidence of rupture is highest in the second and third week of illness and can be the first sign of IM. Clinical symptoms include abdominal pain or pain referred to either shoulder. Because abdominal pain is an unusual symptom of uncomplicated IM, a splenic rupture should be strongly considered in IM cases whenever abdominal pain is reported. Although it is a life-threatening complication, with current management, the mortality rate is very low.

Neurologic Complications

Neurologic complications develop usually during the first 2 weeks of IM and may be the only manifestation of IM. EBV infection can cause a wide spectrum of neurologic diseases, including encephalitis, meningitis, Guillain-Barré syndrome, acute transverse myelitis, and peripheral neuritis. Patients with neurologic complications have an excellent outcome, with most patients recovering completely.

Other Organ Involvement

Although symptomatic heart disease with IM is uncommon, in one cohort of patients, unspecific ST- and T-wave abnormalities were found in 6% of patients. Renal involvement manifested as microscopic hematuria, and proteinuria is seen in 10% to 15% of patients; however, significant renal dysfunction is rare. Airway compromise due to hypertrophy of the adenoids and tonsils or mucosal inflammation and edema is uncommon but potentially fatal.

Diagnosis

Atypical lymphocytosis is the cardinal hematologic finding in IM (see Fig. 52-4). It develops during the first week of the illness and peaks between the second and third week. Atypical lymphocytes represent 60% to 70% of the total white cell count, which ranges between 12,000/mm^3 and 18,000/mm^3. In general, the atypical lymphocytes are large and vary in size. Nuclei are large and eccentrically placed; the cytoplasm is basophilic, and vacuoles are often present. The variable morphologic pattern of atypical lymphocytes in IM distinguishes them from the monotonous appearance of immature leukemic blasts. Atypical lymphocytosis is not pathognomonic for IM and is associated with other diseases such as acute viral hepatitis, cytomegalovirus infections, mumps, toxoplasmosis, rubella, roseola, and drug reactions.

The diagnosis of EBV infection depends on serologic testing. Tests for heterophile antibodies, including the monospot test and slide agglutination tests, are routinely available. The results of these tests are often negative in children less than 4 years of age, but they identify 90% of cases in older children and adults. Of the available EBV-specific serologic tests, VCA-IgM antibodies are most commonly determined to diagnose primary EBV infection in heterophile-negative IM cases; determining antibodies against EA may also be helpful (Table 52-1). VCA-IgG antibodies are positive during acute infections as well as the convalescent period. The presence of anti-EBNA antibodies excludes an acute infection. Isolation of EBV from throat washings is feasible; however, it is of little diagnostic value because 10% to 20% of healthy adult EBV carriers may shed the virus.

Differential Diagnosis

In the majority of cases, the diagnosis of IM is straightforward. The differential diagnosis includes streptococcal and nonstreptococcal pharyngitis, acute infections with cytomegalovirus, human herpesvirus 6, hepatitis viruses, and toxoplasma. Depending on the presentation, other diseases may be considered such as HIV, rubella, and leukemia or lymphoma.

Treatment

Supportive therapy should include rest and analgesia in the acute stage of IM. Contact sports should be avoided until the patient has fully recovered and the spleen is no longer palpable. The use of corticosteroids is not indicated for uncomplicated IM; however, a trial of corticosteroids is warranted in patients with marked tonsillar inflammation and hypertrophy resulting in impending airway obstruction. Although acyclovir reduces EBV shedding into oral secretions, treatment of IM with acyclovir has resulted in no clinical benefit.

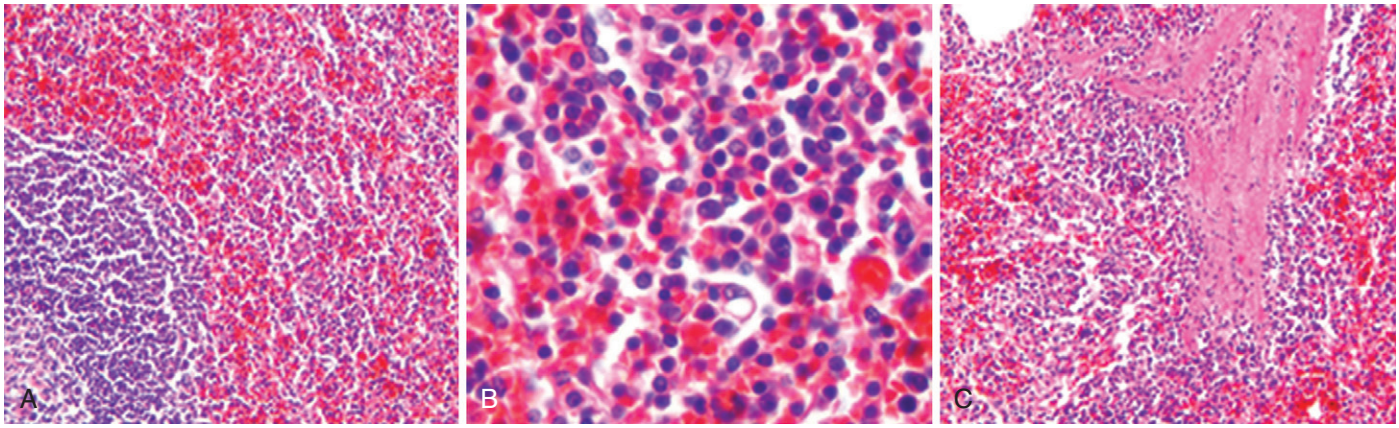

Figure 52-5 RUPTURED SPLEEN FROM PATIENT WITH INFECTIOUS MONONUCLEOSIS. Sections from the spleen show increased white cells in the red pulp (**A** and **B**). These correspond to the proliferating activated lymphocytes seen in the blood. The lymphocytes can infiltrate into the splenic trabeculae **(C)**, weakening the integrity of the spleen and making it more prone to rupture.

OTHER EBV-ASSOCIATED DISEASES

Most individuals recover from the acute phase of primary EBV infection with no long-term sequelae. However, a minority of patients with intrinsic defects in immune function may respond with potentially lethal uncontrolled pathologic inflammation with fever and multisystem organ failure, meeting diagnostic criteria for hemophagocytic lymphohistiocytosis (HLH). Others may develop chronic active EBV infections (CAEBV) with persistent fever, arthralgia, myalgia, and lymphadenopathy. Additional long-term consequences of EBV infection include lymphoproliferative and malignant disorders.

Hemophagocytic Lymphohistiocytosis

HLH is a syndrome characterized by uncontrolled inflammation (see Chapter 50). Diagnostic criteria defined by the Histiocyte Society reflect the clinical features of pathologic immune activation, including persistent fever, splenomegaly, cytopenias, hyperferritinemia, decreased fibrinogen or increased triglycerides, hemophagocytosis (in bone marrow, spleen, or lymph nodes), increased soluble interleukin-2 receptor alpha, and decreased or absent natural killer (NK) cell function. The diagnosis of HLH can also be established by a pattern of familial inheritance or proven gene defects. It was first characterized as an inherited disorder in infants in the 1950s, referred to as "familial hemophagocytic reticulosis."

Gene defects resulting in impaired cytotoxic NK and T-cell function have been associated with autosomal recessive inheritance of HLH, including PRF1, UNC13D, Munc18-2, STX11, Rab27a (Griscelli syndrome, type 2), LYST (Chédiak-Higashi syndrome), and AP3B1 (Hermansky-Pudlak syndrome, type II).[7] EBV infection may trigger HLH in patients with any form of familial disease. Gene defects are identified in only 50% of patients with family history consistent with inherited HLH. Therefore, although a diagnosis "primary" or "familial" HLH may be proven, it is impossible to exclude. Familial HLH commonly presents in young children, but there are reports of new onset of HLH in adults as old as 62 years with mutations in HLH-associated genes. Patients with familial HLH typically require prompt treatment with chemotherapy and immune suppression (etoposide/dexamethasone) followed by hematopoietic stem cell transplant (HSCT).[8] Without therapy, survival of patients with active familial HLH is approximately 2 months. The first international treatment protocol for HLH organized by the Histiocyte Society in 1994 reported long-term survival of over 50%. More recently, survival rates of greater than 90% have been reported with reduced intensity conditioning regimens.[9]

The term *secondary HLH* generally refers to older children (or adults) who present without a family history or known genetic cause for their HLH. EBV is a common trigger for "secondary HLH," ranging from inflammation that resolves spontaneously to unrelenting disease requiring HSCT. Differentiating infectious mononucleosis from EBV-associated HLH (EBV-HLH) is challenging. Clinical criteria for HLH should be evaluated in patients with persistently high cell-free EBV genome copy numbers in plasma, persistent symptoms of inflammation, or severe symptoms. Patients who initially meet clinical criteria for HLH may occasionally improve spontaneously. Patients with less severe presentations may also respond to corticosteroids, intravenous immunoglobulins or cyclosporine. However, in patients with progressive or severe disease, early initiation (within 4 weeks of onset of symptoms) of etoposide is associated with significant improvement in survival.[10] Because it can eliminate EBV-infected B cells, rituximab may be a beneficial addition to other therapies in patients with progressive EBV-HLH. Some patients with apparently self-resolving HLH after primary EBV infection later develop recurrent HLH requiring immunochemotherapy and HSCT. Therefore it remains important to follow patients beyond resolution of initial symptoms. Alemtuzumab has also been reported to be effective in patients with recurrent or refractory disease.[8]

X-Linked Lymphoproliferative Diseases

XLP1

Mutations or deletions in SH2D1A (Src homology 2 domain protein 1A) results in X-linked lymphoproliferative disease (XLP1; Duncan disease), an immunodeficiency characterized by fatal IM meeting the diagnostic criteria for HLH, agammaglobulinemia, or B-cell lymphoma. SH2D1A interacts with SLAM (signaling lymphocyte activation molecule), which plays a central role in the stimulation of B and T cells. SH2D1A controls several distinct key T-cell signaling pathways, and mutant SH2D1A does not bind SLAM, suggesting that it is a natural SLAM inhibitor. SAP association with SLAM receptors is crucial for development of normal NKT cells, formation of normal germinal centers, and NK- and T-cell killing of EBV-infected B cells. T cells from patients with XLP1 are also resistant to apoptosis by reactivation-induced cell death (RICD). Immune hyperactivation induced by primary EBV infection may be due to specific defects in NK- and CD8-positive T-cell cytotoxicity rather than from decreased or absent cytotoxic proteins. Resistance to apoptosis may exacerbate the inflammatory response due to persistence of ineffective activated NK and T cells.

Following infection with EBV, XLP1 patients mount a vigorous, uncontrolled polyclonal expansion of T and B cells. Infiltrating T cells cause extensive tissue destruction of the liver and bone marrow, resulting in death in 50% of XLP1 patients during primary EBV infection. Approximately 30% of patients have acquired hypogammaglobulinemia and 25% of patients develop malignant B-cell lymphomas that are often extranodal, involving the intestinal ileocecal region. It is important to realize that some patients with SH2D1A mutations may only present with hypogammaglobulinemia mimicking common variable immunodeficiency, and a diagnosis of XLP1 should be considered when more than one male patient with hypogammaglobulinemia is encountered in the same family. Patients with fulminant immunologic responses to primary EBV infection may be treated with HLH treatment strategies (steroids and etoposide) and/or rituximab. However, the only curative therapy for XLP1 is hematopoietic stem cell transplantation.

XLP2

A second X-linked immune deficiency characterized by recurrent HLH (with or without EBV infection) is XLP2, caused by BIRC4 mutations and XIAP deficiency.[11] Unlike patients with XLP1, those with XLP2 have less pleotropic clinical manifestations. It rarely results in lymphoproliferation or lymphoma and may be more accurately characterized as "X-linked familial HLH." XIAP is a ubiquitously expressed member of a family of proteins defined by baculovirus IAP repeat (BIR) domains that inhibit apoptosis through inhibition of caspases. The mechanism of XIAP-induced HLH remains uncertain. Paradoxically, unlike in cases of XLP1, in which lymphocytes are resistant to apoptosis, XIAP deficiency in XLP2 confers increased sensitivity to radiation-induced cell death. The clinical manifestations of HLH in XLP2 patients with primary EBV infections appear less severe than in patients with XLP1. However, data remain insufficient to make specific therapy recommendations for XLP1 versus XLP2 or other forms of familial HLH.

CAEBV

CAEBV represents a range of clinical manifestations resulting from persistent, uncontrolled infection of B, T, and/or NK cells by EBV (Table 52-3).[12] Inability to control infection is likely due to defects in cytotoxic immune function. CAEBV has considerable pathologic and clinical overlap with HLH, and immune dysfunction is likely due to a variety of causes. Early descriptions of CAEBV primarily reported disease in Asian patients, and almost all cases were due to

Table 52-3 Classification of Chronic Active EBV Infection

		Clinical Symptoms		
EBV-Infected Lymphocyte	**Geography**	**General**	**Skin**	**Clinical Course**
B cell	Predominant in Western hemisphere	Fever, adenopathy, organomegaly, hepatic, cardiac, or pulmonary dysfunction	None	Chronic
T cell	Predominant in Asia: *Japan, Taiwan, Korea* Also in Native Americans: *Mexico, Central and South America*		Hydroa vacciniforme	Risk for aggressive lymphoma/ leukemia
NK cell			Hypersensitivity to mosquito bites	

proliferation of EBV-infected T or NK cells. A recent review of several centers in the United States found a predominance of B cell–associated CAEBV in the western hemisphere.

To establish the diagnosis of CAEBV, patients must have (a) signs and symptoms for at least 6 months and (b) an abnormal EBV serology with high antibody titers of VCA-IgG and EA-IgG and little or no antibodies against EBNA. Affected individuals may also have measurable EA-messenger-RNA or EBV-DNA in the peripheral blood, serum, or affected tissues. The life-threatening form of CAEBV is characterized by high fevers, hepatosplenomegaly, and extensive lymphadenopathy, followed by hepatic, cardiac, or pulmonary dysfunction. These patients have very high EBV-VCA titers and EBV-DNA levels in their peripheral blood. Although EBV usually resides in B cells, in severe CAEBV, either T cells or NK cells are often infected, predisposing the patient to lethal T-cell or NK-cell lymphomas. Severe, often fatal CAEBV is more common in Japan, whereas mild/moderate CAEBV is more common in the Western hemisphere and is predominantly associated with B-cell infection. These patients do not have XLP-associated SH2D1A or BIRC4 mutations, and the etiology of CAEBV remains poorly understood. Severe allergy to mosquito bites is associated with EBV-infected NK cells, whereas hydroa vacciniforme is associated with EBV-infected T cells. The proposed classification scheme of CAEBV-associated lymphoproliferative disease (LPD) includes three categories: (1) polymorphic LPD without clonal proliferation of EBV-infected cells, (2) polymorphic LPD with clonality, and (3) monomorphic LPD (T- or NK-cell lymphoma/leukemia) with clonality.[13] In the 2008 *WHO Classification of Tumours of the Haematopoietic and Lymphoid Tissues,* LPDs associated with EBV-infected T cells are classified as systemic EBV-positive T-cell LPDs of childhood; LPDs associated with EBV-infected NK cells, as hydroa vacciniforme–like lymphoma.

Although sporadic clinical improvements of mild/moderate CAEBV have been reported after infusion of interleukin 2, high-dose immunoglobulin, antiviral drugs, anti–tumor necrosis factor (TNF)-α antibodies, or steroids, the only curative option for severe CAEBV is HSCT. Survival rates vary between 50% and 95%, with better outcomes for patients who (a) are transplanted early after diagnosis, (b) have fewer complications before transplant, and (c) have received a reduced intensity.[14] Besides HSCT, the adoptive transfer of autologous EBV-specific cytotoxic lymphocytes (CTL) has been explored in five patients with mild or moderate CAEBV. Infusion of EBV-specific CTL resulted in resolution of fatigue, malaise, fever, lymphadenopathy, and splenomegaly lasting for 6 to 36 months. For severe CAEBV in which EBV resides in the T- or NK-cell compartment, the use of EBV-specific CTL has been investigated anecdotally. For example, we have infused donor-derived LMP2-specific T cells with a good partial response as judged by decreasing EBV-DNA load.

Oral Hairy Leukoplakia

Oral hairy leukoplakia (OHL) develops frequently, although not exclusively, in HIV-positive patients. It is a nonmalignant hyperplasia of epithelial cells, and most patients present with white, corrugated lesions on the tongue. Besides IM, OHL is the only EBV-associated disease in which active viral replication is apparent, and multiple strains are often present within the same lesion. Inhibiting EBV replication in vivo with antivirals such as valacyclovir results in resolution of OHL. However, after valacyclovir treatment, EBV replication recurs in normal tongue epithelial cells, indicating that productive EBV replication is necessary but not sufficient to induce OHL.

EBV-Associated Malignancies

Over the past decades, EBV has been associated with a heterogeneous group of malignancies.[15] Although there is strong circumstantial evidence linking EBV to these malignancies, the potential causative relationship between EBV and these tumors remains to be firmly established. The following section focuses on EBV-associated lymphoproliferative disease, Hodgkin disease, NHL (including Burkitt lymphoma), and nasopharyngeal carcinoma (Fig. 52-6 and Fig. 52-7). All EBV-associated malignancies are associated with viral latency, and spontaneous viral replication occurs at a very low frequency. Because antiviral agents, like acyclovir, only prevent viral replication and do not affect latency, these agents are of limited therapeutic value.

Lymphoproliferative Disease

EBV-LPD develops in patients with congenital or acquired immunodeficiencies, including severe combined immunodeficiency, XLP, HIV infection, and immunosuppression in recipients of solid organ transplants (SOT) (see Fig. 52-6, *A, B*) or HSCT.[16] Besides EBV and a dysfunctional cellular immune system, genetic alterations in B cells have also been implicated in the pathogenesis of posttransplant lymphoproliferative disorder (PTLD), especially in SOT recipients, including microsatellite instability, DNA hypermethylation, aberrant somatic hypermutation, and mutations in specific genes such as *MYCC, BCL-6, N-ras,* and *p53*. Most cases of EBV-LPD are lymphomas of B-cell origin, histologic high-grade NHL of the immunoblastic or undifferentiated large cell type that respond poorly to cytotoxic therapy. In the setting of solid organ transplantation, the reported incidence of EBV-LPD ranges from 1% to 25%, with the highest risk in seronegative recipients, patients receiving intensive immunosuppressive therapy, and patients receiving grafts with a high lymphoid content. After HSCT the incidence of EBV-LPD varies with the transplant regimen and may be as high as 25%. Risk factors for the development of EBV-LPD include the use of stem cells from an HLA-mismatched family member or closely HLA-matched unrelated donor, T-cell depletion of the donor cells, intensive immunosuppression, and an underlying diagnosis of primary immunodeficiency. The incidence is much lower when methods that also deplete B cells are employed. The onset of EBV-LPD seems to be preceded by a large increase in virus load as well as the proliferation of

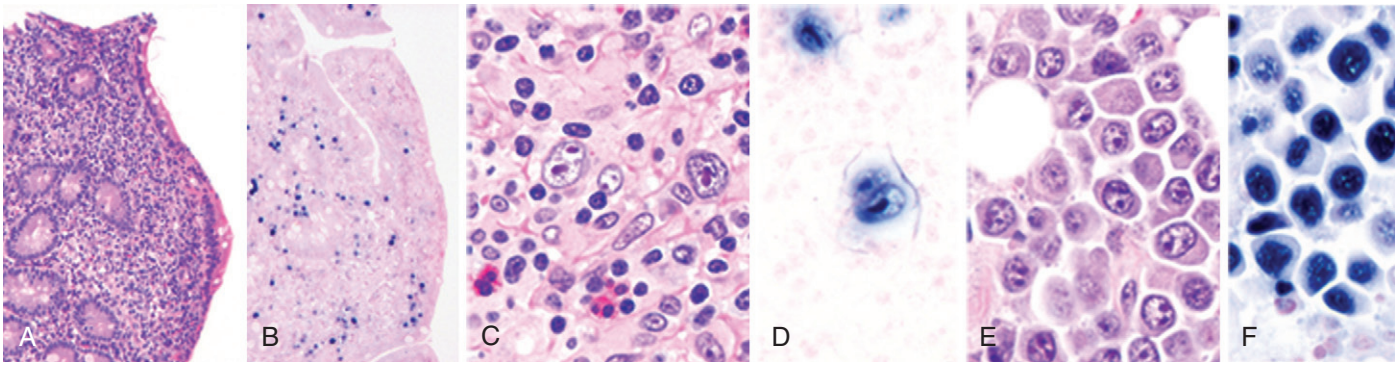

Figure 52-6 EXAMPLES OF EBV-POSITIVE LYMPHOID MALIGNANCIES: Posttransplant lymphoproliferative disorder, Hodgkin lymphoma, and large B-cell lymphoma. PTLD in the duodenum of a 15-month-old **(A)** with history of liver transplant. The PTLD was classified as a polymorphic type and was EBV-positive **(B)**. Hodgkin lymphoma **(C)** and EBV-positive Reed-Sternberg cells **(D)**. Large B-cell lymphoma (plasmablastic type) in an HIV-positive patient **(E)**, diffusely EBV-positive **(F)**. Note, all EBV studies are in situ hybridizations for EBV mRNA, EBER.

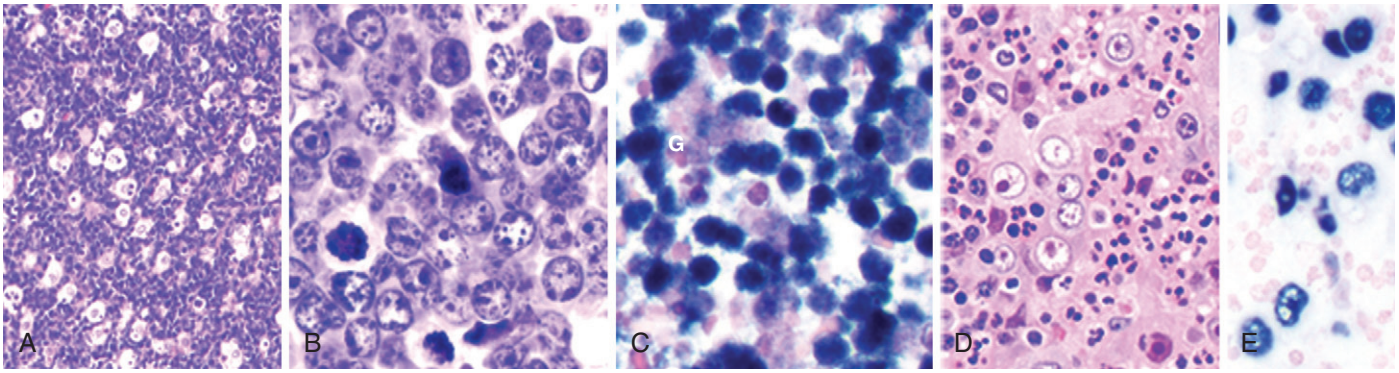

Figure 52-7 FURTHER EXAMPLES OF EBV-POSITIVE MALIGNANCIES: Burkitt lymphoma and nasopharyngeal carcinoma **(A** to **E)**. Low power of Burkitt lymphoma showing the classic "starry sky" appearance **(A)** and higher power illustrating the highly proliferative lymphoma cells **(B)**, which are uniformly EBV$^+$ **(C)**. Nasopharyngeal carcinoma **(D)** with EBV-positive cells **(E)** demonstrated by in situ hybridization for EBV mRNA.

EBV-infected B cells. Frequent monitoring of the EBV-DNA load in peripheral blood is a valuable diagnostic test for early detection of EBV-LPD after HSCT or SOT. The threshold level of EBV-DNA suggestive of impending EBV-LPD varies according to the PCR method of quantifying viral DNA. However, it should be emphasized that not all patients with high EBV-DNA levels, especially those with a solid organ transplant, develop EBV-LPD. Several distinct patterns of EBV latent gene expression have been identified in the memory B cells of high-load EBV carriers, with type III latency conferring the highest risk for EBV-LPD development. Besides EBV-DNA levels, determining the frequency of EBV-specific T cells or the functionality of T cells in patients with high EBV-DNA load might also assist in identifying patients who are at increased risk for developing EBV-LPD. In addition, host factors such as polymorphisms in the promoter regions of cytokines have been implicated in increasing the risk for developing EBV-LPD. Thus an elevated EBV-DNA load can lead to early diagnosis of EBV-LPD, with consequent reductions in mortality and treatment-related morbidity, although additional results such as clinical signs and symptoms, as well as radiographic findings, must be taken into account before therapy is initiated (Fig. 52-8).[17,18]

Treatment of Lymphoproliferative Disease

A variety of treatment approaches have been explored for EBV-LPD (Fig. 52-9). These include reduction or withdrawal of immunosuppression, conventional chemotherapy, radiation for localized disease, monoclonal antibodies, adoptive transfer of T cells or EBV-specific cytotoxic T lymphocytes (CTL), and autologous or allogeneic HSCT for refractory cases.[16,19] Other potential strategies include the use of hydroxyurea to eradicate EBV episomes or inducing the lytic cycle of EBV so that the lymphoma cells become sensitive to ganciclovir. In SOT recipients simple withdrawal of immune suppression can result in the regression of localized EBV-LPD by allowing recovery of the suppressed cellular immune system. This approach is limited by the risk for graft rejection, and it is not useful after HSCT because of the profound immunosuppression and the risk for inducing graft-versus-host disease (GVHD).

Monoclonal Antibody Therapy

The CD20 monoclonal antibody rituximab is currently widely used as prophylaxis and as therapy for EBV-LPD. A comprehensive review of the literature that included articles and abstracts published between 1999 and 2008 reported that the use of rituximab as preemptive therapy prevented the development of EBV-LPD in 90% of 341 HSCT recipients, while therapy was associated with a response rate of 63% in 126 HSCT patients.[20] However, response rates varied widely, likely reflecting heterogeneity in patient populations and the fact that early diagnosis and treatment leads to better outcomes. For EBV-LPD after SOT, a recent multicenter analysis of 80 patients reported that rituximab-based therapy had a 3-year progression-free survival of 70% compared with 21% for patients treated without rituximab.[21] Half of the patients treated with rituximab also received chemotherapy, most of them having bulky disease and a high International Prognostic Index. A recent prospective multicenter study suggests that sequential therapy of rituximab followed by chemotherapy results in excellent disease control and overall survival. However, at present it remains unclear for which group of patients rituximab monotherapy is sufficient. Retrospective studies have identified risk factors including extralymphatic disease, high LDH, low albumin, and poor performance status, but these risk factors need to

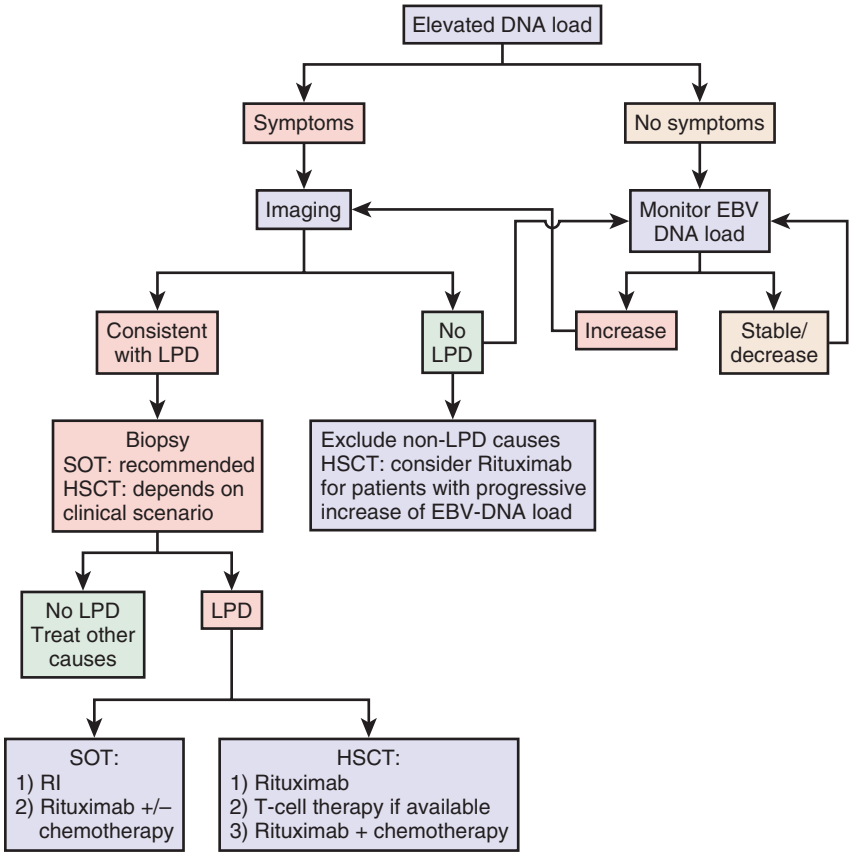

Figure 52-8 RECOMMENDED ALGORITHM FOR FOLLOWING PATIENTS WITH INCREASED EBV-DNA LOAD. *HSCT,* Hematopoietic stem cell transplant; *RI,* reduction of immunosuppression; *SOT,* solid organ transplant.

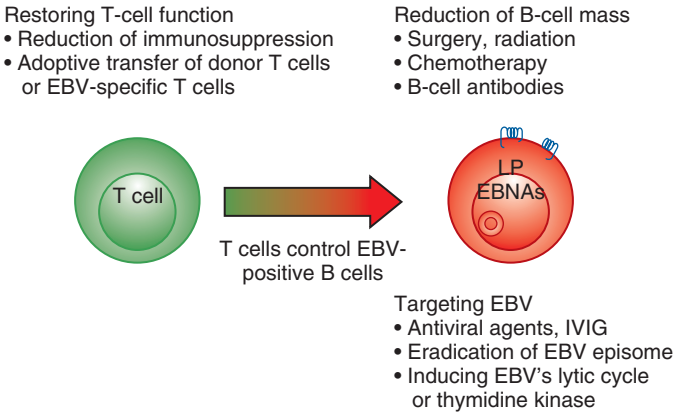

Figure 52-9 TREATMENT STRATEGIES FOR EPSTEIN-BARR VIRUS–ASSOCIATED LYMPHOPROLIFERATIVE DISEASES (EBV-LPD). For an explanation of symbols, see Fig. 52-1.

be validated in prospective studies.[22] In summary, rituximab has led to a dramatic improvement in outcome of EBV-LPD. However, rituximab does not restore the cellular immune response to EBV, which may be crucial for the long-term control of EBV-mediated B-cell proliferation. EBV-infected B cells may therefore increase with B-cell recovery, and EBV-LPD may recur. Although rare, the recurrence of CD20-negative lymphomas with the use of rituximab has been reported. Patients who fail to respond to chemo-immunotherapy strategies may respond to high-dose chemotherapy with HSC rescue.

T-Cell Therapies

Donor T-cell infusions have been used successfully to treat EBV-LPD post-HSC transplantation but carry the inherent risk for GVHD. One strategy to prevent GHVD after T-cell infusion is the administration of donor-derived ex vivo expanded polyclonal EBV-specific CTL. To determine whether adoptive transfer of donor-derived EBV-specific CTL is effective prophylaxis for EBV-LPD, EBV-specific CTL lines were infused into approximately 100 recipients of HSC transplant. Patients infused with CTL experienced no GVHD, survived long-term, and developed reconstituted immunity against EBV, and no infused patient developed EBV-LPD compared with an incidence of 11.5% in a comparable untreated control group.[5] Immunotherapy with EBV-specific CTL was also used to treat 13 HSC transplant recipients who developed overt lymphoma. Eleven of these patients responded well with complete regression of bulky tumors, although infused CTL caused inflammation at the tumor site. One of the responders had central nervous system (CNS) PTLD, indicating that EBV-specific CTL can cross the blood-brain barrier to eradicate CNS lesions. One patient died of progressive disease, a failure attributed to a deletion in the EBV protein EBNA3B in the tumor virus causing resistance to killing by the infused CTL.

In solid organ transplant recipients who develop EBV-LPD, donor-derived T cells are of limited value, because the tumor almost always arises in recipient B cells, and donor T cells are unlikely to survive in the recipient's hematopoietic system. Initial studies using autologous or partly HLA-matched EBV-specific CTL for the treatment or prevention of EBV-LPD after SOT have shown promising results but need further investigation.[23] In our study, 12 SOT recipients at high risk for EBV-LPD, or with active disease, received autologous CTL infusions without toxicity. None of the treated patients developed PTLD. One patient with liver PTLD showed a complete response, and one with ocular disease has had a partial response stable for more than 1 year. However, the expansion and persistence of adoptively transferred EBV-specific CTL was limited in the presence of continued immunosuppression. Drawbacks of EBV-specific T-cell therapies are the facilities needed and the time required (3–4 months) for CTL production using standard methods. Although rapid CTL production protocols are being developed, the use of readily available

"banked" allogeneic EBV-specific CTL is actively being explored. In one multicenter clinical trial 31 SOT and 2 HSCT recipients with EBV-LPD, who had failed conventional therapies, received allogeneic EBV-specific CTL.[24] CTL infusions were well tolerated with no evidence of graft rejection. The overall response rate was 52% at 6 months, including 14 patients with a complete response. Our center has conducted a multicenter clinical trial with banked allogeneic multivirus-specific CTL in 41 HSCT recipients. Eight cell lines were infused because of EBV-LPD with a response rate of 75%. These studies document the feasibility of using banked CTL products and warrant further active exploration.

Several preclinical studies have shown that HDAC inhibitors, proteosome inhibitors, and chemotherapy and/or radiation can induce the EBV lytic cycle, which is associated with the expression of the EBV-encoded thymidine kinase rendering the EBV-positive cancer cells sensitive to acyclovir or ganciclovir. Fifteen patients with refractory EBV-positive malignancies including six with EBV-LPD were treated on one clinical trial with the HDAC inhibitor arginine butyrate followed by ganciclovir.[25] Ten out of fifteen patients had significant antitumor responses with four complete and six partial responses. Three patients experienced complications from rapid tumor lysis. Nevertheless, the encouraging antitumor responses warrant further active exploration of this approach.

EBV-Positive Hodgkin Disease and Non-Hodgkin Lymphomas

EBV is associated with Hodgkin disease as well as NHLs in immunocompetent patients. An increased incidence of EBV-positive diffuse large B-cell lymphomas has been seen in older adults,[26] leading to a separate entity in the 2008 *WHO Classification of Tumours of the Haematopoietic and Lymphoid Tissues.* All EBV lymphomas are associated with the virus latent cycle (see Fig. 52-3).[15] The majority of EBV-associated lymphomas in immunocompetent patients are latency type II and express EBNA1, LMP1, and LMP2, except for Burkitt lymphoma, which is latency type I and only expresses EBNA1.

Hodgkin Disease

Hodgkin disease is a malignant neoplasm of lymphoreticular cell origin, and 40% to 50% of cases in immunocompetent individuals are associated with expression of EBV-derived antigens in malignant Hodgkin and Reed-Sternberg (HRS) cells and their variants (see Fig. 52-6, *B, C*). EBV-positive Hodgkin disease is more commonly seen in young children and in less developed countries. EBV association with Hodgkin disease differs by histologic subtype, being highest with the mixed-cellularity subtype. Evidence linking EBV to the pathogenesis of Hodgkin disease includes the findings that (a) every HRS cell in an EBV-positive tumor mass carries the virus, and (b) the EBV genome is clonal, indicating that the malignant HRS cells originated from a single EBV-infected cell. In addition, LMP1, one of the EBV proteins expressed in HRS cells, activates the transcription factor NF-κB, which is thought to play an important role in the pathogenesis of Hodgkin disease. EBV-positive HD patients also differ in their antibody response to the major EBV-associated antigens in comparison with healthy controls. The overall outcome of EBV-positive and EBV-negative Hodgkin disease is similar; with combination chemotherapy and radiation, the prognosis is excellent for low-stage disease, and overall survival rate for advanced-stage disease is between 65% and 80% (see Chapter 74). Depending on age and histologic subtype, the presence of EBV might be associated with better survival.

Non-Hodgkin Lymphomas

NHLs expressing type II latency include diffuse large B-cell lymphoma, $CD30^+$ Ki-1 anaplastic large cell lymphoma (ALCL) of B-cell type, T cell–rich B-cell NHLs and lymphomatoid granulomatosis. The association of these lymphomas with EBV varies, ranging from 10% to 95%.

EBV-associated NK/T-cell lymphomas include extranodal NK/T-cell lymphoma (nasal type), angioimmunoblastic lymphoma, and large granular lymphocyte (LGL) leukemia/lymphoma (NK- or T-cell type). Between 30% and 100% of these lymphomas are EBV-positive, expressing a type II latency pattern. In addition, CAEBV of NK/T-cell type has been associated with fulminant forms of lymphoma, more than 95% of which are positive for EBV. The overall outcome of EBV-associated NHL depends on histologic subtype and risk factors present at diagnosis, but most are high-grade malignancies with an unfavorable prognosis using current treatment modalities, which are described in detail in Chapters 81 through 84.

Adoptive Immunotherapy for EBV-Positive Hodgkin Disease and Non-Hodgkin Lymphomas in Immunocompetent Individuals

In contrast to EBV-LPD only a limited number of EBV-derived antigens—EBNA1, LMP1, and LMP2—are present in EBV-positive Hodgkin disease and NHL. Nevertheless, EBV-specific CTL infusion has been used to treat 20 patients with EBV-positive Hodgkin disease. CTL localized to tumor sites, persisted for prolonged periods of time, and produced resolution of B symptoms. After CTL infusion, five patients were in complete remission at up to 40 months, two of whom had measurable disease at the time of CTL infusion. One additional patient had a partial response, and five had stable disease. Although these results are encouraging, the antitumor activity of infused CTL was lower than in HSCT recipients treated for EBV-LPD. This lack of efficacy could be due in part to immunosuppressive factors secreted by HRS cells or may simply be quantitative in that the method used for EBV-specific CTL generation produces CTL lines that are dominated by clones reactive to viral proteins not expressed in Hodgkin disease. To improve CTL efficacy, methods to expand CTL specific for the EBV proteins LMP1 and LMP2 expressed in Hodgkin disease and to genetically modify the expanded CTL to render them resistant against inhibitory cytokines have been developed. The authors conducted a study in which they infused 43 patients with EBV-positive Hodgkin disease and NHL with LMP2-specific CTLs[27] or LMP1-/LMP2-specific CTLs. Of 22 high-risk and/or multiply relapsed patients who received LMP-specific CTL as adjuvant treatment, 21 remained in remission for a median of 2.5 years after CTL with a 3-year progression-free survival (PFS) of 80%. Twenty-one patients had detectable disease at the time of CTL infusion, and 17 had clinical responses including 13 complete responses, 3 partial responses, and 1 stable disease with a 3-year progression-free survival of 60%. Current efforts are focused on genetically modifying CTLs to increase their antitumor activity and to simplify the CTL production process in preparation for a definitive efficacy study.

EBV-Associated Non-Hodgkin Lymphoma in HIV Patients

Patients infected with HIV are at high risk to develop NHL. The incidence increases with age, and the male-to-female ratio is approximately 2:1. Depending on certain histologic features, the EBV association ranges from 30% in systemic HIV-related Burkitt lymphoma (HIV-BL) to 70% to 80% in HIV-related immunoblastic lymphoma (HIV-IBL), and virtually all cases of primary central nervous system lymphoma (PCNSL) are EBV positive. In biopsies of EBV-associated HIV-NHL, there is considerable variation in the number of EBV-positive cells, and the pattern of EBV latent gene expression varies among tumor types as in immunocompetent individuals (see Fig. 52-6, *E, F*). In HIV-infected patients, the development of EBV-associated HIV-NHL is preceded by a loss of functional EBV-specific CTL, suggesting that strategies to boost the endogenous EBV-specific

T-cell response might prevent lymphomas. Restoring CD4-positive T-cell counts in HIV patients with highly active antiretroviral therapy (HAART) has decreased the incidence of PCNSL and HIV-NHL. The clinical experience with T-cell therapy for EBV-associated HIV-NHL is limited.

Burkitt Lymphoma

Burkitt lymphoma (BL) is a high-grade malignant small noncleaved B-cell lymphoma. Histology usually reveals a "starry-sky" pattern resulting from numerous benign macrophages that have ingested apoptotic tumor cells (see Fig. 52-7, *A-C*). Although almost all endemic BLs in equatorial Africa are associated with EBV, the virus has been implicated less often in sporadic cases, and in the United States only 20% of BL are EBV positive. In developing countries, an intermediate type of BL has been described, both in its clinical presentation and association with EBV, which varies from 25% to 80%. As with NPC and Hodgkin disease, there is strong circumstantial evidence linking EBV to BL. The EBV genome is clonal as in other EBV-associated malignancies. The majority of BLs carry a translocation between the long arm of chromosome 8, the site of the MYCC oncogene (8q24), and the Ig heavy chain region on chromosome 14, t(8;14). Although the t(8;14) translocation is seen in endemic as well as sporadic BLs, the exact location of the chromosomal breakpoints on chromosome 8 and 14 differ. Other chromosomal translocations seen in BLs are between MYCC and the κ-light chain locus on chromosome 2, t(2;8), or the λ-light chain locus on chromosome 22, t(8;22).

Current treatment strategies rely on intensive chemotherapy, and overall survival depends on extent of disease at presentation, being 90% to 100% for local and 60% to 70% for advanced disease. The prospect for the development of an EBV-specific immunotherapy for BLs is problematic because lymphoma cells evade the immune system by downregulating the expression of EBV latency antigens, cell adhesion molecules, and MHC class I molecules. EBNA1, the only EBV protein expressed in BL, autoregulates its own translation and inhibits HLA class I presentation because of an internal glycine-alanine repeat region. However, the characterization of EBNA1-specific CD4-positive T cells, as well as rare CD8-positive T cells that can recognize BL through EBNA1, has provided impetus to explore the role of CD4-positive T cells in the control and therapy of BL. In addition, EBNA1-specific CD4-positive T cells had potent antitumor activity in a murine model of Burkitt lymphoma. As discussed in the EBV-LPD section, induction of the lytic EBV cycle is another attractive EBV-targeted approach for Burkitt lymphoma.

Nasopharyngeal Carcinoma

Nasopharyngeal carcinoma (NPC) arises from the epithelial cells of the nasopharynx. The WHO classifies NPC into keratinizing squamous cell carcinoma (type 1), nonkeratinizing carcinoma (type 2), and undifferentiated carcinoma (type 3, most common). Type 2 and 3 carcinomas are associated with EBV (see Fig. 52-7, *D, E*)[28]; however, environmental and genetic factors play an important role in oncogenesis, because the incidence of NPC varies 50- to 100-fold from Southern China to Western countries. EBV was initially linked to NPC by the observation that patients had elevated levels of VCA-IgG, VCA-IgA, and EA-IgG antibodies. Further studies showed that EBV-DNA is present in every tumor cell of type 2 and 3 carcinomas with remarkable consistency. As in Hodgkin disease, the EBV episome in an individual tumor is clonal.

EBV antibody responses have been used to follow tumor burden in NPC patients; in addition, VCA-IgA antibodies and antibodies against EBV DNase are predictive for NPC in high-risk populations. More recently, detection of EBV-DNA in serum by different PCR methods has shown to be useful for the diagnosis, prognosis, and monitoring of NPC patients. Most NPC patients are treated with radiation. Other modalities such as surgery, chemotherapy, and combined approaches may be appropriate in selected circumstances, but a detailed discussion is beyond the scope of this chapter. In NPC, as for EBV-positive lymphomas, only a limited number of EBV latent antigens are expressed. Three therapeutic vaccine studies targeting LMP2, LMP1 and LMP2, or EBNA1 and LMP2 have been conducted, and the results of these trials were discussed in the earlier section EBV Vaccine Development.

The adoptive transfer of autologous EBV-specific CTL is being actively explored.[29] Several groups have reported that the infusion of CTLs is safe and has resulted in clinical responses, especially in patients with locoregional disease.[30] Clinical outcome correlated with the presence of LMP2-specific T cells in the CTL product. As for EBV-positive Hodgkin disease and NHL, current research studies are focused on improving the antitumor activity of EBV-specific CTL, simplifying CTL production, and determining how to best integrate the adoptive transfer of EBV-specific CTL with conventional therapy.

FUTURE DIRECTIONS

Since its discovery in 1964, EBV has been linked to a heterogeneous group of diseases. EBV was the first human virus implicated in oncogenesis, and the biology of the virus has been studied extensively on a cellular and molecular level. Over the last decade, successful immunotherapeutic approaches have been developed for EBV-associated lymphoproliferative disease using either monoclonal antibodies or the adoptive transfer of EBV-specific T cells. Further insights into the function of EBV proteins and host-virus interactions hold the promise of improving the outcome of patients with EBV-associated diseases in the future.

CHAPTER 53

PROGRESS IN THE CLASSIFICATION OF MYELOID NEOPLASMS: CLINICAL IMPLICATIONS

John Anastasi and Ronald Hoffman

The myeloid neoplasms are a heterogeneous group of diseases. In general terms, they are clonal hematopoietic malignancies that can arise in or affect a single myeloid lineage (e.g., monocytic) or they can be derived from a pluripotent progenitor cell and can affect multiple or even all myeloid cell types (erythroid, megakaryocytic, monocytic, neutrophilic, basophilic, eosinophilic, and mast cells). The myeloid neoplasms include chronic and acute diseases and those that evolve from an indolent process to a more aggressive state. As such, they can manifest as proliferative disorders, mostly involving primary mature hematopoietic elements, they can predominately affect immature or blastic cells, or sometimes they can be a combination of the two. Also, indolent disorders can evolve to more aggressive forms over time. The diseases can be proliferative, resulting in excess production of blood cells, or they can proliferate in the bone marrow (BM) and exhibit ineffective hematopoiesis, resulting in peripheral cytopenias. Because the diseases range from indolent to acute, they exhibit a wide variation in prognosis. Some disorders are fairly indolent and require only supportive care and transfusional support; others slowly progress but have no successful treatment option; and others are acute and life threatening, even within days or weeks after presentation, but are often curable if appropriately managed. Accurate, timely diagnosis and correct classification can have a tremendous clinical impact on outcome.

The diagnosis of the myeloid neoplasms typically requires a multifaceted team approach that relies on cooperation among the clinician, laboratory personnel, and a skilled pathologist. The precise diagnosis requires compiling accurate historical data, clinical information, general laboratory findings, and carefully interpreted observations from the peripheral blood smear, bone core biopsy, and aspirate merged with information from immunophenotyping, cytogenetic analysis, and molecular studies (Table 53-1). Although in some cases a diagnosis can be made with a quick examination of the blood smear, with a single molecular test, or with a simple immunophenotype, in general, careful assessment of a large body of information gives the most accurate and clinically relevant diagnosis. Future routine diagnostic modalities may include next-generation sequencing, single-nucleotide polymorphism array karyotyping, gene expression arrays, and genome-wide epigenetic studies.

The myeloid neoplasms are grouped and understood as different categories of diseases. These categories seem to constantly be changing in name and in the component disorders, but the refinements have evolved with more understanding of the clinical, pathologic, and genetic basis of the diseases and ultimately serve, or at least strive to, improve diagnosis, treatment, and outcome. Currently, the categories of myeloid neoplasms include the myeloproliferative neoplasms (MPNs), acute myeloid leukemias (AMLs), myelodysplastic syndromes (MDS), and a category of entities with features intermediate between MDS and MPN, the MDS/MPNs (Table 53-2). This generally accepted classification system was derived historically from a number of earlier classification systems,[1-4] with recent revisions from the World Health Organization (WHO) committee working on hematopoietic and lymphoid tumors. The latter was undertaken in conjunction with input from a panel of clinicians with expertise in the specific areas.[5-7] It is likely that newer information from the more recent molecular testing modalities will provide additional insight into the molecular pathogenesis that will further impact the classification and categorization of these neoplasms (Fig. 53-1).[8]

THE MYELOPROLIFERATIVE NEOPLASMS

The MPNs (Table 53-3), formerly referred to as the myeloproliferative disorders (MPDs), are a group of clonal multipotential hematopoietic stem cell disorders that have a proliferative nature, frequently with hypercellular BMs, and an elevation of one or more cell types in the blood. They are insidious in onset, and chronic in course but have a variable tendency to terminate in BM failure or acute leukemia.[9] The MPNs include the model disease, chronic myeloid leukemia (CML) (see Chapter 66). This has become a prototype in medicine because it illustrates how the elucidation of pathways involved in the molecular pathogenesis of a process (i.e., dysregulation of *ABL1* tyrosine kinase signaling) can lead to the rational development of targeted therapy for the disease (i.e., imatinib and other tyrosine kinase inhibitors).[10]

The MPNs also include the rare myeloid (and lymphoid) neoplasms with eosinophilia (listed separately in the WHO schema) (see Chapter 70). Although quite uncommon, these are noteworthy, because similar to CML, they have also been found to be caused by dysregulation of TK signaling (caused by mutations in *PDGFRA, PDGFRB,* or *FGFRA*) and, at least partly, can also be successfully treated with TK inhibition.[11] The other MPNs include the more common *BCR-ABL1*–negative entities, essential thrombocythemia, polycythemia vera (PV), and primary myelofibrosis (see Chapters 67 to 69). These are related biologically, with multipotential hematopoietic stem cell origin, clonal proliferation, and chronic nature. Although they seem to be distinctive because there is very little transformation from one to another, early in their course they can present a diagnostic challenge, and they can be difficult to distinguish from one another because more characteristic features have not yet developed. Recent discoveries in the underlying molecular pathology of these entities have demonstrated that similar to CML and the eosinophilic disorders, they too share TK signaling dysregulation, at least to some degree. This is attributable to an associated mutation in the TK, *JAK2* (*JAK2* V617F), which is present in about 50% to 95% of cases.[12] This association has led to significant revisions in the criteria for diagnosis of these entities but has raised questions of how a single mutation can be associated with such heterogeneous phenotypic characteristics.[13] Unfortunately, the *JAK2* V617F discovery has not yet led to a successful therapeutic approach[14] but has focused attention on issues such as clone size, mutational load, and clonal dynamics that will likely be of clinical importance.[15] Mutations in other genes may also provide a more complete picture of additional pathways involved in these disorders.[16]

Chronic neutrophilic leukemia (CNL) and mast cell disease (see Chapter 71) are also included in the category of MPNs. Although it is surrounded by some controversy as to whether it is truly neoplastic, CNL is a rare entity that is not well understood at either the clinical or molecular level.[17] Mast cell disease is yet another disease related to

Table 53-1 Components in the Routine Clinical Evaluation of the Myeloid Diseases

CURRENT

- Accurate clinical history, including family history and physical examination findings
- General laboratory findings, including CBC, and other specific tests (e.g., EPO) when appropriate
- Evaluation of well-prepared and stained peripheral blood smear with 200 cell differential count
- Review of BM aspirate, including iron stain, and 500 cell differential count
- Evaluation of H&E sections of BM biopsy of sufficient length and reticulin stain
- Phenotyping studies, including cytochemical reactions (nonspecific and specific esterase reactions and myeloperoxidase) and flow cytometric analysis of peripheral blood or BM for phenotype of blasts or other cells when appropriate
- Cytogenetic analysis, including karyotype, and FISH for specific abnormalities when appropriate
- Genetic analysis for particular genetic rearrangements or mutations, including gene sequencing when appropriate

POTENTIAL FUTURE CLINICAL STUDIES

- Next-generation sequencing
- Single-nucleotide polymorphism array karyotyping
- Gene expression arrays
- Genome-wide epigenetic studies

Table 53-2 The Myeloid Neoplasms

The myeloproliferative neoplasms (MPN), including the myeloid and lymphoid neoplasms with eosinophilia and abnormalities of *PDGFRA*, *PDGFRB*, and *FGFRA*
The acute myelogenous leukemias (AML)
The myelodysplastic syndromes (MDS)
The myelodysplastic/myeloproliferative ("overlap") syndromes (MDS/MPN)

abnormal TK signaling, in this case the *KIT* gene.[18] It has a complex classification system, including one type that is a mast cell proliferation associated with a clonal non–mast cell hematopoietic malignancies that can be another myeloid disorder or, less commonly, a lymphoid malignancy.

It is important to emphasize that the diagnosis of the MPNs does not rest solely with the routine microscopic examination of cells and tissues on slides. The diagnostic workup is more far reaching and must include reviewing the clinical history and pertinent physical findings, as well as obtaining and assessing laboratory values, including recent complete blood cell counts. Examination of a well made peripheral blood smear and both BM aspirate and biopsy specimens are still crucial. However, ancillary studies, such as cytogenetic and molecular analysis, as well as other more specific laboratory evaluations, are just as important in formulating the correct diagnosis, and in particular, in distinguishing them from reactive myeloid proliferations. This is particularly true, for example, regarding the *JAK2*

Table 53-3 The Myeloproliferative Neoplasms

Disease	Tyrosine Kinase Involvement
Chronic myeloid leukemia, *BCR-ABL1+*	*ABL1* (100%)
Myeloid and lymphoid neoplasms with eosinophilia TK abnormalities	*PDGFRA*, *PDGFRB*, or *FGFRA* (100%)
Polycythemia vera	*JAK2* V617F (≈95%), *JAK* exon 12 (≈4%)
Primary myelofibrosis	*JAK2* V6174 (≈50%), *MPL* W515 K/L (5%-9%)
Essential thrombocythemia	*JAK2* V617F (≈50%), *MPL* W515 K/L (≈1%)
Chronic neutrophilic leukemia	—
Chronic eosinophilic leukemia, not otherwise specified	—

V617F mutation and its impact on diagnosis of PV and the other more common entities in which the findings of the mutation establishes that the proliferation is clonal and not a physiologic response. Perhaps future testing with deep sequencing and epigenetic studies will become the next level of ancillary evaluations for diagnosis and classification.[19]

THE ACUTE MYELOID LEUKEMIAS

The historical and emerging classifications systems for AML dramatically illustrate the marked heterogeneity of the acute diseases within this category (Chapters 57 and 58). Despite this heterogeneity, however, decisions regarding specific initial treatment seem limited to only a few types of leukemias (e.g., acute promyelocytic leukemia).[20] Perhaps this may change as newer agents targeting molecularly or genetically defined AML become available (e.g., FLT3 inhibitors for FLT3 mutated cases).[21] It is anticipated that the gap between the growing number of unique or genetically defined acute leukemia types and the somewhat limited treatment options may begin to close.

The French–American–British (FAB) classification of AML in 1976 with its subsequent revision provided the first real framework for classifying the AMLs.[2,3] It also provided definitions of diseases that were fairly reproducible. The classification was mainly based on morphologic and cytochemical features of the leukemic blasts in the BM. In general, the FAB scheme required that 30% of the BM nucleated elements be blasts and then defined cases based on the presence of maturation in the granulocytic series, the presence of a monocytic component, and the presence of an erythroid component. Later, as immunophenotyping allowed better identification of myeloid precursors, acute megakaryoblastic leukemia and AML with minimal differentiation were added.[3] The types of AML noted in the revised FAB scheme included one with minimal differentiation (MO), a type without maturation (M1), a type with maturation (M2), acute promyelocytic leukemia (M3), a type with combined monocytic and myeloid (neutrophilic) components (M4), a pure monocytic or monoblastic type (M5A, M5B), a type with a prominent erythroid component (M6), and (as noted) a megakaryoblastic type (M7) (Table 53-4).

Although the FAB provided a framework and defined criteria for different types of acute leukemia, genetic changes associated with the leukemias that began to be recognized in the 1980s seemed to provide more important prognostic information and did not always correlate well with the FAB-defined entities. As the cytogenetic abnormalities became more widely appreciated and their prognostic implications better understood, classification schemes based solely on the "favorable," "intermediate," and "adverse" prognostic cytogenetic findings were introduced and used along with or as an alternative to the FAB scheme (see Table 53-4).[22]

The WHO classification of the acute leukemias published in 2001 provided a different strategy than the FAB in two important ways: it redefined AML as requiring only 20% blasts in the BM or blood and emphasized the importance of the associated cytogenetic abnormalities.[5] The change in blast percentage came from the recognition that patients with 20% to 30% blasts who previously were classified as having MDS (refractory anemia with excess of blasts in

Table 53-4 Classification Schemes for the Acute Myelogenous Leukemias

French–American–British (FAB, 1985)	Cytogenetic	WHO (2001)	WHO (2008)
M0: AML with minimal differentiation	**Favorable**	**Genetic**	**With recurrent genetic abnormalities**
M1: AML without maturation	t(8;21)	t(8;21)	With t(8;21)(q22;q22)
M2: AML with maturation	inv(16)/t(16;16)	t(inv(16)/t(16;16)	With inv(16)/t(16;16)(p13.1;q22)
M3: APL	t(15;17)	t(15;17)	With t(15;17)(q22;q12)
M3v: microgranular variant	**Intermediate**	t(v;11q23)	With t(9;11)(p22;q23)
M4: AMML	Normal	**AML with dysplasia therapy related AML**	With t(6;9)(p23;q34)
M4eo: AMML with abnormal eosinophils	+8	Etoposide	With inv(3)/t(3;3)(q21;q26.2)
M5A: acute monoblastic leukemia	t(v;11q23)	Cytotoxic or radiation	With t(1;22)(p13;q13)
M5B: acute monocytic Leukemia	del(7q)	**Not otherwise specified**	With mutated NPM1 (provisional)
M6: erythroleukemia	+21	With minimal differentiation	With mutated CEBPA (provisional)
M7: acute megakaryoblastic leukemia	+22	Without maturation	**With myelodysplasia related changes**
	Other	With maturation	Previous history of MDS
	Adverse	Myelomonocytic leukemia	Multilineage dysplasia
	del(5q)	Monoblastic leukemia	MDS-related cytogenetic abnormalities
	-5	Monocytic leukemia	**Therapy-related myeloid neoplasms**
	-7	Erythroleukemia	t-AML/t-MDS (t-MN)
	Complex	Erythroid myeloid type	**Not otherwise specified**
	abn (3q)	Pure erythroid	With minimal differentiation
		Megakaryoblastic	Without maturation
			With maturation
			Myelomonocytic leukemia
			Monoblastic leukemia
			Monocytic leukemia
			Erythroleukemia
			Erythroid myeloid type
			Pure erythroid
			Acute megakaryoblastic leukemia
			Acute basophilic leukemia
			Acute panmyelosis with myelofibrosis
			Myeloid sarcoma
			Myeloid leukemia associated with Down syndrome
			Blastic plasmacytoid dendritic cell tumor

transformation [RAEB-T] in the FAB MDS classification) often had outcomes similar to those of AML and frequently required treatment as AML. Furthermore, the inclusion of cytogenetics recognized the important prognostic information associated with these abnormalities, as well as the fact that cytogenetics could point to the underlying molecular pathogenesis, which is critical in developing new drugs and treatment strategies as learned with CML experience. However, the WHO classification recognized that not all acute leukemias could be defined by cytogenetic abnormalities and that some needed to be defined clinically or even still based on morphologic findings. In this regard, the 2001 classification recognized four major subclasses of AML, and these included AML with recurring cytogenetic abnormalities; therapy-related AML (subclassified further as those with etoposide treatment and those with history of cytotoxic drug therapy or radiation); AML with multilineage dysplasia; and cases that did not fit into the other categories, referred to as AML, not otherwise categorized (see Table 53-4).

A revision of this 2001 classification scheme in 2008 made a number of changes (see Table 53-4).[6] In particular, it expanded the cytogenetic abnormality-associated cases to those with some less common translocations. It added provisional entities defined by mutations often occurring in cytogenetically normal cases, namely those with *NPM1* and *CEBPA* mutations. It combined the different types of therapy-related MDS/AML and renamed this category therapy-related myeloid neoplasm (t-MN). It also redefined the dysplasia-associated cases by allowing the cases to be identified by history (of previous MDS), morphology (with multilineage dysplasia) or by cytogenetics (with defined chromosomal changes associated with dysplasia). Additional categories were also added, including AML associated with Down syndrome, acute panmyelosis with myelofibrosis, granulocytic sarcoma, and blastic plasmacytoid dendritic cell tumor. In the end, the current classification defines more than 25 different types of AML. Newer technologies, such as single nucleotide polymorphism array karyotyping,[23] that will likely facilitate the recognition of many of these, may also identify additional variants. Recognizing unique entities, it is hoped will prove beneficial for understanding the diseases and common affected pathways and for developing sorely needed and successful targeted treatments.

THE MYELODYSPLASTIC SYNDROMES

The earliest recognition of myelodysplastic disorders came with the identification of an anemia that was long-standing and refractory to vitamin replacement followed by the recognition that these were sometimes preleukemic (see Chapters 59 and 62).[24] The classic MDS is exemplified by pancytopenia in the blood and by a hypercellular BM with ineffective hematopoiesis characterized by multilineage dysplasia, with or without an increase in blasts. Although this is fairly typical, it belies the wide pathologic spectrum of MDS, which includes cases that are diagnostically challenging and difficult to distinguish on one hand from benign causes of cytopenias in elderly patients and, on the other hand, from AML and other more aggressive clonal myeloid neoplasms.

The first real classification of MDS was proposed by the FAB group in 1982.[4] In this classification scheme, the myelodysplastic disorders were divided into four subtypes with increasing blast percentage or as chronic myelomonocytic leukemia (CMML). The four entities included refractory anemia (RA), refractory anemia with ring sideroblasts (RARS), refractory anemia with excess of blasts (RAEB), and refractory anemia with excess of blasts in transformation (RAEB-T). These entities differed mainly by the percentage of blasts seen in the BM (see Table 53-5). In the FAB scheme, as noted earlier, AML was defined by the presence of 30% or more blasts in the blood or BM.

Chronic myelomonocytic leukemia was included by the FAB in the MDS category, although it was well recognized that CMML differs in that it has a proliferative component with increased circulating monocytes.[25] At times, the peripheral leukocytosis was increased in the so-called myeloproliferative type of CMML, but the process was considered to be a dysplastic type and included in the MDS category when the white blood cell count was less than 13,000/μL.[26]

The classification of MDS presented by the WHO committee in 2001 resulted in significant changes to the classification of both MDS (Table 53-5), as well as in AML as discussed earlier.[5] As mentioned, the most notable change was the reduction in the blast percentage required for a diagnosis of AML from 30% to 20%, leading to the elimination of the RAEB-T category. The new classification also included a new subtype of MDS that, despite the lack of increased blasts (<5%), had a more aggressive course, probably owing to the presence of more pronounced multilineage dysplasia.[27] This category was called refractory cytopenia with multilineage dysplasia (RCMD), and it comprised a substantial proportion of cases previously grouped in the low-grade RA and RARS categories. Although the recognition of RCMD as a relatively more aggressive MDS served to deemphasize

Table 53-5 Evolving Classifications of the Myelodysplastic Syndromes (MDS)

FAB 1982	WHO 2001	WHO 2008	
RA	RA	RCUD RA RN RT	Uni- or bilineage dysplasia,* <1% PB blasts,† <5% BM blasts, <15% RS
RARS	RARS	RARS	No PB blasts, at least 15% RS, <5% BM blasts
	RCMD RCMD-RS	RCMD (-RS)	<1% PB blasts,‡ dysplasia >10% in two cell lines, <5% BM blasts, +/– RS, no AR§
RAEB	RAEB-1	RAEB-1	Cytopenia, <5% PB blasts, <1000/μL monocytes; dysplasia in 1 or more lines 5%-9% blasts, no AR§
	RAEB-2	RAEB-2	Cytopenia, 5%-19% blasts, <1000/μL monocytes, +/– AR; dysplasia in one or more lines, 10-19% BM blasts
		MDS-U	Cytopenia, <1% PB blasts; <10% dysplasia in any one cell line; cytogenetic abnormalities present, <5% BM blasts
		MDS with 5q-	Anemia, normal or increased platelets; isolated 5q, hypolobated megakaryocytes, no AR
		RCC (provisional)	
RAEB-T			
CMML

*If pancytopenia, change to MDS-U.
†If 1% blasts, change to MDS-U.
‡If 2% to 4% PB blasts, upgrade to RAEB-1.
§If AR present, upgrade to RAEB-2.

Table 53-6 The Myelodysplastic/Myeloproliferative Neoplasms

- Chronic myelomonocytic leukemia (CMML)
- "Atypical" chronic myeloid leukemia ("aCML"), *BCR-ABL1* negative
- Juvenile myelomonocytic leukemia (JMML)
- Refractory anemia with ring sideroblasts and thrombocytosis (RARS-T) (provisional)

the importance of the blast percentage for prognosis, the new classification subdivided the RAEB category into two types, with 5% to 9% blasts (RAEB-1) and 10% to 19% blasts (RAEB-2), paradoxically emphasizing the prognostic significance of blast percentage in this category.[28]

A further significant change in the WHO 2001 classification scheme for MDS included the exclusion of CMML from the MDS category and the development of a separate nosologic group for CMML and other diseases in which there were features at diagnosis of both myelodysplasia and myeloproliferation.[29] These "overlap" disorders are mentioned briefly below.

Further refinements in the WHO classification scheme for MDS were made most recently in 2008 (see Table 53-5).[6,30] These included expanding low-grade MDS from refractory anemia to refractory cytopenia with unilineage dysplasia (RCUD), which recognized that the megakaryocyte or granulocyte lineage could be equally affected. The 2008 WHO classification scheme also placed emphasis on the key role of cytogenetic analysis in the diagnosis of MDS, particularly in cases with otherwise insufficient morphologic evidence to substantiate a diagnosis of MDS. This is reflected in the inclusion of the subtype, MDS unclassified (MDS-U), defined by the presence of cytopenia, less than 1% peripheral blasts, less than 10% dysplastic cells in any lineage, and less than 5% BM blasts with the presence of specific cytogenetic abnormalities commonly seen in MDS. In addition, the WHO 2008 classification now includes "MDS with an isolated del(5q)" including the "5q- syndrome".[30] This syndrome had been well known for some time and is characterized typically by its presentation in middle-aged women with macrocytic anemia, splenomegaly, normal to elevated platelet counts, hypolobated megakaryocytes in the BM, and an isolated del(5q). Thus, similar to AML, the specific types of MDS have also been increased and now account for more than 10 different entities.

THE OVERLAP MYELODYSPLASTIC/ MYELOPROLIFERATIVE NEOPLASMS

The overlap syndromes—that is, the MDS/MPNs (Table 53-6)—were introduced by the WHO committee in 2001 because there was no agreement among committee members as to whether CMML was an MDS, as suggested by the FAB, or an MPN, as suggested by a number of investigators. This group of diseases was defined to include disorders that share features of the MPNs and the MDS at the time of initial presentation but do not fit well into either group.[30] Some of the entities in the MPD/MPN category are not well understood and may represent a disease in transition from MDS or MPN, although a case should not be placed in this group if initially diagnosed as MDS or MPN. However, without the complete knowledge of the historical pathology of each individual patient, it is useful to have this category for a more reasonable classification. The overlap syndromes consist of CMML, including the juvenile type and juvenile myelomonocytic leukemia (JMML) (see Chapter 62) in addition to "atypical" chronic myeloid leukemia (atypical CML, *BCR-ABL1* negative) and an "unclassifiable" category that includes refractory anemia with ring sideroblasts and thrombocytosis (RARS-T). The MDS/MPNs share proliferative features in some cell lineages but also have dysplastic features, including ineffective hematopoiesis in others. Similar to the MPNs, the overlap syndromes require a full evaluation of clinical and morphologic findings and evaluation of ancillary studies before a firm diagnosis can be rendered.

CHAPTER 54

CONVENTIONAL AND MOLECULAR CYTOGENETIC BASIS OF HEMATOLOGIC MALIGNANCIES

Vesna Najfeld

Dedicated to the loving memory of Eta Najfeld, MD, a holocaust survivor and an amazing mother.

Over the past 53 years, cytogenetic analysis of cells belonging to the array of hematologic malignancies has been an area of prolific growth. Chromosome studies and karyotype information provide information of both biologic and clinical significance. Refinements in cell culture methods and the application of chromosome banding techniques have advanced our understanding of disease-specific abnormalities, and molecular cytogenetic methods now have made possible the identification of genes involved at translocation breakpoints in specific chromosomal rearrangements. These advances in molecular cytogenetic methods permit mapping of structural rearrangements within a single gene and fundamentally contribute to our knowledge of the biology of leukemia. This evolution in our understanding of cancer genetics has resulted in distinct terminology (Table 54-1). Application of conventional and molecular cytogenetic methods has identified almost 600 fusion genes involving 250 different genes and approximately 1000 recurrent balanced translocations in human cancers.[1] Application of these methods has played a pivotal role in the diagnosis, treatment, and prognosis of the hematologic malignancies. This chapter discusses specific cytogenetic events and delineates molecular phenotypes that are important in order to understand the molecular pathogenesis of hematologic malignancies and provides several genetic testing algorithms. The remarkable hypothesis put forward by Boveri at the turn of the 20th century—namely, that an abnormal chromosome pattern is intimately associated with the malignant phenotype of a tumor cell—has proven correct. Knowledge of the molecular cytogenetic phenotype of hematologic malignancies has led to innovative and specifically tailored treatments. The first example of such gene-targeted therapy has already been successfully applied to chronic myelogenous leukemia (CML).

METHODS

Cytogenetic Analysis

Cells arrested in metaphase are obtained by exposing marrow cells sequentially to mitotic inhibitors, hypotonic KCl, and fixative. Chromosomes obtained from leukemic marrow are then subjected to the most widely used banding method, trypsin-Giemsa banding (Fig. 54-1). The criteria used to define clonal abnormalities are listed in Table 54-1 and described in the International System for Human Cytogenetic Nomenclature.[7]

Fluorescence In Situ Hybridization

Fluorescence in situ hybridization (FISH) is a molecular method that allows detection of the number, size, and location of DNA and RNA segments within individual cells in a tissue sample. It is based on the ability of single-stranded DNA to anneal to complementary DNA. In hematologic disorders, the target DNA is the marrow or peripheral blood DNA present in interphase cells or the DNA of metaphase chromosomes that is fixed on a microscope slide. Other biologic material that may be involved in the leukemic process, such as spleen cells, ascites, and spinal fluid, are particularly useful for FISH studies. In lymphoma, the target DNA is present in lymph nodes, and FISH studies are performed on touch preparations, frozen sections, or paraffin-embedded tissue.

Fig. 54-2 shows four types of FISH probes that are used alone or in combination to determine both numerical and structural rearrangements: (a) centromere enumeration probes, which, as the name implies, are used most frequently in interphase nuclei for detection of numerical chromosome anomalies, (b) whole chromosome painting probes, which are used only on metaphase cells and are very useful in delineating complex rearrangements or the origin of a marker chromosome, (c) subtelomeric probes, and (d) unique gene loci probes applied to both interphase and metaphase cells in single, dual, triple, or multiple colors to determine specific chromosomal rearrangements, deletions, or amplifications.

The four FISH probe strategies are used in probe design for detection of chromosomal translocations in hematologic malignancies (Figs. 54-3 and 54-4): (a) conventional strategy, (b) extrasensitive strategy, (c) dual-fusion strategy, and (d) "breakapart strategy." The first application of FISH technology for detection of chromosomal translocations in hematologic malignancy was when the BCR-ABL hybrid gene was identified using two-color FISH in interphase cells as well as in metaphase marrow-derived CML cells. In the standard strategy for interphase evaluation of chromosomal translocation, a DNA probe comprising sequences mapped proximally to the breakpoint in one of the chromosomes involved in reciprocal translocations is combined with a differentially labeled DNA probe that includes sequences mapped distantly to the breakpoint in the other chromosome. Positive nuclei for the translocation display one dual-color fusion signal, representing one of the derivative chromosomes generated by the translocation, and two single-color signals, one for each of the normal alleles. This standard FISH strategy has been used for detection of translocations in hematologic disorders at diagnosis.

For detection of minimal residual disease, the conventional strategy lacks specificity because cells with random spatial co-localization of normal signals with different colors, found at a frequency from 1% to 10% of scored nuclei, are seen as false positive. To minimize this problem, an extrasensitive method was developed in which a probe for one abnormal chromosome is designed to generate extra, smaller signals in positive nuclei. Hybridization using this strategy results in abnormal cells with co-localization of two signals in dual colors, an additional two signals in one single color and one signal in another single color. Application of the extrasensitive probe has been useful in discriminating between BCR-ABL fusion-positive blast crisis of CML and de novo acute lymphoblastic leukemia (ALL).

A dual-fusion strategy was developed not only to minimize false-positivity but also to detect additional deletions at translocation breakpoints. The dual-color/dual-fusion strategy includes a probe set with DNA sequences that encompasses proximally and distally the translocation breakpoints on both chromosomes involved in the translocation. The sequences for each chromosome are labeled with a specific color, and the translocation generates fused signals in both derivative chromosomes. Positive nuclei exhibit two copies of fusion

Table 54-1 Glossary of Cytogenetic and Fluorescence In Situ Hybridization Terminology

Aneuploidy	Abnormal chromosome number, either gain or loss.
Balanced translocation	Exchange of chromosomal material that creates no extra or missing DNA.
Banding	Set of dark and pale segments along the length of chromosomes, resulting from treatment with enzyme before staining. Each chromosome identified by its unique set of bands.
Breakpoint	Specific site on a chromosome containing a break in the DNA that is involved in chromosomal structural rearrangement, such as translocation or deletion.
Centromere	Constriction on the chromosome at the spindle site attachment. During cell mitosis two copies of the DNA in each chromosome are separated by shortening of the spindle fibers attached to opposite sides of the dividing cell. Position of the centromere determines whether the chromosome is metacentric (X-shaped; e.g., 1, 3, 19, 20), submetacentric (centromere positioned more toward the short arms; e.g., 2, 4, 5, 6-12, 16-18, X), or acrocentric (inverted V-shaped; e.g., 13-15, 21, 22, Y).
Centromere enumeration probe (CEP)	Highly repetitive α (or β) satellite DNA, located in the heterochromatin of the centromeric area of chromosomes. CEP targets repetitive α (or β) sequences and produces bright compact signals; particularly useful for detection of numerical loss or gain of chromosomes.
Comparative genomic hybridization (CGH)	Molecular cytogenetic technique that provides a copy-number karyotype at the chromosome and band level. Array CGH is a higher-level CGH technology that provides gene copy information. Variety of arrays include disease specialized, chromosome arm specific, and others.
Chromosomal rearrangement	Aberration in which chromosomes are broken and rejoined.
Clonal abnormality	In cytogenetic analysis, two cells showing the same additional or structural abnormality or three cells with loss of the same chromosome. In FISH analysis, any abnormality present after the probe has been validated and normal reference range established, above the normal reference range. Cytogenomics is the application of molecular biology to determine genomic copy number.
Deletion	Segment of chromosome that is missing (terminal) or segment of chromosome missing between two breakpoints (interstitial).
DNA sequence	Order of nucleotides in a DNA segment, usually displayed from the 5′-triphosphate (5′ end) to the 3′-hydroxyl (3′ end) nucleotides.
Enhancer	DNA sequence that increases the rate of transcription.
Exon	Portion of gene that encodes protein.
Fiber FISH	Application of FISH technology to extended DNA or free DNA fibers.
FISH	Fluorescence in situ hybridization, a method for detection of the number and location of DNA sequences (genes) in tissue section or cell population.
Fluorochrome	Fluorescence molecule that, when conjugated to a molecule, binds to a hapten to facilitate detection of the chromosomal probe. By definition, a fluorochrome is a molecule that will become excited by the light of one wavelength.
Gene construct	Recombinant DNA containing a gene of interest surrounded by sequences engineered to promote a measure of its expression.
Gene map	Order of genes within a chromosome or entire genome.
Genotype	Genetic constitution, usually with reference to particular alleles at a locus.
Haploid	Half of a normal complement (i.e., 23 chromosomes).
Haploinsufficiency	Deletion or inactivation of one allele producing disease due to inadequate activity of the remaining allele.
Hybrid gene	Fusion of two different genes as a result of a structural chromosomal rearrangement that functions as one transcriptional unit.
Hybridization	Method for rejoining (reannealing) complementary DNA or RNA strands.
Hyperdiploid	Additional chromosomes (e.g., 47 or 48 chromosomes).
Hypermetaphase FISH	Application of FISH to accumulated large number of metaphase cells.
Hypodiploid	Loss of chromosomes (e.g., 45 or 44 chromosomes).
I-FISH	Interphase fluorescence in situ hybridization, application of FISH to nondividing (resting) cells.
Interphase	Stage of mitosis in which the cell is not dividing.
Inversion	Structural chromosomal rearrangement as a result of two breaks occurring in the same chromosome. Paracentric inversion refers to both breaks occurring on the same side of the centromere. Pericentric inversion refers to breaks occurring on the opposite side of the centromere.
Isochromosome	Structural chromosomal rearrangement that consists of doubling of one of the two chromosome arms (connected by the centromere) and loss of the other arm.

Continued

Table 54-1 Glossary of Cytogenetic and Fluorescence *In Situ* Hybridization Terminology—cont'd

Karyotype	Arrangement of metaphase chromosomes from a particular cell according to size and banding so that the largest chromosome is placed first and the smallest one last (see Fig. 54-1).
kb (kilobase)	Unit of DNA/RNA length = 1000 base pairs of DNA.
Locus	Unique location of a gene on a chromosome.
Locus (sequence)-specific probe (LSI)	Probe targeted to unique sequence region of the chromosome. Useful for localization of genes on normal chromosomes (gene mapping) and for detection of gene amplification, deletion, inversion, or translocation.
Marker chromosome	Chromosome whose morphology cannot be identified using banding method. Marker chromosomes are frequent in hematologic neoplasms.
M-FISH	Multicolor FISH karyotyping, which allows identification of 24 different human chromosomes (22 autosomes, and the X and Y chromosomes) (see text for details).
Oncogene	Locus that is activated in association with tumor growth. One abnormal allele is sufficient to cause tumor formation or cancer.
PCR	Polymerase chain reaction, by which individual gene segments are amplified through sequential cycles of polymerization, heat denaturation, and reannealing.
Pseudodiploid	Diploid number of chromosomes (46) accompanied by structural rearrangement.
Recurrent abnormality	Structural or numerical abnormality observed in multiple patients with the same or similar disease. Recurrent chromosome abnormalities in hematologic neoplasms have prognostic significance.
Telomeric probe	Used to detect repeated DNA sequences present at the end of the chromosome, which is called the *telomere*. Telomeric DNA contains 10-15 kb of TTAGGG repeats. Adjacent to the telomere is a region called the *proximal subtelomeric region,* and centromeric to it is a unique chromosome telomeric region. Chromosome-specific telomeric probes are useful for detection of cryptic translocations involving ends of chromosomes.
Translocation	Structural chromosome abnormality resulting from a break in at least two chromosomes with an exchange of material. In reciprocal or balanced translocation, no loss of chromosomal material occurs. In unbalanced translocation, loss of chromosomal DNA occurs.
Tumor suppressor gene	Locus that prevents tumor growth when at least one allele is functional. Loss of both alleles, first through constitutional and then through somatic mutation, is associated with tumor formation or cancer.
Whole chromosome painting probe (WCP)	Spans the entire length of chromosomal DNA sequences and, as the name implies, targets the entire length of DNA sequences. Useful for identification of complex or cryptic structural rearrangements as well as for identification of marker chromosomes.
Nomenclature	
p	= Short arm
q	= Long arm
+	When placed before the chromosome, denotes a gain of a whole chromosome (e.g., +8)
–	When placed before the chromosome, indicates a loss of a whole chromosome (e.g., –7); in rare situations, when placed after the chromosome, as in 5q–, indicates loss of a part of the long arms of chromosome 5
t	translocation
del	deletion
der	derivative
inv	inversion
i	isochromosome
mar	marker chromosome
con	connected
nuc ish	nuclear in situ hybridization
nuc ish 21q22 (D21S65X2)	two copies of D21S65 DNA segment on chromosome 21
nuc ish 9q34 (ABL x2), 22q11.2 (BCRx2) (ABL con BCRx1)	two ABL and two BCR loci, but one of each locus is juxtaposed on one chromosome as a result of t(9;22)

Figure 54-1 NORMAL ARRANGEMENTS OF CHROMOSOMES IN A KARYOTYPE FROM A BONE MARROW METAPHASE CELL SHOWING A SLIGHTLY FUZZY MORPHOLOGY COMPARED WITH A NORMAL KARYOTYPE OBTAINED FROM PHYTOHEMAGGLUTININ-STIMULATED PERIPHERAL BLOOD CELLS.

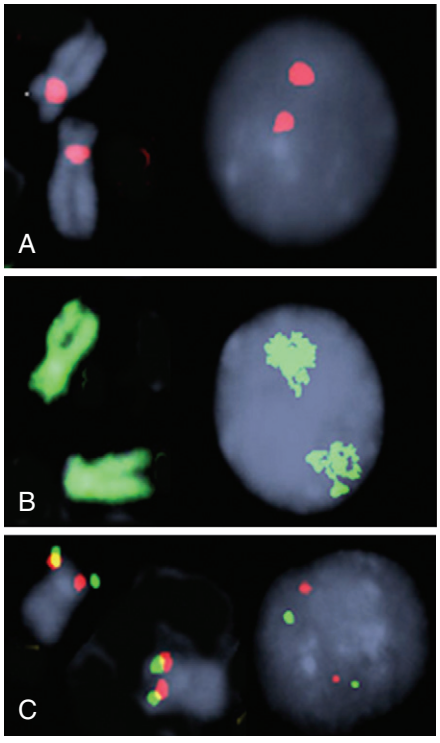

Figure 54-2 TYPES OF CHROMOSOMAL PROBES (SEE TEXT FOR DETAILS). **A,** Pair of chromosome 12 *(left)* and interphase cell *(right)* after FISH study with centromere enumeration probe (CEP) showing two hybridization signals *(red)* in the centromeric area of chromosome and two tight signals in interphase cell consistent with disomy (normal copy number). CEP probes are most useful for detection of numerical abnormalities. **B,** Hybridization with whole chromosome 8 painting probe showing the hybridization signal *(green)* along the length of the entire chromosome 8 *(left)* and hybridization domains in interphase cell *(right)*. Whole chromosome painting probes are useful for identifying unknown chromosomes in metaphase cells. **C,** Target of locus-specific indicators (LSI) are specific gene sequences such as P53 seen after hybridization as two small signals *(red)* on chromosome 17, band p13. The main applications of LSI probes are gene mapping, numerical enumeration in interphase cells, and detection of translocations. Telomeric probe, shown in green for the short arms of chromosome 17, are repetitive probes and are useful for detection of cryptic translocations involving ends of chromosomes. Chromosomes and nuclei are counterstained with DAPI *(blue)*.

signals and one copy of each of the signals representing the normal alleles. If a third color is added for detection of particular sequences, such as deletion of chromosome 9 at the site of the Philadelphia (Ph) translocation (Figs. 54-5, *C* and 54-6; see also Fig. 54-4), the lack of one copy with the third color is consistent with sequence deletion at the site of the translocation of one derivative chromosome. Dual-color/dual-fusion probes are very useful in differentiating various leukemia and lymphoma-associated translocations.

Multiple translocation partners are well known for genes commonly associated with leukemias such as mixed-lineage leukemia (MLL), the retinoic acid receptor α (RARA) gene, and the anaplastic lymphoma kinase (ALK) gene. The fourth FISH strategy, with breakapart probes, was developed to address this issue. The breakapart probe includes DNA sequences mapped proximally and distally to the breakpoint within a critical gene (the 3′ end and the 5′ end) labeled with two different fluorochromes. The fused fluorescence signals represent a normal gene, whereas nuclei with rearrangements within the target gene show one single-color signal and one for each derivative chromosome, regardless of which chromosome is the partner in translocation.

One of the most significant advances in diagnostic leukemia cytogenetics has been the application of interphase FISH. Interphase

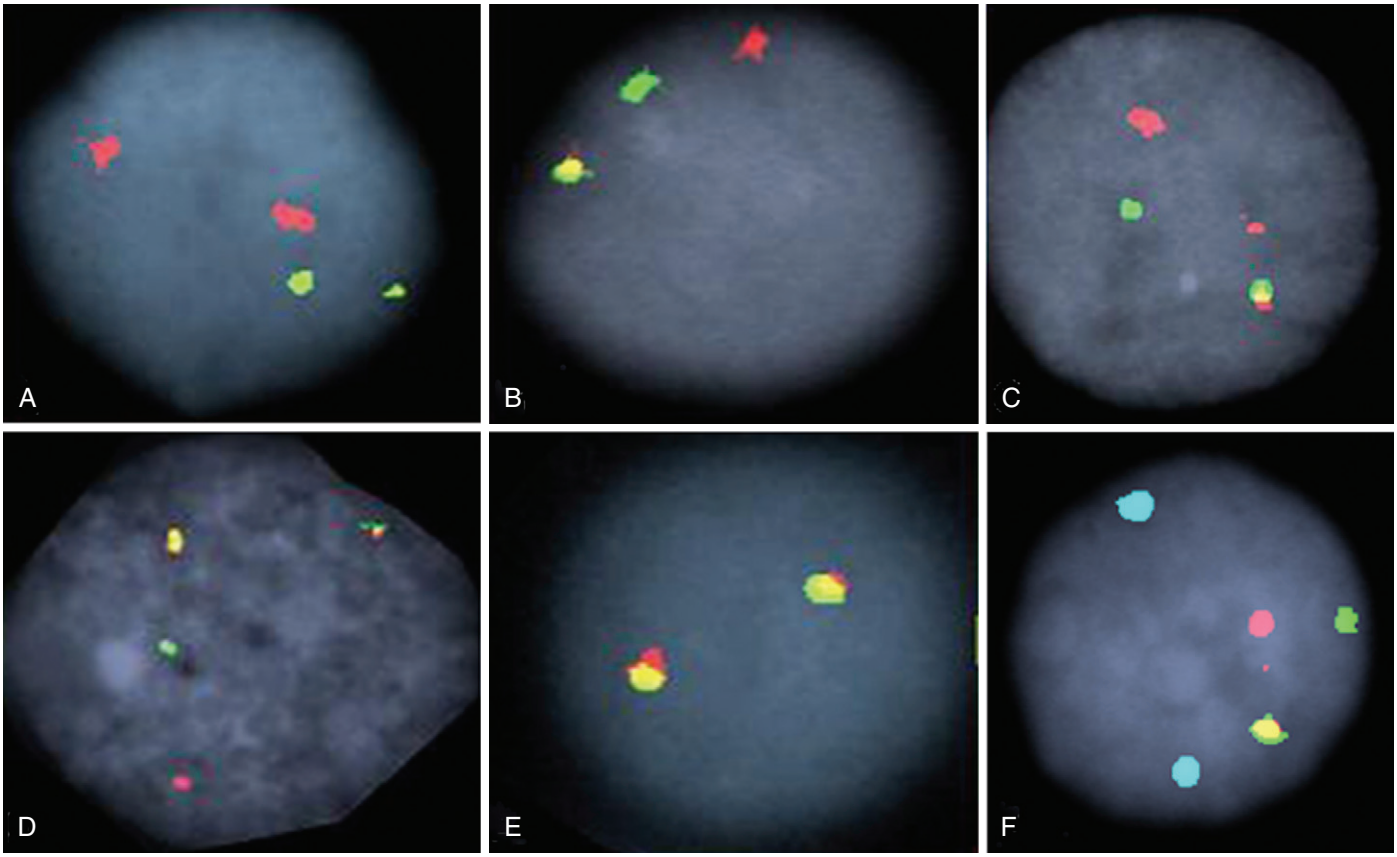

Figure 54-3 FOUR DIFFERENT PROBE STRATEGIES FOR DETECTION OF CHROMOSOMAL TRANSLOCATIONS (SEE TEXT FOR DETAILS). **A,** Normal cell after in situ hybridization with BCR *(green)* and ABL *(red)* showing a normal distribution of two red and two green single signals. **B,** Conventional fusion strategy after in situ hybridization shows one fusion *(yellow)* signal representing derivative chromosome generated by the translocation and one single-color signal, red and green, for normal homologues in positive nuclei. **C,** An extrasensitive fusion approach generates an extra small *(red)* signal, as well as a fusion signal *(yellow)* and one signal in single color *(green and red)* on normal homologues. **D,** Dual-fusion strategy generates two fusion signals *(yellow)* on two derivative chromosomes and one single-color signal on each of two normal chromosomes. **E,** Breakapart approach in a normal cell appears as two fusion signals *(yellow).* In this strategy, the 3′ end and the 5′ part of the gene are labeled in two colors. **F,** When the rearrangement occurs, the normal chromosome shows co-localization of red and green *(yellow)* as a result of the proximity of the sequences on the chromosome, whereas abnormal derivative chromosomes each have one single red and single green signal, indicating that the rearrangement occurred between the two ends of the gene separating the green and red signals on two different chromosomes. The third-color probe *(blue)* can be used as an internal control (usually CEP probe) to determine the disomic number of chromosomes.

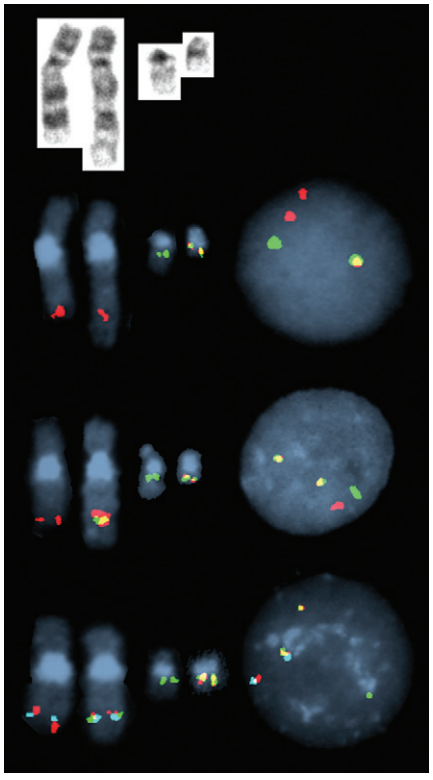

Figure 54-4 CURRENT FISH PROBE STRATEGIES FOR DETECTING BCR-ABL1 FUSION. Partial karyotype showing the Philadelphia chromosome as a result of t(9;22)(q34;q11.2) *(top row).* The same chromosomes 9 and 22, as well as a bone marrow nucleus, after hybridization with BCR *(green)* and ABL1 *(red)* using an extrasensitive (ES) dual-color, single-fusion FISH strategy *(second row).* Chromosomes and a nucleus are counterstained with DAPI *(blue).* In the ES strategy, a part of ABL1 *(red)* remains on der(9) and is shown in interphase nucleus as a smaller red signal, whereas the normal-size ABL1 hybridization signal is seen on normal homolog 9. The other part of ABL1 is on the Ph chromosome and is seen co-localized with BCR as yellow in interphase nucleus. Therefore interphase nuclei will have one normal-size red signal, one smaller-size red signal, one normal-size BCR signal, and co-localization of BCR and ABL1, producing a yellow signal both in interphase cells and metaphase chromosomes. In the dual-color, dual-fusion strategy *(third row),* there are two co-localized signals on both der(9) and the Ph chromosome, as well as one red signal of ABL1 on chromosome 9 and one green signal of BCR on normal chromosome 22. In the triple-color, dual-fusion strategy, ASS gene *(aqua)* is added. It is used to determine whether sequences from der(9) are deleted at the time of the Ph formation. As shown in the fourth row, ASS is localized centromeric from ABL1 on 9q34, and in patients without deletion, ASS is present as two signals in nucleus and on the chromosome 9 (see Fig. 54-6).

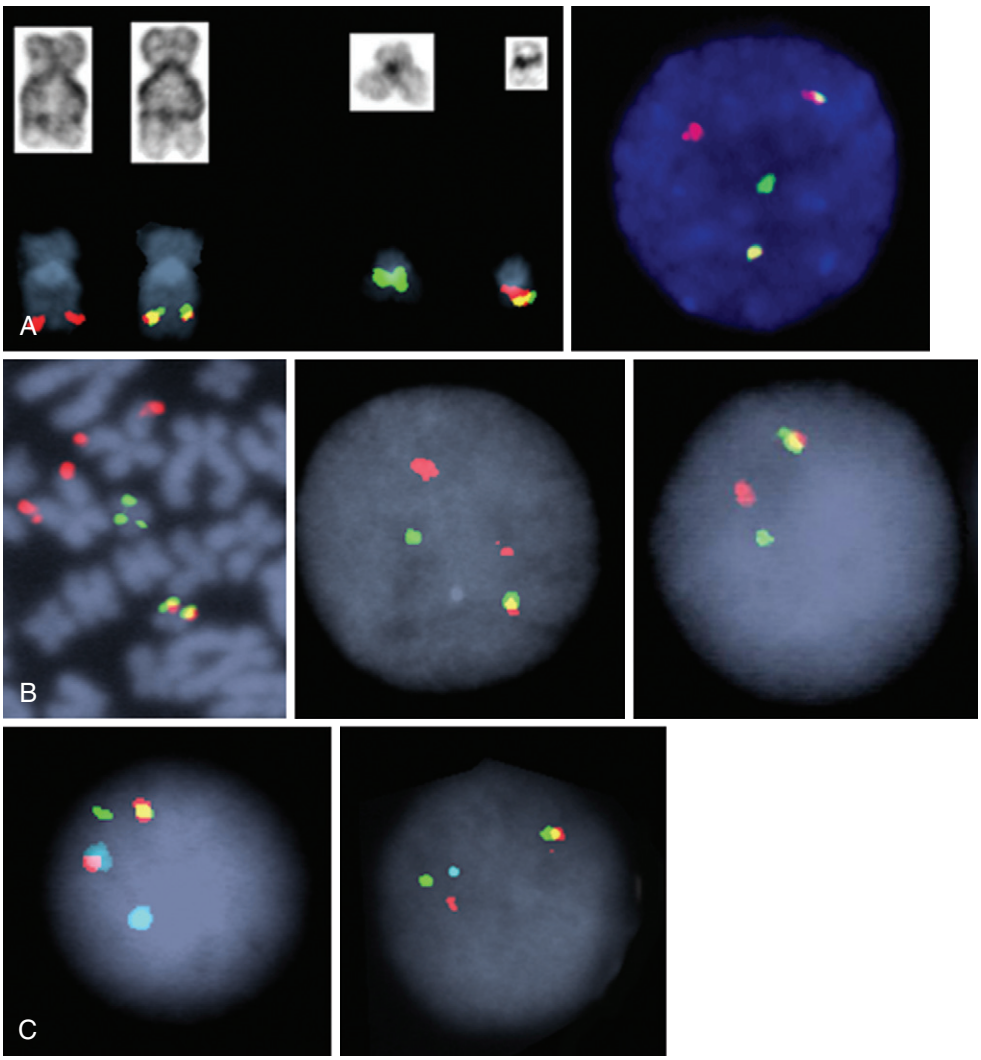

Figure 54-5 IDENTIFICATION OF THE PHILADELPHIA (PH) CHROMOSOME. **A,** Conventional cytogenetics *(left)* shows t(9;22)(q34;q11.2), and metaphase FISH with dual-color/dual-fusion BCR-ABL probe *(underneath)* shows two fusion signals *(yellow)* on abnormal chromosomes 9 and 22, one red single signal on normal homologue 9, and one single green signal on normal chromosome 22. *Right,* Nucleus after hybridization with dual-color/dual-fusion probe, indicating two fusion signals. **B,** Metaphase cell *(left)* and interphase cell *(middle)* after hybridization with BCR-ABL extrasensitive probe, indicating a fusion signal *(yellow)* on the Ph chromosome, BCR *(green)* on normal chromosome 22, ABL *(red)* signals on normal chromosome 9, and part of ABL on der(9) to reduce the number of false-positive cells. The interphase nuclei on the right are hybridized with a single-fusion BCR-ABL probe showing one fusion signal *(yellow)* and one single red and green signal on normal homologues. **C,** Two interphase nuclei after hybridization with triple-color BCR-ABL-ASS probe in which ASS is aqua. The left nuclei indicate a BCR-ABL fusion and disomy for ASS. The right nucleus shows deletion for ASS locus, consistent with deletion of der(9) (see Fig. 54-11).

cytogenetics is the term used to describe detection of chromosomal abnormalities in nondividing, interphase nuclei (Fig. 54-7). Six aspects of interphase FISH are particularly useful. (1) Interphase cytogenetics allows screening of a large number of cells. This permits investigation of hematologic malignancies with a low mitotic yield, such as chronic lymphocytic leukemia (CLL) or multiple myeloma (MM). (2) Interphase cytogenetics permits detection of chromosomal rearrangements in peripheral blood samples, thus obviating the need for marrow aspiration. For instance, in CML, which rarely yields a large number of dividing cells in peripheral blood, conventional cytogenetics usually is uninformative. However, detection of BCR-ABL, a molecular equivalent of the Ph, in peripheral blood using interphase FISH provides reliable, fast, quantitative results (see the section on Chronic Myelogenous Leukemia later in this chapter). (3) Interphase FISH offers a quantitative assay for monitoring disease progression or detection of minimal residual disease after ablative chemotherapy or hematopoietic cell transplantation (HCT). (4) Use of specific probe sets allows detection of specific disease-associated abnormalities such as t(8;21), which denotes the M2 subtype of acute myeloid leukemia (AML), or t(15;17), which is associated with acute promyelocytic leukemia, in a very short time period, allowing for timely and appropriate therapy. (5) Abnormalities can be detected accurately in archival specimens stored to 15 years. (6) Simultaneous use of interphase FISH and immunophenotyping is a powerful tool for investigation of lineage involvement in diseases such as myelodysplasia and to determine which cell population carries the specific chromosome abnormality. FISH nomenclature is described in the International System for Human Cytogenetic Nomenclature.

Higher resolution of chromosomal abnormalities can be achieved when fluorescently labeled probes are hybridized to extended DNA

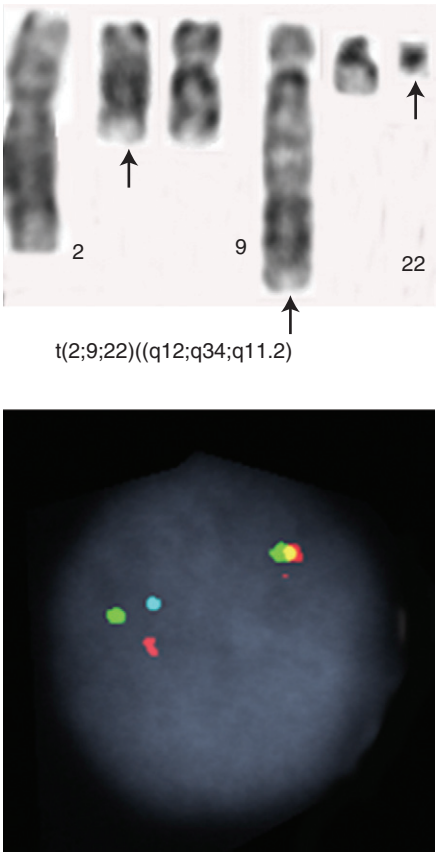

Figure 54-6 APPLICATION OF TRIPLE-COLOR BCR-ABL-ASS PROBE TO CELLS FROM A PATIENT WITH CHRONIC MYELOGENOUS LEUKEMIA AND T(2;9;22) KARYOTYPE *(TOP).* Interphase cell *(bottom)* shows BCR-ABL fusion signal *(yellow)* on the Philadelphia chromosome and one ASS *(aqua)* signal, indicating loss of DNA sequences from derivative chromosome 9 as a result of this complex translocation.

or free chromatin (chromatin strands released from their chromosomal scaffold) or free DNA fibers. This approach is termed *fiber FISH* (Fig. 54-8, *top*). The hybridized signals have the appearance of a "string of pearls" along the fiber rather than tight fluorescing spots observed in interphase cells. Although at the present time fiber FISH has limited clinical applicability because it requires special techniques of target DNA preparation on a glass slide, it has been successfully applied to map chromosomal breakpoints of the cyclin D gene in mantle cell lymphoma and for detailed mapping of the breakpoint site region in the BCL2 gene in follicular lymphoma.[10,11]

Multicolor karyotyping permits examination of the entire genome in a single analysis (Fig. 54-9). In 1996 it became possible to identify 24 different human chromosomes (12 autosomes and the X and the Y sex chromosomes), each with a unique color, with the help of fluorochrome-specific optical filters. This method is called *multicolor FISH (M-FISH)*. When interferometer-based spectral imaging is used, the method is called *spectral karyotyping*. The starting point in both methodologies is the use of whole chromosome painting probes for each chromosome. Thus each chromosome is labeled with a different combination of fluorescent dyes. The fluorochrome colors are not distinct enough for the unaided human eye to distinguish the combination with which the chromosome is labeled. In M-FISH, images are sequentially obtained using five different fluorochrome-specific optical filters. A computer program combines the data and displays each chromosome as if it were stained with a distinct color. Spectral karyotyping is based on the use of an interferometer (used by astronomers to measure the light spectra of distant stars) to determine the full spectrum of light emitted by each stained chromosome. A computer program then displays all the chromosomes simultaneously, each with its own unique color. These methods are applied with increasing frequency to resolve complex karyotypes, to detect cryptic translocations in patients with normal karyotype, and to define karyotypes with deletions. Their clinical use may be limited because the cost of equipment and probes is beyond what can be afforded by most clinical laboratories. The M-FISH technology cannot be used to discriminate structural intrachromosomal rearrangements such as duplications, deletions, and inversions.

Another powerful method used for identifying the location of chromosomal gains, losses, deletions, or amplifications, without prior knowledge of the chromosomal target that may be altered, is comparative genomic hybridization (CGH). Briefly, isolated DNA from leukemic marrow or tumor tissue is labeled with a one-color fluorochrome (e.g., red), whereas DNA isolated from normal control tissue is labeled with a different color (e.g., green). These differently labeled DNAs are hybridized against each other in a competitive hybridization reaction onto normal metaphase spreads. Computer-assisted image analysis detects colors generated after hybridization, which indicate equal hybridization, relative excess, or deficiency of the target DNA (relative to control). The ratio of color intensity provides a "copy number" karyotype. CGH has been successfully applied to study many leukemias, but its clinical use remains limited because it cannot detect balanced translocations, which are the hallmark of many hematologic malignancies. Nevertheless, CGH is an efficient approach to scanning the entire genome for variations in DNA copy number.

A particularly useful investigational approach is a "microchip array" in which labeled DNA or RNA from the sample of interest is hybridized with defined target sequences immobilized on a solid support (see Chapter 2).[2] The advantage of this method is its ability to screen genes that are amplified or deleted from the genome on a large scale or, in the case of RNA, to learn whether such genes are expressed at a particular stage of disease. The first example of successful RNA application of the microchip array technique was the differentiation of AML from ALL based solely on gene expression. As shown in Fig. 54-8 *(bottom panel),* in the "array CGH" procedure, large-insert genomic clones, oligonucleotides, or single-nucleotide polymorphisms (SNPs) have replaced metaphase chromosomes used in the regular CGH. Array CGH is a higher-resolution CGH technology and provides diagnostic information for diseases associated with DNA dosage. It also can be used to discover previously unexpected sites of gene dosage associated with specific hematologic malignancy type. The concept of obtaining gene copy number from multiple genome locations in a single measurement has been used to characterize numerous hematologic malignancies over the last 5 to 6 years, and its clinical utility is demonstrated throughout this chapter (see also Chapter 2).[3]

These modern cytogenomic methods have increased the resolution at which chromosomal rearrangements can be identified. Whereas in conventional cytogenetics the targets are whole chromosomes in metaphase spreads at a resolution of approximately 5 Mb, molecular cytogenetics methods may be used to analyze interphase nuclei at a resolution of 50 kb to 2 Mb or fiber FISH analysis of chromatin strands at a resolution of 5 kb to 500 kb. Moreover, the current resolution of array CGH is restricted only by clone size and by the density of clones on the array, some of which may contain resolution at the level of a single nucleotide.

Conventional cytogenetics and FISH methodologies are complementary. Each has its own advantages and limitations in investigating genomic rearrangements of malignant cells. Although conventional cytogenetics is the comprehensive study of all chromosomes, it requires a large number of dividing cells, which, in some diseases, such as myelofibrosis, is difficult to obtain. Furthermore, many small deletions or structural rearrangements are beyond the microscopic level of detection. FISH can be used in conjunction with conventional cytogenetics with both interphase and metaphase cells. It is a more sensitive method and can detect rearrangements smaller than 1 kb. The main disadvantage of interphase FISH is that it cannot be used unless a known abnormality is suspected. When the abnormality is known, interphase FISH can pinpoint the clonal aberration at the single-cell level in a very short period of time.

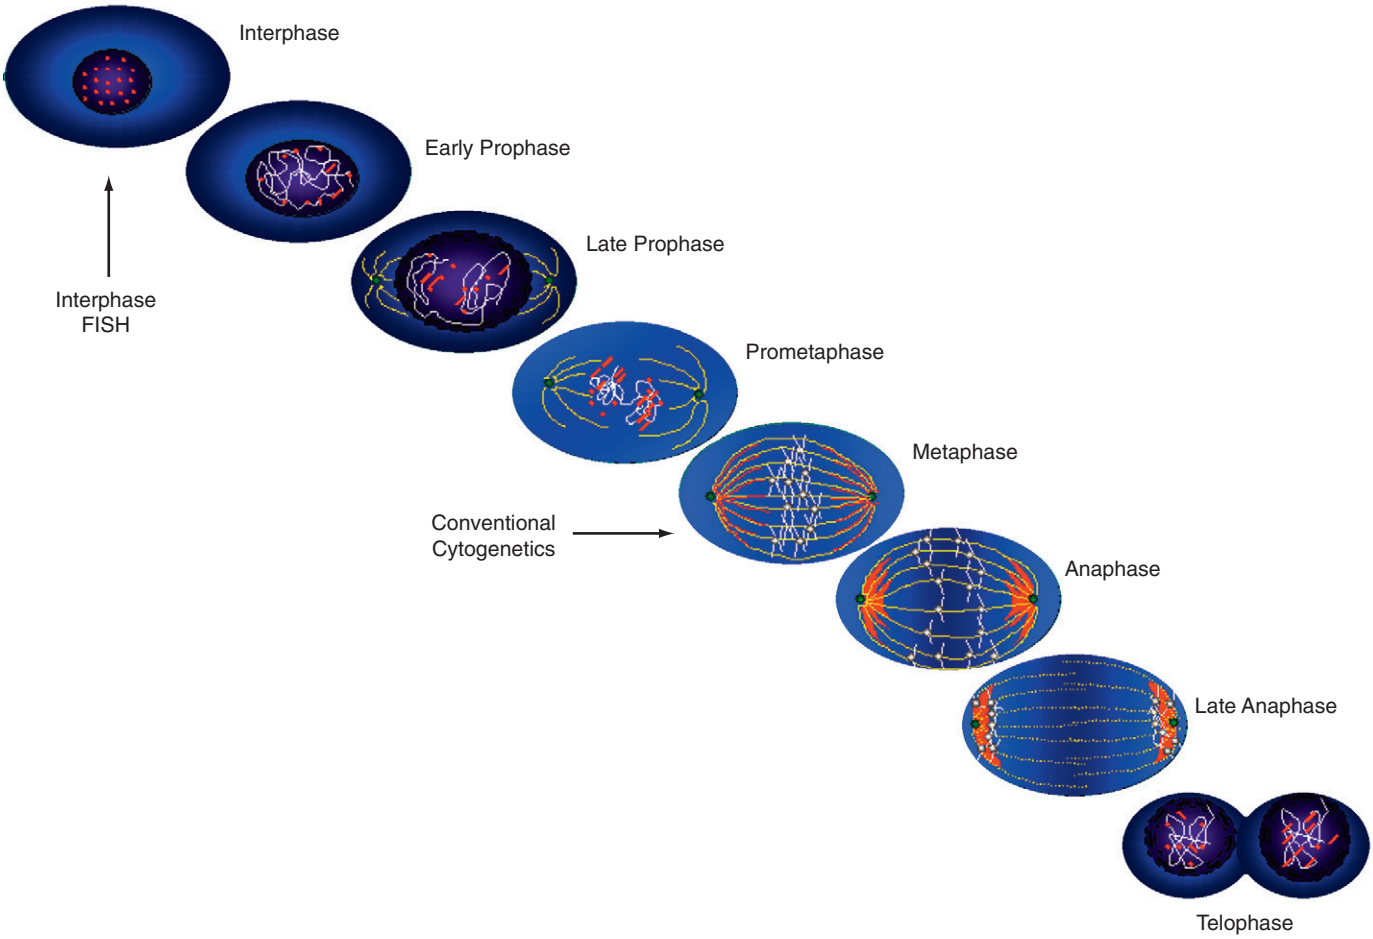

Figure 54-7 SCHEMATIC REPRESENTATION OF CELL DIVISION. Most clinical FISH studies are performed on nondividing interphase cells, whereas conventional cytogenetics is performed at the metaphase stage of cell division. *(Courtesy Dr. Ari Melnik, Mount Sinai Medical Center, New York.)*

Clonal Origin of Leukemia

The question of whether cell proliferation is monoclonal or polyclonal is fundamental to understanding the underlying etiology of hematologic malignancies. Markers of clonality are used to determine the origin of disease; to differentiate malignant from nonmalignant populations; to establish hematopoietic hierarchy, clonal evolution, and clonal remission; and to delineate steps involved in the multistep pathogenesis of hematologic malignancies.

The clonal origin of leukemias and lymphomas can be assessed by either intrinsic or extrinsic cellular markers. Intrinsic cellular markers are specific for a cell population, arising either during normal differentiation or as a part of disease process. For instance, cell surface-associated immunoglobulin (Ig) markers such as the λ or κ light chain or idiotypes and T-cell receptors (TCRs) can be useful for evaluating lymphoid diseases. Application of Ig markers demonstrated for the first time that MM was of clonal origin. Somatic cytogenetic alterations are useful intrinsic markers for identifying abnormal clones and following disease progression. Thus the observation of identical chromosome anomalies in different cells of the same tumor is evidence of clonality. Since the discovery of the Philadelphia chromosome (Ph) in 1960, it is well established that nonrandom, recurrent chromosomal abnormalities characterize many hematopoietic malignancies. The finding of the Ph in different CML-derived hematopoietic cell lineages led to the hypothesis that CML might originate in a single precursor cell and may have a clonal development. Moreover, the presence of additional recurrent chromosomal abnormalities in the Ph-positive clone (such as trisomy 8, duplication of the Ph, or trisomy 19) not only indicates the clinical progression of the disease and the occurrence of the accelerated phase or blast crisis, but also demonstrates the subclonal evolution of the Ph-positive clone. Currently, disease-associated somatic genomic mutation, such as rearrangements of MLL, AML1, TEL/ETV6, PML-RARA, and many others, can be identified by polymerase chain reaction (PCR)–based assays or by FISH assay and may serve, with or without conventional cytogenetics, as intrinsic marker of disease processes.

On the other hand, extrinsic marker systems use cellular mosaicism that is completely independent of the disease being studied and is not restricted to the cell lineages. Individuals with Turner or Klinefelter syndrome are mosaic for XX or XY and X cells or XXY and XY cells, respectively. The mosaicism created by X-chromosome inactivation in females is much more widely applicable and has provided fundamental insights into the pathogenesis of hematologic malignancies. Original studies with X-linked glucose-6-phospate dehydrogenase (G6PD) as a marker of clonality were based on the Lyon hypothesis, which asserts that early in embryogenesis, one X chromosome in females is inactivated in somatic cells and the activation status is stably transmitted to daughter cells during mitosis (Fig. 54-10)[4]. The choice of maternal versus paternal X-chromosome inactivation is random; however, once it occurs, it is maintained in all daughter cells.[37] Random X inactivation occurs by embryonic day 6.5 around the start of gastrulation and results in a mosaic pattern that characterizes adult females.[38-40] Therefore an adult female is a mosaic for two-cell populations, one expressing genes from an active X chromosome and the other expressing genes from the inactive X chromosome. Incidentally, mammalian X-chromosome inactivation is a mechanism that equalizes the dosage of X-linked genes between sexes. Although the exact mechanism of X-chromosome inactivation

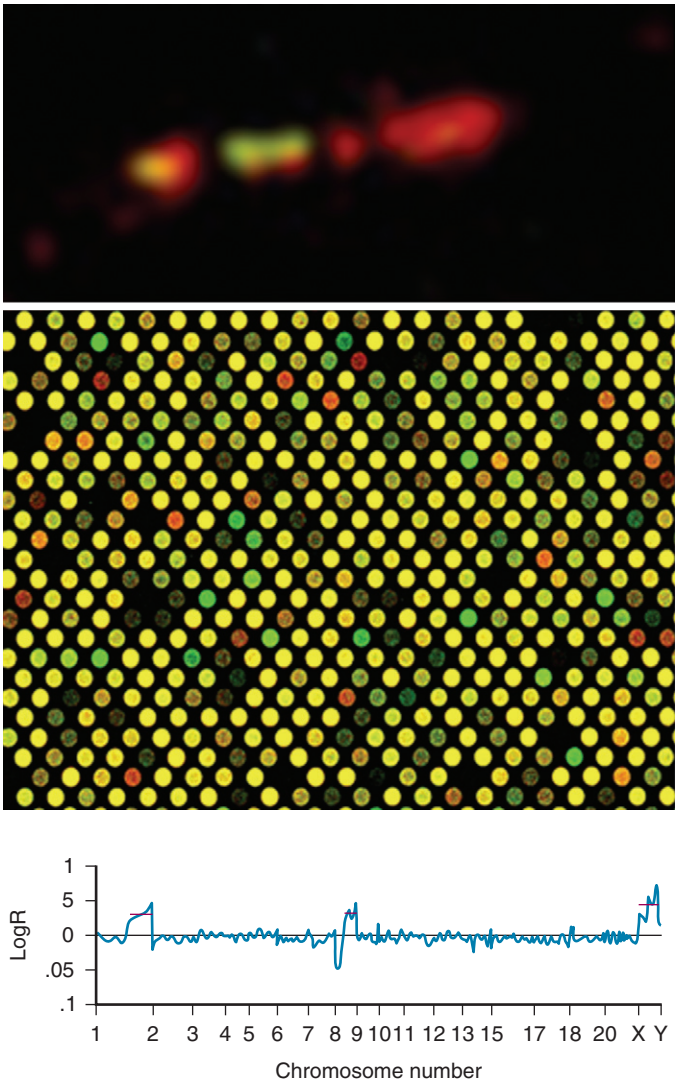

Figure 54-8 *Top panels,* Application of higher-resolution FISH (fiber FISH) to extended DNA fibers. The hybridization signals have the appearance of a "string of pearls" along the fiber, rather than tight fluorescing spots observed in interphase nuclei. *Bottom panel,* Portion of array CGH image. The tumor or normal cell fragmented DNA sample was labeled with Cy5 or CY3, respectively. Yellow spot indicates the intensity signal of the genomic element on that spot in the tumor equals that of the normal cell reference. Red or green spot indicates intensity of the tumor is greater or less than the reference, suggesting copy-number change for the genomic element on that spot. Graph underneath is the copy-number change profile. Y-axis is the log2 ratio of the intensity of each gene in the order of its position on the genome in tumor sample versus that of normal liver sample. Gained or lost regions are marked by red or green line, respectively. Gains of 1q and 8q and loss of 8p were observed in this tumor. *(Courtesy Dr. D. Weijia Zhang, Mount Sinai School of Medicine, New York.)*

remains to be elucidated, the process of X inactivation starts with methylation of CpG islands. The inactivation process is believed to occur before differentiation of embryonic stem cell into various cell lineages. Hematopoietic cells do not originate from a single embryonic stem cell but from several progenitors, thereby allowing for mosaic expression from both X chromosomes.

The observation that human females are heterozygous for the G6PD variant A and A^- and that two mosaic cell populations may be distinguishable by electrophoretic mobility was reported in the 1960s. The X-inactivation G6PD mosaic system was then applied to the study of clonality in human tumors in 1964 by Gartler and Linden. They studied uterine leiomyomas and recognized that the presence of normal cells might mask the ability to detect individual clonal uterine leiomyomas. In females who are heterozygous for the G6PD polymorphism and have malignant hematologic disorders such as CML, the finding of a single G6PD type in marrow or blood cells and both the A and B type G6PD in tissues not involved by the malignant process demonstrated that CML was of clonal origin and provided evidence that the malignant transformation occurred at the level of a stem cell common to most cell lineages. Additional studies with heterozygous G6PD females who had CML demonstrated that some CML-derived B lymphocytes had a single G6PD type, but these clonal cells were Ph-negative; thus leukemic transformation predates development of the chromosomal abnormality. This observation provided evidence that CML has a multistep pathogenesis. Application of G6PD studies to hematologic malignancies demonstrated the clonal and stem cell origin for AML, ALL, Ph-negative chronic myeloproliferative neoplasms (MPNs), myelodysplastic syndrome (MDS), and CLL. In some patients with AML, G6PD studies demonstrated a single-enzyme phenotype without the presence of the diagnostic cytogenetic abnormality at the time of hematologic remission, indicating a clonal remission and a possibility of clonal preleukemic phase of AML. This observation provided evidence that a stepwise evolution occurs in AML, as it does in CML. In MDS, similar studies demonstrated that lymphoid cells were part of the MDS clone. Particularly informative were patients with myelofibrosis whose marrow cells had trisomy 8. In sharp contrast, cultured marrow fibroblasts had disomy 8 and expressed both B and A G6PD types in equal amounts similar to control skin fibroblasts, whereas marrow-derived granulocytes, erythrocytes, and platelets expressed only type A enzyme. This indicated that marrow fibroblasts were not clonal and were not part of the disease process. G6PD studies were particularly useful in the investigation of red blood cells and platelets in hematologic malignancies because the absence of nuclei in these cells means they cannot be studied by cytogenetics or DNA analysis. Although it is now considered "common knowledge" that hematologic malignancies have a clonal development, this understanding is greatly due to what is now known as classic Fialkow's work, whose profound insight contributed much to current concepts and understanding.

Despite the importance of the G6PD approach, it is limited by the rarity of females who are heterozygous for the G6PD isoenzyme. An alternative and more extensive DNA-based X-chromosome clonal assay uses common polymorphic markers that are caused by changes in DNA methylation patterns that accompany inactivation of the X chromosome.[5] These X-linked loci, such as phosphoglycerine kinase, hypoxanthine phosphoribosyltransferase, DXS25 (M27β), and human androgen receptor (HUMARA), have been extensively used in assessment of clonality, and now it is possible to identify clonal cell populations in virtually all females. DNA-based marker systems rely on a sequence polymorphism that has adjacent differences in methylation on the active and inactive X chromosomes. The inactive X chromosome is more highly methylated than its active homologue, but this is only true for certain regions of genes as 10% to 20% of X-linked genes escape inactivation and can be found both in clusters and in isolation. The most widely used HUMARA assay appears to maintain the stringent methylation differences. The number of CAG tandem repeats differentiates the maternal from the paternal X chromosome.

The DNA-based X-chromosome clonal assay is limited to females younger than 60 years because they usually have 1:1 distribution of two-mosaic–cell population. A ratio greater than 3:1 is found in women older than 60 years, probably as a result of stem cell kinetics influenced by X-linked genetic factors. When the ratio of two cell populations is greater than 3:1, this phenomenon is called a *skewed X-inactivation pattern*. With the HUMARA assay, acquired unequal or skewed X-chromosome inactivation (excessive lyonization) is found in 35% to 40% of women older than 60 years. Thus X-chromosome–based clonality studies must incorporate age-matched controls. Despite the enormous contribution of clonality assays to the understanding of disease processes, they are usually performed in research investigations and are rarely used as diagnostic tools.

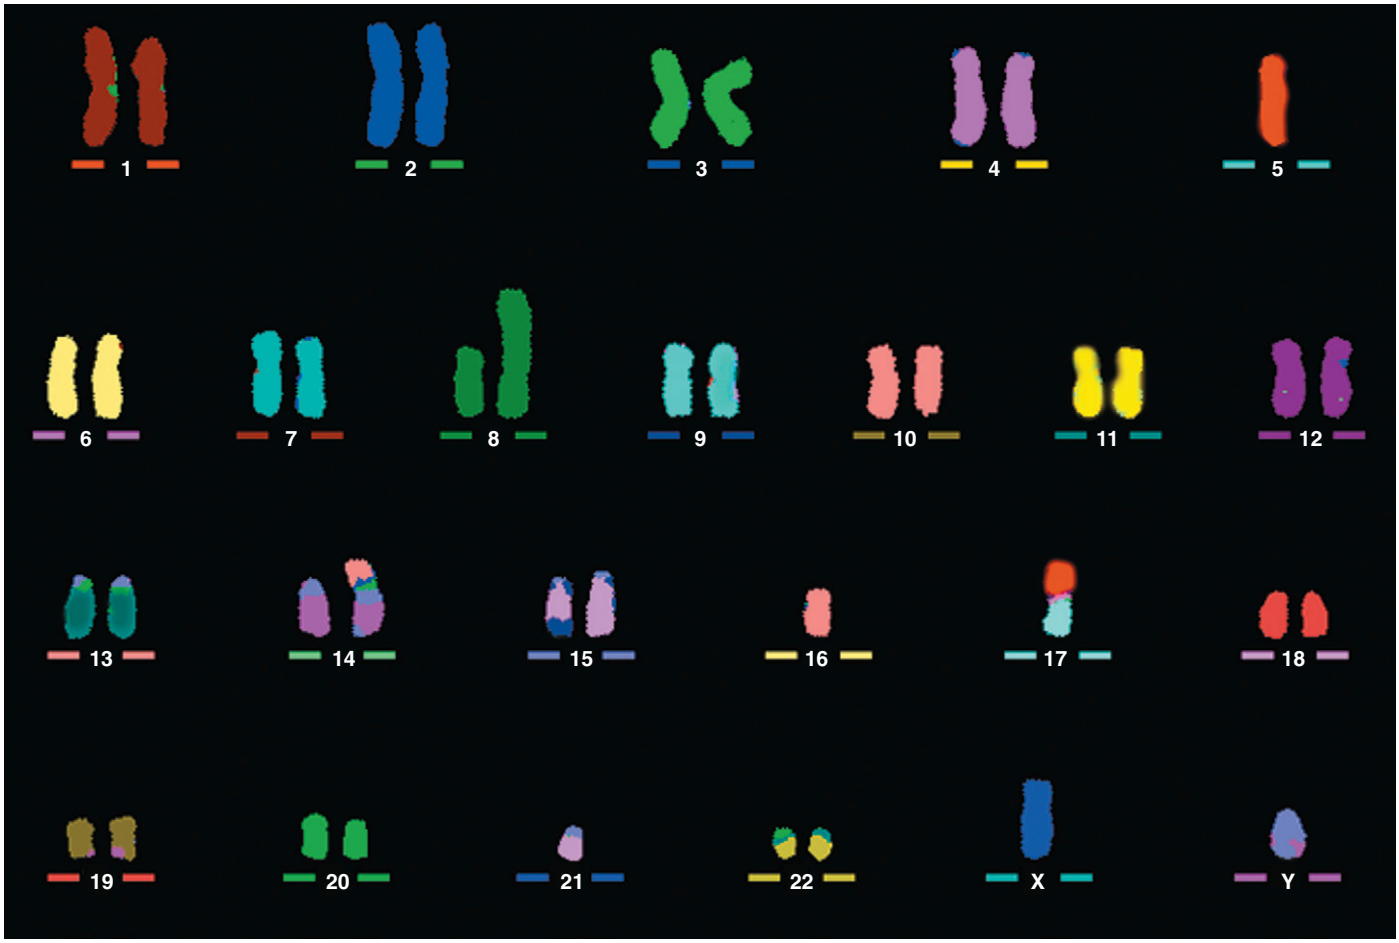

Figure 54-9 Multicolor metaphase FISH of a bone marrow cell from a patient with myelodysplastic syndrome documenting 43,XY, −5, der(8)t(8;8)(p23;q11.2), der(14;16)(p12;p11.1), inv(15)(q21;q24), der(17)t(5;17)(p13;p13), −21 karyotype. The origin of t(8;8) and der(14;16) could not have been determined by conventional cytogenetic study alone.

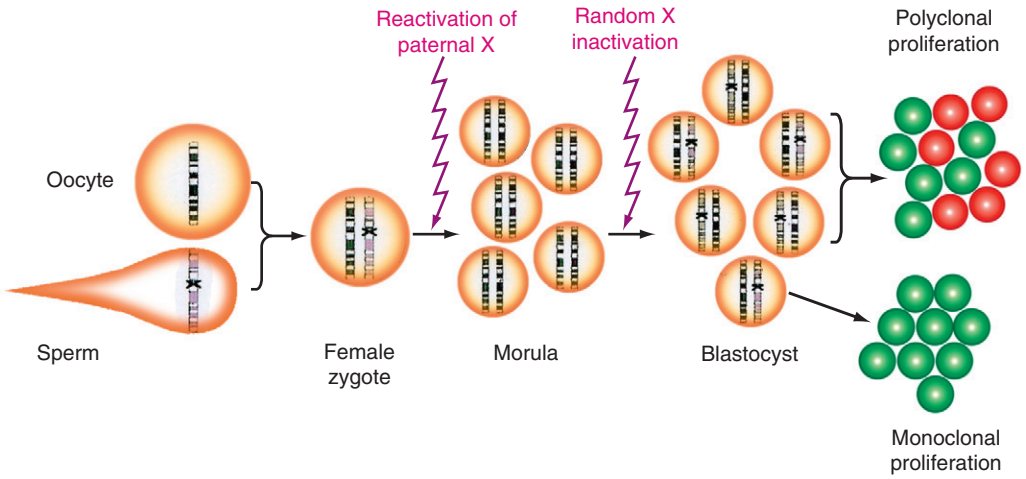

Figure 54-10 X-CHROMOSOME–LINKED ENZYME GLUCOSE-6-PHOSPHATE DEHYDROGENASE (G6PD) AS A MARKER TO INVESTIGATE CLONAL DEVELOPMENT OF HUMAN HEMATOPOIETIC DISORDERS. Early in embryogenesis, regions of all but one X chromosome are inactivated in each cell containing two or more X chromosomes. The choice of maternal versus paternal X chromosome for inactivation is random. Once the inactivation occurs, it is fixed and is stably transmitted to daughter cells during mitosis (Lyon hypothesis). Females who are heterozygous for the common B type and the less frequent A type, G6PD (localized on Xq27), are mosaic. This cellular mosaicism is used to study monoclonal versus polyclonal cell proliferation and development of malignant hematopoietic diseases. *(Courtesy Dr. W Raskind, University of Washington, Seattle.)*

CHRONIC MYELOPROLIFERATIVE NEOPLASMS

The World Health Organization (WHO) characterizes MPNs as clonal stem cell disorders. CML has a unique place among hematologic malignancies and is described separately from the other Ph-negative MPNs. CML is characterized by the t(9;22) or the BCR-ABL1 fusion confirmed by cytogenetic, FISH (see Figs. 54-4 and 54-5), or PCR analysis.

Chronic Myelogenous Leukemia

Knowledge of the origins of CML has accumulated over the last 52 years and serves as a classic example of the fruits of molecular medicine (Table 54-2). The Ph chromosome is the first example of a specific chromosomal abnormality associated with a malignant disease. ABL1 and BCR genes are the first oncogenes (see Chapter 66) localized at the site of a chromosomal breakpoint in t(9;22)(q34;q11). The BCR-ABL1 fusion leads to a "hybrid" gene, resulting in the production of a dysregulated tyrosine kinase protein. Finally, imatinib mesylate, a specific tyrosine kinase inhibitor, was the first rationally designed gene-targeted form of cancer therapy.

The Ph, named in honor of Philadelphia, the city of its discovery, was described for the first time in 1960.[6] It represents a signature genomic rearrangement occurring in more than 95% of patients with CML. Approximately 3% of all pediatric leukemias are Ph-positive CML. The Ph results from a balanced translocation t(9;22)(q34;q11.2)[7] (see Fig. 54-5, *A*). The Ph arises postzygotically, being found only in hematopoietic tissue. The findings of the Ph in myeloid cells, erythroid cells, eosinophils, monocytes/macrophages, basophils, and B lymphocytes, along with the absence of the Ph in cultured marrow fibroblasts, support the concept that the Ph results from a specific rearrangement in a multipotent hematopoietic stem cell and that it is an acquired rather than an inherited abnormality.[8] Of interest, the Ph is rarely identified in T cells. T lymphocytes are long-lived cells and may antedate the development of CML. These observations combined with G6PD heterozygotes and have CML provide further evidence for the concept that CML is a clonal disease arising in a stem cell capable of differentiation into most of the hematopoietic cell lineages.

In a review of 1129 Ph-positive patients, the 9;22 translocation was identified in 1036 (92%) cases. Karyotypic analysis of marrow cells in patients with CML is a time-consuming task. However, it demonstrates not only the presence of the Ph but also other chromosomal rearrangements (clonal evolution) of clinical significance.

The reciprocal nature of the Ph translocation was confirmed when studies showed that its molecular consequence is the translocation of the ABL gene from chromosome 9, band region q34, and subsequent fusion to the breakpoint cluster region (BCR) gene on chromosome 22, band q11 (see Fig. 54-5, *A, second row*). This creates a hybrid BCR-ABL1 gene that is transcribed into a chimeric BCR-ABL1 messenger RNA (mRNA) and translated into a specific chimeric protein.

Three major breakpoint locations along the BCR gene on chromosome 22 result in three chimeric proteins. They include $P210^{BCR\text{-}ABL1}$, $P190^{BCR\text{-}ABL1}$, and $P230^{BCR\text{-}ABL1}$ and are associated with three distinct types of leukemia. $P210^{BCR\text{-}ABL}$ is found in the majority of patients with classic Ph-positive, BCR-ABL1-fusion–positive CML and approximately 30% of patients with Ph-positive ALL.

Table 54-2 History of Discovery of Philadelphia Chromosome and BCR-ABL Fusion

1960	Philadelphia chromosome (Ph) is identified.
1973	Ph is t(9;22)(q34;q11.2).
1983	ABL is translocated from chromosome 9 to chromosome 22.
1984	BCR is localized to 22q11.
1987	Ph′ is BCR-ABL fusion.

Expression of $P190^{BCR\text{-}ABL1}$ is seen in 20% to 30% of adults and 80% of children with ALL, in rare CML patients, and in the majority of patients with rare Ph-α–positive AML, whereas expression of $P230^{BCR\text{-}ABL1}$ is associated with a rare indolent chronic neutrophilic leukemia variant and up to 1.6% of CML (approximately 50 patients in the worldwide literature have been described).

The BCR-ABL1 fusion is present in both standard and variant forms, in cases where chromosome 9 involvement is cytogenetically not detectable, and when a masked Ph is present. In the majority of patients, the fusion of ABL1 and BCR takes place on chromosome 22 (Fig. 54-11; see also Fig. 54-4). However, in a small group of patients the BCR gene is translocated to chromosome 9, and the fusion of the two genes is localized to 9q34. The prognosis of these patients may be inferior, but the number of reports is too small for a definitive conclusion. The BCR-ABL1 fusion transcript is present

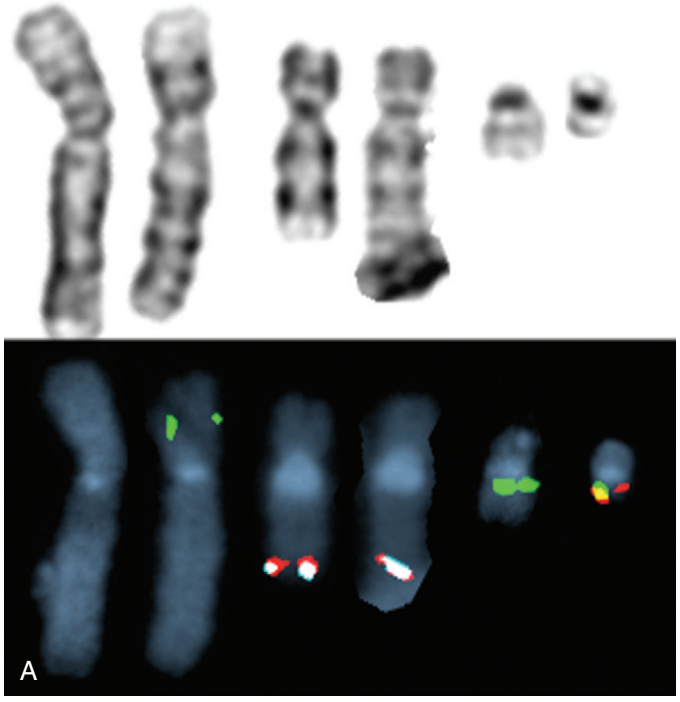

Figure 54-11 IDENTIFICATION OF BCR-ABL1 FUSION IN PATIENTS WITH COMPLEX KARYOTYPEs. Partial karyotype from a patient with chronic myelogenous leukemia showing t(2;9;22)(p21;q34;q11.2) **(A)** and from a patient showing a four-way translocation with t(7;9;22;22) karyotype **(B),** indicating the BCR-ABL 1 is on the Philadelphia chromosome even in complex chromosomal translocations.

in neutrophils, monocytes, eosinophils, erythrocytes, B cells, rarely in T cells, and in CD34 cells and is associated with increased proliferation of CD34 myeloid progenitor cells but not of other more mature myeloid precursors. These observations confirm the hypothesis that CML originates in a multipotent stem cell capable of differentiating to all hematopoietic cell lineages with the exception of T cells. Studies provide evidence for the existence of clonal BCR-ABL1 fusion–negative stage. The formation of BCR-ABL1 and Ph occurs in an already abnormal and genetically unstable clone of pluripotent hematopoietic cells. Thus it is the preexisting genetic instability that predisposes to formation of BCR-ABL1 and Ph. Once Ph formation occurs, it has a further selective growth advantage over normal cells, resulting in overwhelming BCR-ABL1–positive, Ph-positive marrow cells at the time of diagnosis of CML.

In the 5% of patients with CML who are Ph-negative by cytogenetic studies, clonal and stem cell origin of these hematologic malignancies can still be demonstrated, and molecular analysis reveals the BCR-ABL fusion in approximately 2% to 3% of these patients (Fig. 54-12). In the majority of Ph-negative patients, an ABL insertion from chromosome 9 to 22q11.2 results in a BCR-ABL1–fusion product without reciprocal translocation of sequences from chromosome 22 to chromosome 9. Approximately 2% of patients truly are Ph negative, BCR-ABL fusion negative. These patients may not have CML but rather another myeloproliferative neoplasm. The concept that the BCR-ABL fusion plays a central role in the pathogenesis of CML is strongly supported by two lines of evidence: (a) retroviral transduction experiments in which $P210^{BCR\text{-}ABL1}$ is expressed in murine marrow cells, resulting in a myeloproliferative disorder resembling CML, and (b) the fact that imatinib, a tyrosine kinase inhibitor, selectively inhibits the BCR-ABL fusion protein in mice and specifically inhibits the growth of human Ph-positive cells in vitro and in vivo. Although considered necessary, BCR-ABL may not be initial or sufficient to cause the malignant transformation in CML.

Genomic PCR and Southern blot analysis can determine the exact breakpoints of DNA fusion products. Reverse transcriptase PCR (RT-PCR) and Northern blot analysis allows detection of BCR-ABL transcripts at the RNA level. Current FISH studies for detection of BCR-ABL1 fusion at diagnosis use a dual-color BCR-ABL ES probe or BCR-ABL1 dual-fusion probe (Fig. 54-13; see also Figs. 54-4 and 54-5, *A* and *B*). A triple-color BCR-ABL1-ASS probe is used for detection of deletions on both chromosomes 9 and 22 (see Fig. 54-13). Approximately 12% to 15% of patients with CML have large deletions adjacent to the Ph translocation breakpoint on the derivative 9 chromosome, and initial reports demonstrated inferior survival in these patients (see Fig. 54-5, *C*). Subsequent quantitative PCR and FISH studies have demonstrated that deletions are heterogeneous and may involve both chromosomes 9 and 22 (majority of cases), only chromosome 9 (8% of patients with deletions) (see Fig. 54-13), or only chromosome 22 (4% of cases with deletions). FISH analysis using multiple large genomic probes along the length of chromosomes 9 and 22 show that the deletion size is variable ranging from 0.5 Mb to greater than 10 Mb. A more refined recent study, applying genomic SNP microarrays revealed three common deletion regions: (1) a 162 kb loss at 9q34, (2) a 138 kb deletion at 22q11.2, and (3) a 102 kb deletion at 22q11.2. It appears that the partial deletion of the ABL1-BCR fusion (not the pathogenetic form) on derivative 9 chromosome occurs as a part of the same process as the formation of the BCR-ABL1 translocation. Before imatinib therapy, these deletions were associated with adverse prognosis, inferior survival, and higher probability of relapse after hematopoietic cell transplantation. A multivariate analysis of 339 patients, with a median observation of 7 years, confirms that deletions involving 9q alone, spanning the ABL1-BCR breakpoint, were significant independent predictors of an adverse prognosis. However, in a recent study of 521 CML patients, including 60 with the del(9q) during the early chronic phase of imatinib treatment, the cumulative incidence of complete cytogenetic response and major molecular response and the overall survival are comparable at the 5-year follow-up between CML patients with and without the del(9q). These results indicate that 9q deletions have a negative impact only on those patients with large deletions or one involving both BCR and ABL1, which may be overcome in the majority of patients with TKI therapy.

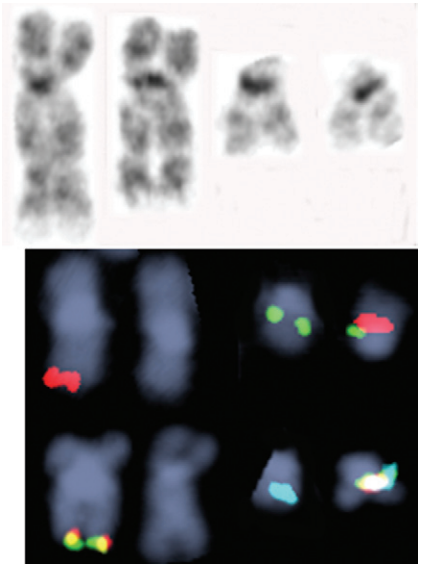

Figure 54-12 PARTIAL KARYOTYPE FROM A PATIENT WITH PH-NEGATIVE CHRONIC MYELOGENOUS LEUKEMIA *(TOP)* SHOWING NORMAL CHROMOSOMES 9 AND 22. Two pairs of chromosomes 9 and 22 after hybridization with dual color *(middle)* and triple color *(bottom)* demonstrating BCR-ABL fusion on the Ph chromosome without apparent t(9;22). Tricolor strategy showed ABL and ASS in close proximity and appearing as fusion on normal 9 (*bottom left* chromosome) and BCR-ABL-ASS fusion *(white)* on normal 22.

At diagnosis, conventional cytogenetics remains the gold standard because the chromosome analysis will identify not only the t(9;22) but also other chromosomal abnormalities that may indicate accelerated or blast phase of the disease or clonal proliferation of Ph-negative cells. The current international recommendation is that FISH studies should be performed at diagnosis in conjunction with conventional cytogenetics to determine deletion status on der(9q) and to identify patients who are BCR-ABL1 but lack the Ph- karyotype.

Imatinib mesylate (Gleevec, formerly known as STI-157) has revolutionized therapy for CML and, for many patients, has transformed a deadly disease into a chronic disorder that is compatible with normal life.[10] The standard method for monitoring a patient's response to therapy is conventional cytogenetic analysis of cells obtained from a marrow aspirate. In the phase III International Randomized Interferon and STI-571 (IRIS) study, 89% of patients had Ph-negative marrow aspirates as determined by conventional cytogenetics at 5 years. However, conventional cytogenetics has limited sensitivity. The degree of tumor load reduction is determined to be an important prognostic factor for patients with CML on therapy. CML patients without discernible Ph detected by conventional cytogenetics analysis may still harbor up to 10^{10} leukemic cells.

Hypermetaphase FISH has greater sensitivity compared with conventional cytogenetics and may detect 31% of BCR-ABL1 metaphase cells in patients who are Ph-negative as assessed by conventional cytogenetics. Interphase FISH does not depend on the cycling status of cells, and use of double-fusion probes has reduced false-positive results to approximately 1%. However, if peripheral blood cells rather than marrow aspirate cells are used to monitor residual disease, the high percentage of BCR-ABL1 fusion-negative lymphoid cells may underrepresent actual residual tumor load. In most direct comparison studies, interphase FISH of peripheral blood compared with conventional cytogenetics of marrow in patients who are treated with imatinib showed good correlations ($r = 0.91$-0.97). Real-time quantitative PCR (RQ-PCR) is by far the most sensitive method. It provides an accurate measure of the total leukemia cell mass and the degree to which BCR-ABL1 transcripts are reduced by therapy, and it correlates with progression-free survival.[9]

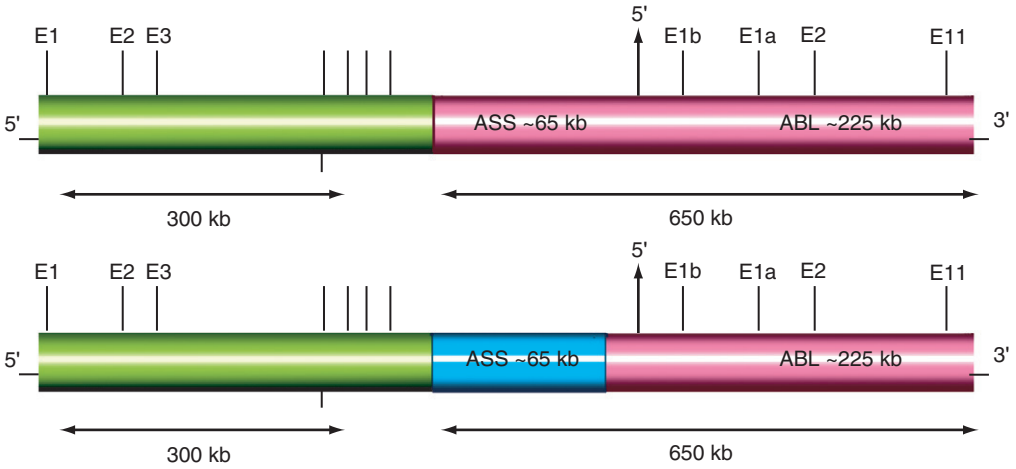

Figure 54-13 SCHEMATIC REPRESENTATION OF THE MOST FREQUENTLY USED BCR-ABL PROBES. Dual-color/single-fusion extrasensitive probe strategy, as indicated in text, uses a 650-kb probe in which two loci, ABL and ASS, both are labeled in red. BCR-ABL fusion-positive nuclei show three red signals: one small red signal on der(9), one red signal on normal homologue 9, and a third red signal in fusion with BCR. When a triple-color probe is applied, the ASS locus usually is labeled in aqua and the BCR-ABL fusion-positive cells show two aqua signals, unless there is deletion of der(9). The most useful application of triple-color probe is documentation of deletion of derivative chromosome 9.

The goal of therapy in CML is to achieve a molecular remission as measured by the reduction or elimination of BCR-ABL1 transcripts. In IRIS, at 5-year follow-up, complete cytogenetic response combined with major molecular response at 12 months is associated with a 97% progression-free survival rate. This compares with an 89% progression-free survival for those with complete cytogenetic response but without major molecular response. Current international recommendations for optimal molecular monitoring of patients receiving imatinib treatment includes an RQ-PCR assay expressing the BCR-ABL1 transcript levels on an internationally agreed scale.[9] The term *major molecular response (MMR)* corresponds to ≤0.1% BCR-ABL1, whereas the designation *CMR (complete molecular response)* should be used only for patients with undetectable BCR-ABL1, where the limit of detection is confirmed to be at least ≈4.5 log reduction from IRIS baseline response. The two major obstacles to successful imatinib-based therapy for patients with Ph-positive, BCR-ABL1 fusion-positive CML are the persistence of BCR-ABL fusion-positive cells and relapse of the disease due to emergence of resistance to imatinib. Acquired resistance to imatinib treatment is manifested in two ways: amplification of BCR-ABL1 fusion product (Fig. 54-14) and mutations in the ABL kinase domain. Currently, 100 different ABL1 kinase domain mutations have been described, although only about 15 are common and they account for more than 85% of all mutations detected.

Between 5% and 8% of patients undergoing treatment with imatinib will develop chromosomal abnormalities such as trisomy 8, monosomy 7, del(20q), and other anomalies in BCR-ABL1 fusion-negative cells. Imatinib may induce chromosomal abnormalities in BCR-ABL1$^-$ cells. Alternatively, imatinib may uncover chromosomal abnormalities present before therapy after significant reduction of overlying Ph-positive cells (Fig. 54-15). Presence of +8 and other chromosomal anomalies in Ph-negative cells in patients treated with imatinib suggests that CML has a multistep pathogenesis and that clonal Ph-negative cells precede the development of the Ph-positive clone (Fig. 54-16).[11] This important observation about the pathogenesis of CML demonstrates the power of conventional cytogenetics, even in the era of molecular assays, and should be used at least annually while patients are undergoing imatinib treatment.

CML patients who cannot tolerate or are resistant to imatinib may benefit from the second and now third generation of tyrosine kinase inhibitors, such as dasatinib and nilotinib. These agents bind to the

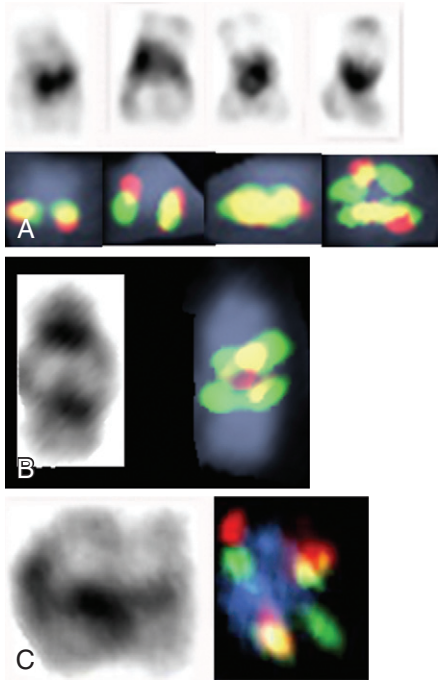

Figure 54-14 EXAMPLES OF UNUSUAL Ph CHROMOSOMES ASSOCIATED WITH IMATINIB RESISTANCE AND BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA. **A,** Amplification of the Ph chromosome *(top row)* and the BCR-ABL fusion in a patient treated for 3 months with imatinib. The patient developed five copies of the Ph chromosome and 5 copies of the BCR-ABL fusion *(yellow)*. **B,** G banding of dicentric Ph chromosome *(left)* dic der(22)t(9;22)(q34;q11.2) and after FISH studies *(right)* showing two copes of BCR-ABL fusion. **C,** G-banding of isoderivative Ph, ider(22)t(9;22)(q34;q11.2) *(left)* and after FISH studies showing two copies of BCR-ABL fusion *(yellow)* on the end of both arms.

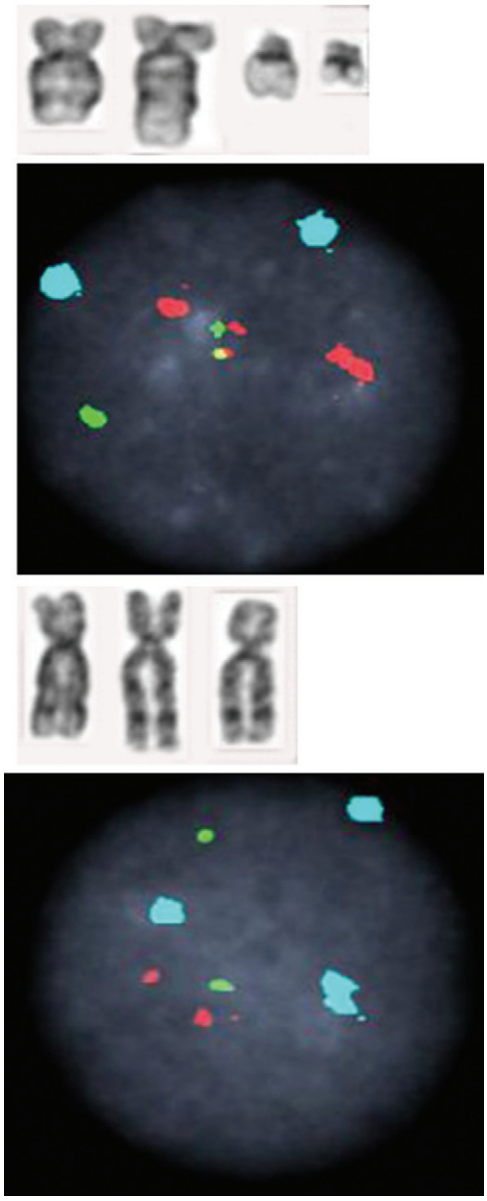

Figure 54-15 TWO DIFFERENT CELL POPULATIONS FROM A PATIENT TREATED WITH IMATINIB. One population shows t(9;22) (*top row,* partial G-banded karyotype) and the BCR-ABL fusion signal *(yellow, second row)* as well as disomy 8 *(aqua).* In contrast, the second population shows trisomy 8 (*third row*, partial G-banded karyotype) in the BCR-ABL fusion-negative cells *(fourth row),* showing disomy for the *BCR (green),* ABL *(red)* as well as trisomy for chromosome 8 *(aqua)* (see text for details).

ABL kinase domain in a matter distinct from that of imatinib and thereby retain activity against nearly all imatinib-resistant mutations (see Chapter 66).

The mechanism of transformation to advanced-phase CML is heterogeneous and poorly understood. In blast crisis of CML, 80% to 85% of patients show karyotypic evolution, that is, new chromosomal abnormalities in very distinct patterns are present in addition to the Ph. The most common changes include gain of chromosome 8 (33%) or +19 (12%), gain of a second Ph (30%), i(17q)(20%), alone or in combination, to produce modal chromosome numbers of 47 to 50 (Fig. 54-17). Isochromosome 17q occurs almost exclusively in myeloid blast crisis. Others less frequently observed include monosomies of chromosomes 7 and 17, loss of Y, and trisomies of chromosomes 17 and 21. In addition to these common karyotypic evolutions, additional chromosomal aberrations specific for acute myelogenous leukemia—for example, t(8;21) (Fig. 54-18), inv(16), t(3;21)(q26;q22), and most frequently, inv(3q)/t(3;3), resulting in the overexpression of EVI1—have been observed. Complete cytogenetic remission for patients in accelerated phase or blast crisis CML treated with imatinib is rarely accompanied by a normal karyotype; however, 6% to 17% of these patients may have some cytogenetic response (see box on Genetic Testing for Chronic Myelogenous Leukemia).

Genetic Testing for Chronic Myelogenous Leukemia

At diagnosis of CML, perform quantitative cytogenetic analysis of bone marrow aspirate, which is sine qua non because peripheral blood cells rarely contain blast cells at the time of presentation. If the bone marrow aspirate is a "dry tap," perform interphase FISH using either a BCR-ABL extrasensitive or BCR-ABL dual-fusion color probe. Triple-color BCR-ABL-ASS is particularly useful for identifying patients with deletion on either chromosome 9 or chromosome 22. To monitor patients with CML during therapy, use FISH to study blood or bone marrow to track changes in the percentage of cells with BCR-ABL fusion at 3-month intervals. Once the patient is in complete cytogenetic and FISH remission, the international recommendation is to perform real-time quantitative polymerase chain reaction and to follow the patient at 3-month intervals until molecular remission is achieved. At relapse, perform a chromosome study to assess the karyotype of the malignant clone and to determine whether a new chromosomally abnormal clone has developed or a new subclone in the Philadelphia chromosome (Ph)–positive clone.

High-resolution cytogenomic studies have demonstrated that in contrast to the chronic phase (which is characterized only by genomic imbalances in or around BCR and ABL1, specifically deletions), during the blast phase, many additional genomic imbalances occur. Using aCGH, 44 patients in chronic phase of CML (11 in myeloid and 1 in lymphoid blast crisis) were investigated, and a spectrum of recurrent genomic imbalances were associated with disease progression, including losses at 1p36, 5q21, 9p21, and 9q34 and gains at 1q, 8q24, 9q34, 16p, and 22q11. Moreover, analysis of 78 CML patients in lymphoid blast crisis found a unique signature of genomic deletions within the immunoglobulin heavy-chain and T-cell receptor genes, indicating that their presence is essential for the development of a malignant clone with the lymphoid phenotype. The most common mutations in myeloid blast phase occur at tumor suppressor gene TP53 (≈25% of cases) and runt-related transcription factor gene (RUNX1) in about 40% of cases. In lymphoid blast crisis, 50% of patients have mutation in cycline-dependent kinase inhibitor CDKN2A. Recently, mutations in genes frequently found in Ph-negative MPNs such as CBL, TET2, ASXL11, and IDH1/2 were also identified in patients in accelerated/blast phase. Moreover, deletions of RB1, gain of function mutations in GATA-2 and RAS are just some of the spectrum of cytogenomic changes characterizing progression of CML. The current thinking is that progression of CML is the result of increased genomic instability combined with defective or insufficient ability to repair DNA.

Ph-Negative Chronic Myeloproliferative Neoplasms

Ph-negative MPNs are disorders arising in a single clone of multipotent precursor cells in which one or all myeloid lineages are abnormally amplified. Classic and more frequently encountered Ph-negative MPDs include polycythemia vera (PV), primary myelofibrosis (PMF), and essential thrombocytopenia (ET). Their cytogenetic profiles are included in Chapters 67, 68 and 69

Less frequently encountered are neutrophilic leukemia, hypereosinophilic syndrome/chronic eosinophilic leukemia, systemic mast cell proliferations, atypical CML, and unclassifiable myeloproliferative neoplasms. Rare recurrent balanced abnormalities in

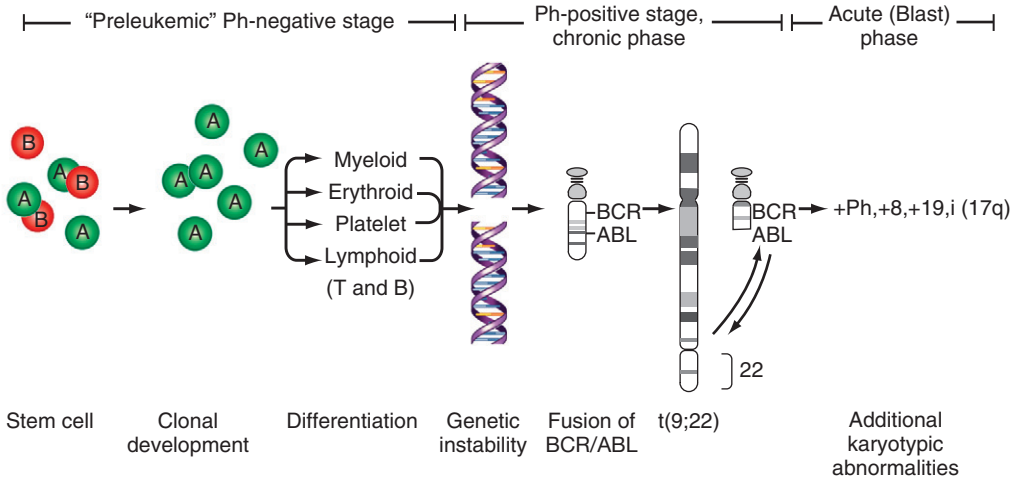

Figure 54-16 HYPOTHETICAL MODEL OF MULTISTEP PATHOGENESIS OF PH-POSITIVE CHRONIC MYELOGENOUS LEUKEMIA. The first detectable event is a clonal proliferation of cells that are capable of differentiating to all hematopoietic lineages. These cells are genetically unstable and give rise to BCR-ABL fusion and the Ph chromosome. The blast crisis is characterized by nonrandom abnormalities occurring in a genetically unstable Ph-positive clone. At least six events can be delineated. *(Courtesy Dr. W Raskind, University of Washington, Seattle.)*

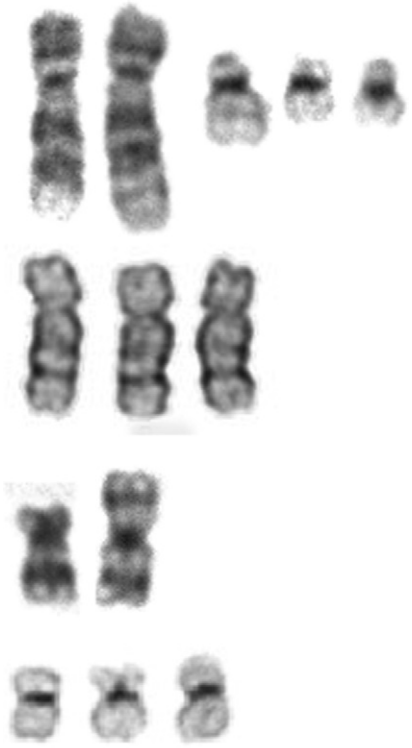

Figure 54-17 THE FOUR MOST FREQUENT ABNORMALITIES ASSOCIATED WITH THE BLAST CRISIS OF CHRONIC MYELOGENOUS LEUKEMIA. Duplication of the Ph chromosome *(top row)* is identified in ≈30% of patients, trisomy 8 *(second row)* is found in 30%, isochromosome of the long arms of chromosome 17 *(third row)* is found in 20% and gain of chromosome 19 *(fourth row)* is seen in approximately 12% patients with blast crisis of chronic myelogenous leukemia.

atypical Ph-negative MPN generally involve the PDGFRB gene found at 5q33, FGFR1 gene on 8p11 (these disorders are referred to as *myeloproliferative syndrome* or *stem cell leukemia syndrome*), and PDGFRA gene on 4q12. The best described are t(5;12)(q33;p13), resulting in ETV6-PDGFRB fusion protein, and t(8;13)(p11;q12), resulting in the ZNF198-FGFR1 fusion gene. These disorders are also known as *8p11 myeloproliferative syndrome* (EMS) or *stem cell leukemia/lymphoma* and were recently recognized and classified by WHO as belonging to the group of myeloid neoplasms associated with eosinophilia and increased incidence (≈30%) of T-cell lymphoma, suggesting that the target cell of transformation is a multipotent progenitor cell (Table 54-3).

The most frequent recurrent abnormality is the cryptic deletion on 4q12 as a result of FIP1L1-PDGFRA fusion gene reported to occur at frequencies ranging from 3% to 56% in patients with chronic eosinophilic leukemia/hypereosinophilic syndrome (see Chapters 7 and 71). The disparity in frequencies reflects differing levels of stringency criteria in the diagnosis of disorders with hypereosinophilia as well as different methodology used for detection of FIP1L1-PDGFRA fusion. The most recent investigation of 376 patients with persistent unexplained hypereosinophilia revealed an 11% incidence of FIP1L1-PDGFRA fusion detected using highly sensitive RQ-PCR. Patients with FIP1L1-PDGFRA fusion are characterized by male predominance, marrow fibrosis, increased number of mast cells, elevated serum tryptase levels, and a favorable response to low doses of imatinib. Most of these patients have a normal karyotype because a cryptic deletion of CHIC2 locus on 4q12 is only 800 kb in size, but a more sensitive FISH technology and RQ-PCR will detect the majority of cases with this deletion at diagnosis. Moreover, the most recent commercially available tricolor FISH probe will detect not only deletion 4q12 as a result of FIP1L1-PDGFRA but also a rare BCR-PDGFRA fusion resulting from the t(4;22)(q12;q11.2) rearrangement (Fig. 54-19). Serial monitoring with RQ-PCR demonstrates exquisite sensitivity of FIP1L1-PDGFRA–positive patients to low-dose imatinib treatment.

Although translocations involving PDGFRB at 5q32 region were identified with 22 different fusion partners, they are indeed very rare, and any patient with a 5q31-q33 chromosomal abnormality with or without eosinophilia should be investigated by FISH testing for PDGFRB rearrangements. At the molecular level, EMS is characterized by various translocations fusing at least 11 different 5′ partner genes to the 3′ part of the FGFR1 gene (8p11) that encodes the tyrosine kinase domain. They include LRRFIP1 (2q37), FGFR10P (6q27), TRIM24 (7q34), CUX1 (7q22), CEP110 (9q33), Nup98 (11p15), FGFR1OP2 (12p11), CPSF6 (12q15), ZMYM2 (13q12), MYO18A (17q11), HERVK (19q13), and BCR (22q11). The most frequent translocation is t(8;13), and cases with the submicroscopic deletion of the 5′ part of the FGFR1 gene were also reported, similar to the formation of t(9;22) with deleted sequences from der(9q) and/or 22q identified in CML.

Once the PDGFRA, PDGFRB, and FGFR1 rearrangements are excluded, the only other recurrent secondary abnormalities

Modified from De Keersmaecker K, Cools J: Chronic myeloproliferative disorders: A tyrosine kinase tale. *Leukemia* 20:200, 2006.
AL, Acute leukemia; *ALL*, acute lymphoblastic leukemia; *AML*, acute myelogenous leukemia; *CEL*, chronic myeloproliferative disorder; *CML*, chronic myelogenous leukemia; *CMML*, chronic myelomonocytic leukemia; *CMPD*, chronic eosinophilic leukemia; *ET*, essential thrombocytopenia; *MDS*, myelodysplastic syndrome; *MF*, myelofibrosis; *MPD*, myeloproliferative disorder; *T-ALL*, T-cell acute lymphoblastic leukemia.

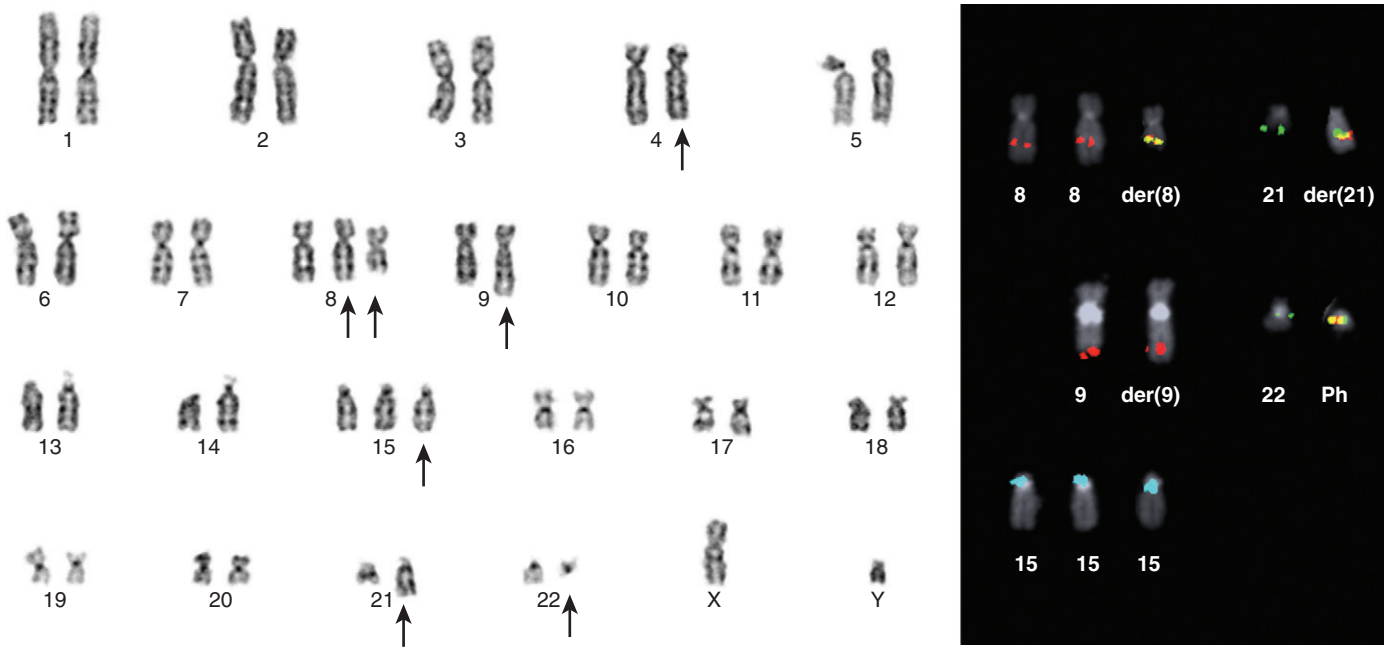

Figure 54-18 A karyotype *(left)* from a patient with chronic myelogenous leukemia who failed three tyrosine kinase inhibitors treatment and progressed into blast crisis showing 46,XY, del(4)(q31q33),t(8;21)(q22;q22),+8,t(9;22)(q34;q11.2),+15. Metaphase FISH studies *(right panel)* confirmed that in the BCR-ABL1 fusion–positive cells (*middle row, yellow* co-localization), the patient had RUN1-RUNXT1 fusion as a result of t(8;21) [*yellow* signals on der(8) and der(21)] and a gain of chromosome 8 *(top row)* as well as trisomy 15 *(bottom row)* as shown using centromeric FISH probe specific for chromosome 15 *(aqua)*.

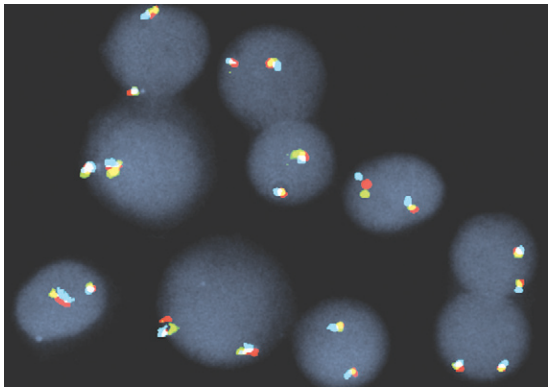

Figure 54-19 BONE MARROW INTERPHASE NUCLEI AFTER FISH STUDIES USING TRICOLOR PROBE FOR CHROMOSOME 4, BAND REGION q12. The *green* color covers an approximately 750-kb region centromeric from FIP1L1. The *red* probe is telomeric of the FIP1L1 gene. The *aqua* color probe begins between exons 15 and 16 of the PDGFRA gene and extends toward the 4q telomere. In normal nuclei, as shown here, the probe appears as two tricolor fusions because of close proximity of probes in interphase DNA. Patients with hypereosinophilic syndrome (HES) have fusion of FIP1L1 and PDGFRA genes by interstitial deletion and produce one signal with *green-aqua* fusion and a missing orange signal. If the translocation involves the PDGFRA gene with loci on other chromosomes, the expected signal pattern is one *orange–green* fusion and one separate aqua signal.

include trisomy 8 and trisomy 21. Once the patient transforms to acute leukemia, various other abnormalities have been reported. Conventional and molecular cytogenetic findings in atypical Ph-negative MPNs, as well as the presence of the JAK2 V617VF mutation in typical Ph-negative MPNs, provide support that abnormalities in tyrosine kinase genes are central to the molecular pathogenesis of these disorders (see box on Genetic Testing for Ph-Negative Myeloproliferative Neoplasms).

Genetic Testing for Ph-Negative Myeloproliferative Neoplasms

At diagnosis, perform JAK2V617F real-time alleles-specific polymerase chain reaction, as well as cytogenetic analysis of marrow cells. Unstimulated peripheral blood can be used instead of marrow aspirate for patients with primary myelofibrosis. Perform FISH studies with BCR-ABL1 for patients with essential thrombocythemia. FISH studies can be performed when cytogenetics is uninformative for detection of most frequent abnormalities: +8, +9, +9p, del(13)(q14), and del(20)(q11q13). The panel of five probes include CEP9, P21 at 9p21, D8Z2 as a centromeric probe for chromosome 8, RB1 for deletion 13q, and D20S108 for deletion of 20q12. At diagnosis and to monitor patients with hypereosinophilic syndrome, perform FISH using triple-color FIP1L1 probe. For 5q32 rearrangements perform FISH with PDGFRB FISH probe.

MYELODYSPLASTIC SYNDROMES

The MDSs (see Chapter 59) are a clinically heterogeneous group of hematologic neoplasms with differing biology and clinical manifestations. They have in common a clonal origin, dysplastic cellular morphology, abnormalities of cellular maturation, increased propensity to develop acute leukemia (20%-40%), and multistep pathogenesis. Cytogenetic studies are important for patients with these disorders because the results can provide both diagnostic and prognostic information. A chromosomally abnormal clone can be detected in 40% to 60% of patients with de novo MDS and in approximately 90% of patients with therapy-related MDS. There appears to be a correlation between the frequency of chromosomal abnormalities and the severity of disease. Approximately 35% of patients with less aggressive MDS, such as refractory anemia and refractory anemia with ring sideroblasts, have clonal chromosomal rearrangements, whereas approximately 60% to 70% of patients with refractory anemia with excess blasts in transformation have such chromosomal abnormalities. A single or complex chromosomal abnormality may be present

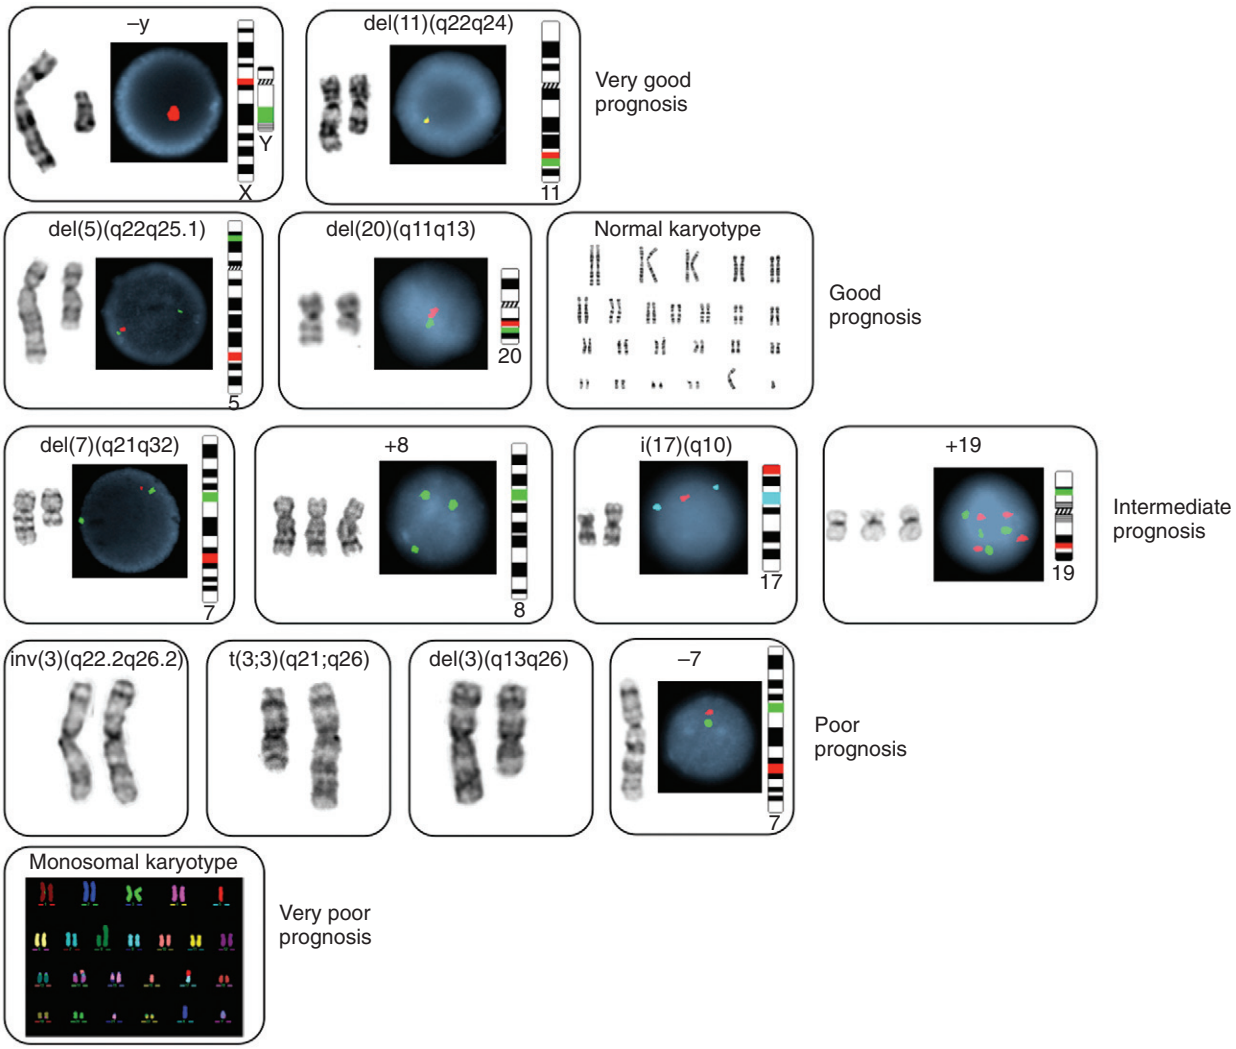

Figure 54-20 PROGNOSTIC SIGNIFICANCE OF THE RECURRENT CHROMOSOMAL ABNORMALITIES IN MYELODYSPLASTIC SYNDROME, ACCORDING TO THE NEW COMPREHENSIVE CYTOGENETIC SCORING SYSTEM.

initially, and evolutionary change may occur during the course of the disease. Even at diagnosis of MDS, complex genomic lesions involving five or more different chromosomes are not unusual. Despite heterogeneity of chromosomal defects (gain, loss, deletion, amplification, rare balanced translocations, transcriptional silencing via methylation or point mutation), the unifying concept of genetic instability in MDS is hemizygosity of specific genes or chromosomal regions. The most common chromosome anomalies in MDS involve gain of 1q, del(5q)/−5, del(7q)/−7, trisomy 8, del(11)(q23), del(12p), +13/del(13q), t(11q23), del(12p), del(17p), del(20)(q11q13), +21, and idic(X)(q13) (Figs. 54-20 and 54-21).

The clinical relevance and the power of conventional cytogenetics in MDS were recognized by the WHO classification for hematologic malignancies, which accepted a strong association between del(5)(q13q33) and 5q− syndrome, and idic(X)(q13) and refractory anemia with ring sideroblasts. The 5q− syndrome is a unique subtype of low-risk MDS with a favorable prognosis, lack of other cytogenetic abnormalities, low rate of leukemic transformation, and more common occurrence in older adult females (Fig. 54-20, *second row*).

Among patients who do not have 5q− syndrome (with or without other chromosome abnormalities), interstitial deletions of the long arms of chromosome 5 occur in 10% to 15% and are among the most frequent chromosomal abnormalities in MDS (see Fig. 54-20, *second row*). The finding of del(5q) in $CD34^{+}CD38^{-}$ cell indicates its occurrence in a stem cell capable of differentiating into myeloid and lymphoid cell lineages and represents an early event in the pathogenesis of MDS. Data on 1432 patients with del(5q) show a significant amount of heterogeneity in breakpoints. FISH methods delineated the commonly deleted segment, currently estimated to be 1.5 Mb in size, on 5q31.1. The clustering of genes responsible for growth and differentiation of hematopoietic cells and the recurrent nature of −5/del(5q) in MDS caused many investigators to speculate that a tumor suppressor gene(s) was located in the 5q31 or 5q22-23 band region. Despite numerous efforts for more than 20 years, mutations in genes located in the chromosomal regions affected by del(5q) have been unsuccessful, in part because no homozygous deletion has been detected and because 5q31 is a very gene-rich region. To date, the tumor suppressor gene responsible for MDS on 5q has not been identified. Because the mechanism causing the interstitial del(5q) is elusive, perhaps haploinsufficiency or inactivation due to methylation, rather than a typical tumor suppressor gene, is involved in these patients.

Patients with isolated del(5q) have a more favorable prognosis and live longer than patients with additional chromosomal abnormalities. Specifically, patients with del(5)(q13q31) have significantly longer survival than do patients with other 5q deletions, indicating that the type of 5q deletion may significantly affect prognosis and therapy. Indeed, a normal marrow karyotype is achieved in 44% of 148 patients with interstitial del(5q) treated with lenalidomide. The sensitivity of del(5q) to lenalidomide remains to be elucidated.

In de novo MDS, isolated monosomy 7 or 7q deletion (Fig. 54-22; see also Fig. 54-20, *third row*) occurs with a frequency of 20%.

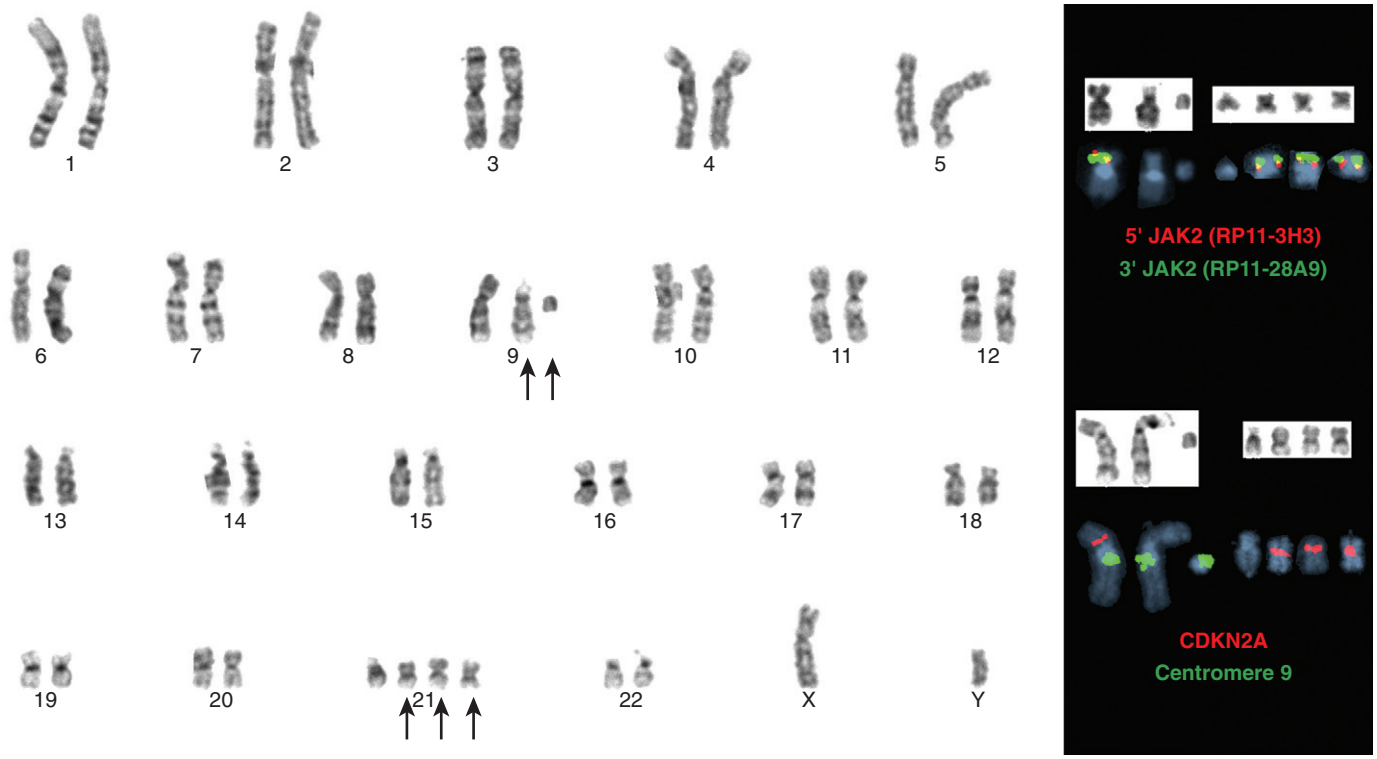

Figure 54-21 A bone marrow karyotype *(left panel)* from a patient with MDS showing 49,XY,add(9)(p12),+der(9)del(9)(p12p24)del(9)(q12q34)der(21)t(9;21)p21p24;p11),+der(21)t(9;21)(p21p24;p11)x2. FISH testing with JAK2 *(top part)* and CDKN2 and centromere 9 *(bottom panel)* revealed 70% of cells to have a deletion of 9p, including CDKN2 and 4 copies of unrearranged JAK2, suggesting that in some patients with MDS the underling mechanism may be a gain of JAK2.

Frequently, chromosome 7 abnormalities occur with other chromosomal abnormalities, most commonly rearrangements of 3q or del(12p) (see Fig. 54-20, *third* and *fourth row*). Monosomy 7 is present in all MDS subtypes and is seen predominantly in males with clinical characteristics similar to those of juvenile CMML. In pediatric patients with constitutional disorders associated with a predisposition to development of myeloid leukemia, such as individuals with Fanconi anemia, congenital neutropenia, neurofibromatosis type 1, Down syndrome, or Kostmann syndrome, –7/del(7q) may be seen as an isolated abnormality. Therefore the question as to whether these patients have genetic imprinting and preferentially lose chromosome 7 from one parent is relevant to understanding the origin of the genetic abnormality. Unequivocal evidence shows that preferential parental origin of the missing chromosome 7 is not present because approximately half of patients have loss of either the maternal or paternal homologue, excluding the genomic imprinting phenomenon as a cause for monosomy 7. Embryonic origin of partial chromosome 7 deletion in monozygotic twins with juvenile chronic myelomonocytic leukemia has been reported.

According to the IPSS, patients with chromosome 7 abnormalities present either as a single anomaly or in combination with other anomalies and are considered a high-risk karyotype group.[12] However, more recent results have indicated that patients with del(7q) as a single abnormality have a distinct clinical–pathologic profile with an overall better prognosis than seen in patients with an isolated monosomy 7. Isolated del(7q) is more frequent in patients with less advanced MDS according to the WHO classification or the International Prognostic Scoring System. Their characteristics include association with fewer blasts in bone marrow than other cytogenetic groups and significantly superior survival when compared with patients with isolated monosomy 7. The presence of additional chromosomal abnormalities in patients with del(7q) shortened the overall survival. The current recommendation is that isolated del(7q) should not be considered in the same prognostic category as monosomy 7 (see Fig. 54-20). Allele typing studies implicated three regions in patients with deletion 7q that are most frequently deleted: 7q22, 7q31.1, and 7q31.3. Cytogenetic results indicated that retention of 7q31 band may be associated with longer survival (Fig. 54-22). Consequently, there is speculation that a putative myeloid suppressor gene(s) is located in the regions that are frequently deleted. Because prototypic tumor suppressor genes have not been identified in patients with 7q deletions, an alternative explanation may be haploinsufficiency whereby the level of protein is critical, or a complex of two cooperating proteins is affected as a result of inactivation due to methylation.

Trisomy 8 (see Fig. 54-20, *third row*) is the third most frequent chromosomal abnormality in MDS. As a sole abnormality, it is found in 11% of patients with MDS and overall is found in 17%. A significantly higher incidence of trisomy 8 occurs in males than in females. Trisomy 8 is present in all age groups of patients with MDS. Although trisomy 8 is detected in hematopoietic stem cell of patients with MDS, a sizable fraction of stem cells is disomic but functionally abnormal, suggesting that trisomy 8 is a secondary event in MDS pathogenesis. These findings provide evidence for a multistep pathogenesis of MDS, whereby gain of chromosome 8 is not an early event in stepwise evolution. Although trisomy 8 carries an intermediate risk when detected at diagnosis, findings suggest that MDS patients treated with the hypomethylating agent 5-azycytidine have a significantly better survival than patients with other chromosomal abnormalities.

The first series of patients with MDS or MDS/MPN associated with trisomy 11 as a sole abnormality or as a part of noncomplex karyotype was recently reported. This rare recurrent abnormality has an overall frequency of approximately 0.3% and is associated with a significantly inferior survival in patients with IPSS intermediate-risk disease ($P = 0.0002$) but comparable to the poor-risk group ($P = 0.97$). Trisomy 11 correlates with clinical aggressiveness and represents a high-risk cytogenetic abnormality.

Deletions of 17p are seen in 3% to 4% of MDS and AML patients. These patients often display several other chromosomal

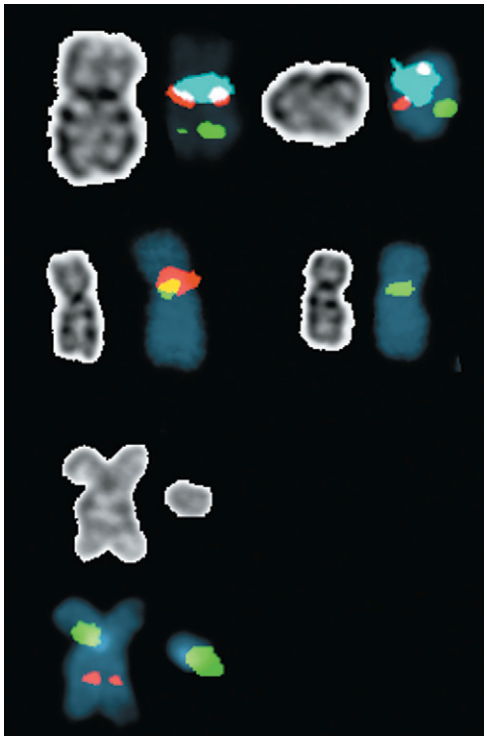

Figure 54-22 EXAMPLES OF CHROMOSOME 7 ABNORMALITIES IN MYELODYSPLASTIC SYNDROME (MDS). Ring chromosome 7 is a recurrent but rare formation. In the case shown in the *top row,* FISH study *(right)* demonstrates retention of centromeric region *(aqua),* 7p12 (*red*), and 7q31 *(green)* regions. Retention of 7q31 region is associated with longer survival. Deletion 7p *(second row)* is less frequent than del(7q) and may be missed by conventional cytogenetics. Note loss of 7p12 band in the patient with MDS by FISH study *(right),* showing only the centromeric *(green)* signal and no red signal for the EGFR gene, localized at 7p12. Loss of both the short and long arms of chromosome 7 in pediatric and adult patients with MDS often may appear as a marker chromosome *(third row),* but FISH study with dual-color probes for centromere *(green)* and 7q31 *(red)* revealed the presence of only the centromeric region on the minute chromosome *(fourth row).*

rearrangements, including monosomy 17, isochromosome 17q (see Fig. 54-20, *third row*), and unbalanced translocations between chromosome 17 and another chromosome. Approximately 30% of these deletions are related to therapy. Most patients who develop MDS or AML are treated with hydroxyurea, usually for a prolonged period of time. The extent of 17p deletion in all cases involves the p53 gene. There appears to be a close correlation between dysgranulopoiesis (e.g., pseudo–Pelger-Huet hypolobulation) and small vacuoles in neutrophils with 17p abnormalities and p53 deletion. Median survival of these patients is poor.

An isodicentric X chromosome in Xq13-idic(X) is a rare but recurrent abnormality that has been suggested to be specifically associated with refractory anemia with ringed sideroblasts. All MDS patients with idic(X)(q13) are females, most likely because formation of idic(X) would result in nullisomy for Xq13-qter in males. Median age at the time of diagnosis is 73.5 years. The outcome of idic(X)-positive cases is variable; some investigators report aggressive and rapidly fatal disease and others a relatively favorable clinical course with survival for several years despite the generally advanced age of the patients. The fact that idic(X) most often occurs as the sole cytogenetic abnormality suggests that it may in itself be sufficient for leukemogenesis. Using a high-resolution SNP array, the breakpoints on idic(X)(q13) were mapped into two distinct breakpoint clusters, at approximately 70.9 MB (five cases) and 72.1MB (seven cases) on the X chromosome. None of the 11 breakpoints occurred in a gene, strongly indicating that the idic(X)(q13) does not result in a fusion gene. Instead, the functional outcome of the abnormality is a gene dosage effect due to the concurrent gain of Xpter-q13 and loss of Xq13-qter. This region of X chromosome is enriched for repeated sequences and most likely, these repeats may facilitate the formation of idic(X). The isodicentric X chromosome was inactive in some patients and active in other patients; hence idic(X) appears to be leukemogenic regardless of X_a or X_i involvement.

Gain of 1q, usually in the form of unbalanced translocation, is a recurrent abnormality in MDS and appears to be a marker of disease progression. Specifically, the gain of 1q in the form of jumping translocations either at diagnosis or the subsequent acquisition of jumping 1q translocations appears to be associated with imminent transformation to AML in patients after an average of 9 months (Fig. 54-23). Once acquired, prognosis tended to be dependent on a copy number of 1q, indicating that gain of jumping 1q translocations was associated with both disease progression and poor prognosis. In MDS, the average time to develop jumping 1q was less than 2 years. Treatment (azacitidine, chemotherapy, or stem cell transplant) may temporarily reduce or eradicate the clone, but the responses were not durable. These findings did not provide any common pattern as to the role of the partner chromosomes in unbalanced jumping 1q translocations. However, 81% of recipient breakpoints were localized in pericentric regions whereas the remaining 19% were telomeric fusions. Decondensation of pericentromeric heterochromatin of chromosome 1 together with centromere and repeat DNA sequences interspersed with histones and acetylated sequences may favor illegitimate recombinations leading to jumping 1q translocations. Moreover, exposure to azacitidine has been shown to be associated with alterations of pericentromeric heterochromatin of chromosome 1, as well as an increase in Alu DNA repeats amplification. The most frequent rearrangement of chromosome 3 involves two bands on chromosome 3—band 3q21 and 3q26 simultaneously—which produces either t(3;3)(q21;q26) or inv(3)(q21q26) (see Fig. 54-20, *fourth row*). These chromosomal rearrangements are present in de novo and therapy-related MDS, as well as in AML and megakaryoblastic crisis of CML. The incidence of the 3q rearrangements is 2% to 5%. Characteristic clinical features include an elevated platelet count, marked hyperplasia with dysplasia of megakaryocytes, and a poor prognosis with minimal or no response to chemotherapy and a short survival. In addition to similar clinicopathologic features, patients with 3q21q26 chromosomal abnormalities share molecular heterogeneity in both the breakpoints and the expression pattern of the genes near these breakpoints. The chromosomal breakpoints, defined by FISH, in 3q26 are scattered over several hundred kilobases in either the 5′ or the 3′ region of the EVI1 gene, whereas the breakpoints in the 3q21 region are restricted to two smaller different genomic clusters approximately 100 kb downstream of the RPN1 gene. EVI1 overexpression is observed in the majority of patients, but some patients with the 3q21q26 rearrangement do not have detectable EVI1 expression, and at least 9% of AML patients without 3q26 abnormalities overexpress EVI1. Therefore the poor prognosis in these patients may be independent of EVI1 expression, despite the fact that extensive 3q26 breakpoint FISH mapping on both metaphases and interphase nuclei suggests EVI1 involvement in numerous novel sporadic and recurrent 3q26 rearrangements. A fusion transcript of RPN1-EVI1 is rarely observed in patients with 3q21q26 rearrangements. However, evidence suggests that overexpression of GATA2 at 3q21 may be responsible for erythroid and megakaryocytic dysplasia observed in patients with 3q21q26 chromosomal abnormalities.

A monosomal karyotype (MK), a new cytogenetic category, is defined as a karyotype showing two or more distinct autosomal chromosome monosomies or one single autosomal monosomy (excluding isolated loss of X or Y) in the presence of a structural abnormality (see Fig. 54-20, *bottom row*). Initial reports indicated that the MK in MDS, with or without monosomy for chromosomes 5 and 7, was prognostically worse than other complex karyotype, although later reports could not confirm these results. The reason may be that treatment with azacitidine may have reduced the negative impact of MK in high-risk patients with MDS.

Figure 54-23 JUMPING 1q TRANSLOCATIONS FROM TWO PATIENTS WITH MPN AND ONE PATIENT WITH MDS. The *top row* shows five different clones created as a result of a gain of 1q translocated to chromosomes 4, 14, 19, 21, and 22. The *middle row* shows four different cell populations identified in a patient with MDS, all characterized by trisomy 1q translocated to X chromosome as well as to chromosomes 13, 19 and 21. The *bottom row* shows a follow up bone marrow from a patient with MPN that at diagnosis had i(9)(p10) and with progression of disease acquired jumping 1q to Y chromosome, to chromosome 6 and 7, as well as an insertion within the long arms of 1, resulting in duplication of 1q.

The clinical significance of loss of the Y chromosome, observed in 10% of MDS patients and approximately 7% of older adult males without MDS, is undefined, although older adult males with MDS and loss of Y chromosome who achieve complete hematologic remission show the Y chromosome in their marrow cells.

The prognosis of patients with MDS is very heterogeneous. In 1997, based on the cytogenetic abnormalities identified in 816 patients with MDS, as well as percentage of blasts and number of cytopenia, an International Prognostic Scoring System (IPSS) was proposed.[12] According to the IPSS, 86% of all cytogenetic findings can be explicitly classified according to their prognostic impact. The system is highly reproducible and very simple to use, but it has certain limitations. Moreover, the remaining 14% of patients with cytogenetic abnormalities have unknown prognostic significance. This limitation underscores two major cytogenetic classification problems in MDS: the profound heterogeneity of acquired cytogenetic aberrations in MDS and the associated challenge of designing a comprehensive cytogenetic scoring system that predicts the prognostic impact of rare abnormalities. A new and comprehensive cytogenetic scoring system based on an international data collection of 2902 patients was recently proposed (see Fig. 54-20). Patients included were from the German-Austrian MDS Study Group ($n = 1193$), the International MDS Risk Analysis Workshop ($n = 816$), the Spanish Hematological Cytogenetics Working Group ($n = 849$), and the International Working Group on MDS Cytogenetics ($n = 44$) databases.[13] In total, 19 cytogenetic categories were defined, providing clear prognostic classification in 91% of all patients. All abnormalities were arranged according to overall survival and development of AML in order to classify their prognostic impact. The abnormalities were classified into five prognostic subgroups: very good ($n = 81$) included del(11q) and loss of Y chromosome (median OS, 61 months); good ($n = 1809$) included normal karyotype, del(5q),del(12p), and del(20q) (all as single anomaly) and double abnormalities including del(5q) (median OS 49 months); intermediate ($n = 529$) included del(7q), +8, i(17q)(q10), +19, +21, any other single abnormality, independent clones, and double abnormalities not harboring del(5q) or −7/del(7q) (median OS 26 months); poor ($n = 148$) included inv(3)/t(3q)/del(3q), −7, and double abnormalities including −7/del(7q) and complex (three abnormalities; OS of 16 months); and very poor ($n = 197$) included complex with more than three abnormalities (OS of 6 months) (see Fig. 54-20). Both internal and external validation of the new scoring system was performed, and results confirmed that the score efficiently predicts outcome in patients with MDS. This new scoring system proposed should be viewed as a dynamic model, open to further refinement as the knowledge in karyotypic abnormalities of MDS continues to evolve.

Genetic Testing for Myelodysplastic Syndrome Disorder

The best genetic test at diagnosis is conventional cytogenetic studies. FISH is useful for some clinical situations, such as marrow samples lacking analyzable metaphases, or to follow the percentage of abnormal cells with known cytogenetic anomalies for patients undergoing treatment (see Fig. 54-20 for selection of appropriate fluorescence in situ hybridization probes).

Cytogenetic and FISH studies have relatively similar sensitivities in detecting an abnormal clone among patients with MDS. A FISH test for MDS should use probes to detect numerical and structural anomalies of chromosome regions 1q, 3q, 5q, 7q, 7q31, 8, 11q, 12p, 13q, 17p, 20q, and 21. Occasional patients with normal chromosomes show an occult neoplastic clone by FISH. On the other hand, in conventional cytogenetic studies, some patients exhibit a neoplastic clone that is not detected by FISH (see box on Genetic Testing for Myelodysplastic Syndrome and Fig. 54-20).

In contrast to the wealth of genetic profiling data for most leukemias, MDS has not been analyzed extensively, probably as a result of MDS heterogeneity both on the clinical and genomic level.

Familial MDS is very rare. However, a recent description of four families with telomerase mutations, both in the RNA component (TERC) and in the reverse transcriptase (TERT), has raised the awareness of the pathologic role of telomerase mutations in development of MDS/AML. The telomerase activity of the mutations identified in the 4 of 20 families with familial MDS/AML was between 0% and 11% of the wild-type levels. Patients with telomerase mutations have short telomeres. The recognition of familial MDS/AML arising from constitutional mutations in TERC or TERT is important because these mutations probably act as initiating mutations. Moreover, next generations present with increasingly more severe phenotypes at an earlier age so that each successive generation inherits progressively shorter telomeres, which increasingly promote genomic instability and may lead to earlier development of marrow failure, MDS, or AML. The recommendation is that inherited lesions always be considered in a young patient presenting with MDS, even in the absence of preexisting morphologic or hematologic abnormalities. Another constitutional abnormality that appears to predispose to MDS/AML is a deletion of band region q22.1-q22.2 of chromosome 21 with a complex phenotype (dysmorphic features, organ malformations, growth delay, and mental retardation), germline RUNX1 deletion, and congenital thrombocytopenia. Three of nine reported patients subsequently developed MDS/AML.

ACUTE MYELOID LEUKEMIA

AML refers to a group of heterogeneous diseases with respect to clonality, chromosomal aberrations, and response to treatment (see Chapters 57 and 58). AML develops clonally and has a multistep pathogenesis. In adults, at the time of diagnosis all hematopoietic cell lineages are clonal. In children younger than 16 years, erythroid cells and platelets often are not part of the leukemic clone. Observations made by the International Workshop on Chromosomes in Leukemia asserted that cytogenetics findings provide the single most important factor in AML; these observations were subsequently validated through studies conducted by the Medical Research Council (MRC), the Cancer and Leukemia Group B (CALGB), and the Southwest Oncology Group. Finally, in 2008 the WHO incorporated cytogenetic analysis of leukemic blasts along with morphology, immunologic markers, and molecular genetics into the classification system for AML. Cytogenetics is the most powerful independent prognostic factor in AML and provides the framework for risk stratification schemes that have been generally adopted to guide treatment approach. Based on karyotype status, two major groups of AML can be distinguished: (a) those with an abnormal karyotype, which accounts for approximately 52% of patients, and (b) those who demonstrate a normal karyotype by conventional cytogenetics, which accounts for 48% of AML patients.[14]

AML patients with a normal karyotype who present between the ages of 16 and 60 years carry an intermediate prognosis. However, cytogenetically normal AML is highly heterogeneous at the molecular level, both mutations and overexpression of single genes have been identified, and their complex interactions are frequently refined to provide more accurate risk stratification. Within the normal cytogenetic category, 45% to 62% of patients with AML have NPM1 mutations (localized on chromosome 5, band q35), 23% to 33% show FLT3 (localized on chromosome 13, band q12), 5% to 10% have MLL tandem duplications (localized on chromosome 11, band q23), and 8% to 15% have CEBPA mutations (localized on chromosome 19, band q13.1). The prognosis of patients with normal karyotype differs in the presence of each of these mutations (Table 54-4 and Fig. 54-24). Patients with NPM1 mutations alone have a

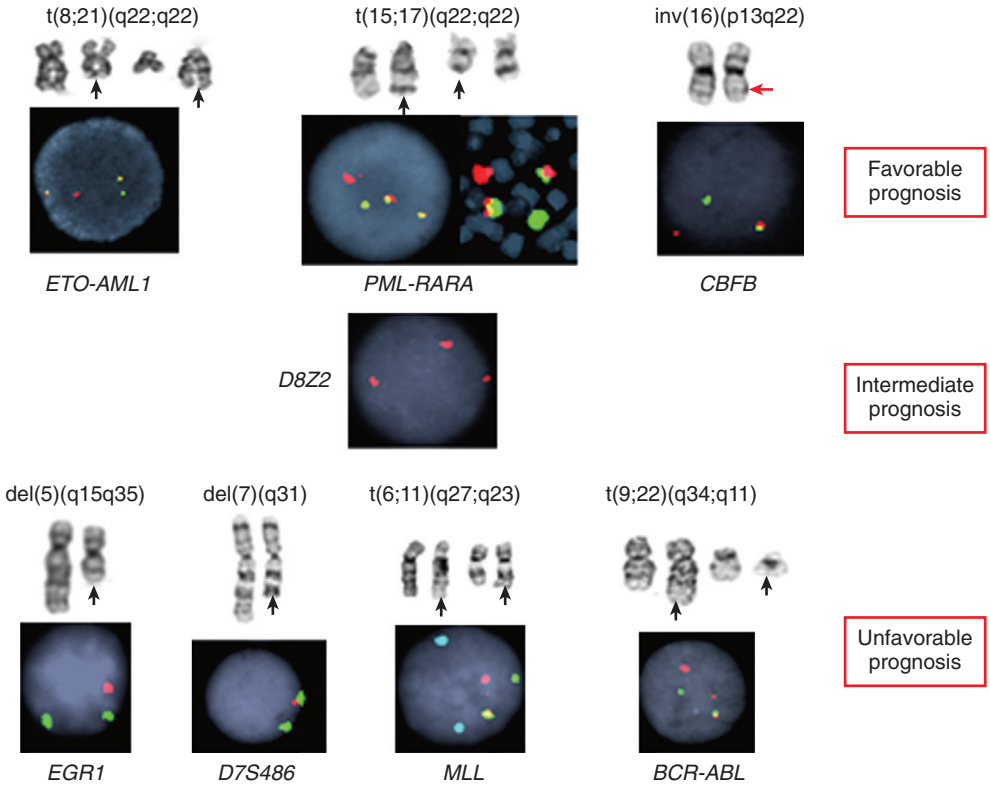

Figure 54-24 PROGNOSTIC CYTOGENETIC RISK CATEGORIES IN ACUTE MYELOID LEUKEMIA. Favorable prognosis includes t(8;21) and ETO-AML1 fusion, t(15;17) and PML-RARA fusion, and inv(16) and rearrangements of *CBFB* on 16q22. Trisomy 8 is associated with intermediate prognosis. Unfavorable cytogenetic risk categories include monosomy 5/del(5q), –7/del(7q), and translocations of 11q23 and MLL, represented here by t(6;11), and the Philadelphia chromosome.

Table 54-4 Gene Mutations in Patients With Acute Myelogenous Leukemia and Normal Karyotype

Gene	Frequency (%) of Patients With a Normal Karyotype	Prognosis
NPM1	45-62	Favorable, increased CR rates and prolonged OS in the absence of FLT3 mutation
FLT3-IDT	30	Unfavorable, specifically when the mutant to WT allelic ratio is high
FLT3-TKD	7-10	Controversial
CEBPA	15	Favorable
MLL-PTD	10	Not known
WT1	10	Not known (possibly favorable)
RAS	10-15	Not known
IDH1	15-20	Most likely unfavorable
IDH2	20	Most likely unfavorable
DNMT3A	36	Most likely unfavorable
TET2	5	Likely unfavorable

Table 54-5 Over-Expression of Single Genes in Acute Myelogenous Leukemia and Normal Karyotype

	Prognostic Implications	
Gene	Frequency (%)	Prognosis
BAALC	50-60	High expression, inferior EFS, and shorter OS
ERG	30	High expression, inferior CR rates, and decreased DFS
MN1	Variable	High expression, shorter OS
AFq1	80-90	High expression, shorter OS
EVI1	10	High expression, shorter OS
Id1	65	High expression, decreased CR rates, and shorter OS

favorable prognosis, with 60% of patients living longer than 11 years. Even in patients age 70 or older, the presence of an NPM1 mutation is an independent predictor of a more favorable outcome. More than 20 different mutations have been described in the C-terminal portion of the protein that lead to loss of tryptophan residues and generation of a nuclear export signal that acts in concert to cause delocalization of nucleophosmin (NPM) from the nuclei to the cytoplasm. In contrast, the presence of FLT3 and MLL mutations is associated with an adverse prognosis, and coexistence of FLT3 and NPM1 does not improve the prognosis. NPM1 mutation is considered to be a primary lesion in the pathogenesis of AML, being very stable over the disease course. In childhood AML with normal cytogenetics, NPM1 mutations are relatively uncommon, occurring at a frequency of 8%. Currently, a newly diagnosed patient with AML and a normal karyotype should be checked for more common mutations such as FLT3, NPM1, CEBPA, RUNX1, MLL-PTD, or EVI1, which may have prognostic and possibly therapeutic implications, whereas patients with overexpression of other single genes should stay, until more data are collected, in a research setting of clinical trials (Table 54-5).

Among patients with an abnormal karyotype, 25% have balanced translocations [t(8;21),t(15;17),inv(16)], and 27% showed unbalanced abnormalities [−5/del(5q), −7/del(7q), or complex karyotype].

The pretreatment karyotype in AML constitutes an independently prognostic determinant for attainment of complete remission and

Table 54-6 Cytogenetic/Molecular Risk Categories in Acute Myelogenous Leukemia

Category	Abnormality
Favorable (45%)	t(8;21)/RUNX1-RUNXT1 (8%),* t(15;17)/PML-RARA (11%), inv(16)/CBFB-MYH11 (5%) with or without other abnormalities Normal karyotype with NPM1+, FLT3-ITD Neg/WT1 wt (18%)
Intermediate (17%)	+6, +8, +21, +22, Y, del(9q) Normal karyotype with CEBPA+ biallelic/FLIT3-IDT Neg (3%)
Unfavorable (38%)	–5/del(5q), –7/del(7q), abn(3q) t(9;22),t(6;9), abn(11q), 20q, or 21q, abn(17p), complex karyotype, RUNX1 mut, MLL-PTD, FLT3-IDT/NPM1 wt

*Without deletion 9q or complex karyotype.

risk for relapse and survival.[15] Four broad cytogenetic risk categories of AML are applied in clinical practice: favorable, intermediate, unfavorable, and unknown (see Fig. 54-24 and Table 54-5). It is important to perform appropriate cytogenetic and FISH studies to establish the correct cytogenetic risk category. Tables 54-6 and 54-7 list 166 of approximately 200 recurrent chromosomal translocations in leukemia, including AML (Fig. 54-25; see also Fig. 54-24). Because of their specific association with distinct subtypes of leukemia, some AML-specific translocations have been incorporated into the WHO classification as the criteria for subclassification of AML, including t(8;21), t(15;17), inv(16), and 11q23 rearrangements, regardless of the morphology or percentage of blast cells.

Two specific cytogenetic types of AML—t(8;21)(q22;q22) and inv(16)(p13q22) or t(16;16)(p13;q22) (see Fig. 54-24)—are called core-binding factor (CBF) AML and are usually grouped and reported together in clinical studies because of similarities between their molecular and prognostic features. However, the morphologic features of these two AML subtypes are very different. Patients with t(8;21) exhibit large myeloid blasts with abundant basophilic cytoplasm, numerous azurophilic granules, and occasional Auer rods. Patients with 16q22 abnormalities show a variable number of eosinophils, usually in increased numbers, in all stages of maturation. The immature eosinophilic granules are larger than normal and may contain purple-violet cytoplasmic granules. The t(8;21) subtype may be present alone, although 30% to 35% of patients also display loss of Y chromosomes in males and loss of X chromosome in females (see Fig. 54-24, *top left*). Another 20% of patients with t(8;21) show deletion of 9q12-23, including a commonly deleted segment that spans 7 to 8 Mb. Trisomies for chromosomes 4 and 8 together with t(8;21) are observed in 6% to 10% of patients. Virtually all patients with t(8;21) achieve complete remission. Additional cytogenetic abnormalities, irrespective of their nature or complexity, do not have a deleterious effect on remission, relative risk, and overall survival. The t(8;21) interrupts two genes—RUNX1 (AML1, CBFA2) on chromosome 21, band q22, in intron 5, and RUNX1T1 (ETO [eight, twenty-one gene], also called MTG8-myeloid translocated gene) on chromosome 8, band q22—and joins them to form a new chimeric gene on the abnormal der(8) chromosome. RUNX1 is a gene on chromosome 21, also known as CBFA2/AML1 because it encodes for a DNA-binding component of CBF and binds DNA through a specific sequence called the *runt domain*. The AML1 gene locus on chromosome 21 spans 120 kb; the RUNX1T1 (ETO) gene on chromosome 8 is distributed over 87 kb.

The RUNX1 (AML1) gene has been identified in more than 39 chromosomal translocations in leukemia and plays a critical role during hematopoiesis. The fusion gene is located on the partner chromosome in the majority of AML1 translocations. Its disruption

Table 54-7 Recurring Chromosome Translocations in Leukemia and the Genes Involved

Translocations	Genes Involved	Associated Diseases
CBF (AML1/CBFA AND CBFB)- AND TEL/ETV6-ASSOCIATED TRANSLOCATIONS/INVERSIONS

is associated with the development of myeloid and lymphoid leukemias. Therefore AML1 is viewed as a master regulatory switch that controls development of a definitive hematopoietic lineage. Moreover, the RUNX1T1 (AML1) transcription factor is critical for proliferation and differentiation of hematopoietic stem cells. Haploinsufficiency of AML1 has been linked to a propensity to develop AML, and biallelic nonsense mutations in the AML1 gene have been identified in most immature AMLs of the FAB M0 subtype. The RUNX1 (ETO) protein belongs to the ETO family of proteins involved in protein–protein interactions but not in protein-DNA interactions.

In the hybrid RUNX1-RUNXT1 (AML1-ETO) protein, the C-terminus of RUNX1 (AML1) is replaced by the entire ETO protein. A main functional characteristic of RUNX1-RUNX1T1 (AML1-ETO) chimeric protein is its ability to bind DNA containing AML1 binding sites and thereby exert a dominant negative inhibition of the

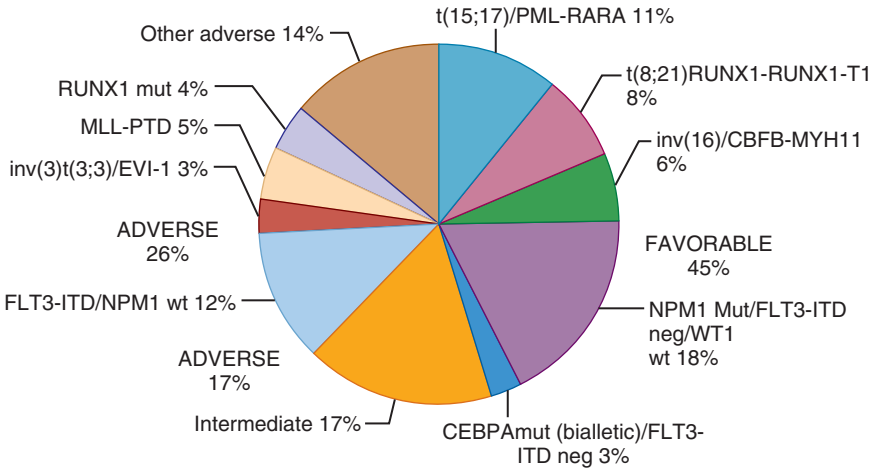

Figure 54-25 INTEGRATION OF CYTOGENETIC ABNORMALITIES AND MOLECULAR MARKERS TO REFINE RISK GROUPS IN AML. *(Reprinted from Smith ML, Hills RK, Grimwade D: Independent prognostic variables in acute myeloid leukemia.* Blood Rev *25:39, 2001; with permission.)*

endogenous AML1 protein. The exact function of the RUNX1-RUNX1T1 (AML1-ETO) fusion protein in the onset and progression of AML is not fully understood; however, accumulating evidence indicates that even a point mutation in the AML1 protein, responsible for assembling and organizing the machinery for hematopoietic gene expression at multiple sites in target genes, results in a block of differentiation of myeloid progenitors to granulocytes. AML1/RUNX1 mutations are present in 46% of AML patients with the M0 subtype and in 80% of AML patients with trisomy 13. As mentioned earlier, FLT3 is localized on chromosome 13, and quantitation of FLT3 transcript levels is associated with a fivefold increase in patients with AML1/RUNX1 mutations and trisomy 13 compared with patients without trisomy 13. The exact cooperation of FLT3 and AML1/RUNX1 in leukemogenesis remains unknown. Multiple copies of ETO-AML1 fusion have been demonstrated (Fig. 54-26). The t(8;21) is the most common translocation in pediatric AML patients (10%-20%). Prenatal origin of t(8;21) was established for approximately 50% of pediatric patients using Guthrie card analysis.

Although 60% to 70% patients with t(8;21) achieve complete and long-term remission, monitoring minimal residual disease is important in identifying patients with a high risk for relapse. Multiparametric approaches, such as flow cytometry, RQ-PCR, and interphase FISH, are complementary methods and provide useful clinical information on relapse kinetics, although each has limitations. It should be noted that 18% of healthy individuals have RUN1-RUNXT1 transcript by PCR and the fusion transcript was also detected in 40% of cord blood samples, suggesting that RUNX1-RUNXT1 by itself may not have overt clinical manifestations.

In patients with 16q22 abnormalities such as inv(16)(p13;q22) and t(16;16)(p13;q22) (Fig. 54-27), the marrow contains an increased percentage of abnormal eosinophils. Combined May-Grünwald-Giemsa staining with FISH demonstrates that the abnormal eosinophils have inv(16) and are therefore part of the leukemic clone. Trisomy 22 is a frequent accompanying abnormality. Both inv(16) (see Fig. 54-24, *top right*) and t(16;16) (see Fig. 54-27) are abnormalities of the core-binding factor β (CBFβ) gene at 16q22 and are associated with M4Eo subtype, according to the French-American-British classification of AML. Both rearrangements result in fusion of CBFβ and MYH11 (myosin heavy-chain) gene on 16p13. The exact role of the resulting hybrid protein, CBFβ-SMMHC (smooth muscle myosin heavy chain), is unknown, but it probably is involved in impaired hematopoietic differentiation. Both t(8;21) and inv(16) rearrangements result in abnormal repression of CBF target genes. CBF is a heterodimeric transcription factor complex that consists of three distinct DNA-binding CBFα subunits (RUNX1, RUNX2, and RUNX3) and a common CBFβ subunit, which is non–DNA-binding. The binding affinity of RUNX1 subunit to the DNA promoter sequences is significantly increased by association with CBFβ, which does not directly interact with DNA and protects RUNX1 subunit from proteolysis. The breakpoints in t(8;21) affect RUNX1 exon 5

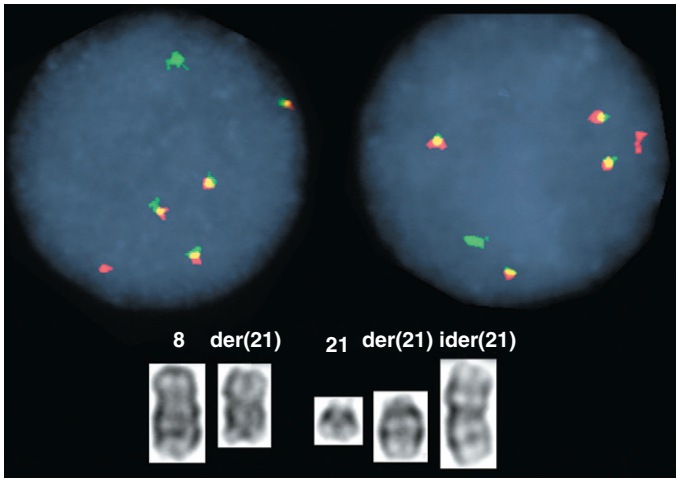

Figure 54-26 Four copies of ETO-AML1 (RUNX) fusion *(yellow)* shown in two interphase cells *(top)* from a patient with acute myeloid leukemia and t(8;21) *(bottom)* karyotype, as well as ider(21). This formation is equivalent to the Ph duplication in the blast crisis of chronic myelogenous leukemia because of duplication of der(21) without accompanying t(8;21).

and RUNX1T1 exon 2. The breakpoint in MYH11 involved in aberrations inv(16) and t(16;16) is variable and gives rise to at least 10 different fusion variants. In contrast, the breakpoints in CBFB at 16q22 are in intron 5. Both translocations are associated with a favorable prognosis, but they exhibit different leukemic cell morphology.

Approximately 4% of patients with CBFB-MYH11 rearrangement do not have a cytogenetically detectable inv(16) or t(16;16). Cytogenetic detection of inv(16) may be difficult, and interphase FISH with a dual-color CBFβ probe at diagnosis is a crucial genetic test. Detection of CBFβ-MYH11 fusion by either RT-PCR or FISH is found in patients without eosinophilia; therefore CBFβ testing should be included in the standard testing panel for genomic rearrangement in AML. The presence of additional abnormalities, such as trisomy 8, does not adversely affect clinical outcome. The CBFβ-MYH11 chimeric fusion is detected in utero with approximately 10 years of postnatal latency before development of childhood leukemia. This observation suggests that formation of CBFβ-MYH11 is not sufficient to cause leukemia and that subsequent genetic events must occur before clinically recognizable leukemia is identified.

Most clinical studies have found that the CBF AML group is associated with a better complete remission rate, overall survival, and lower relapse risk than patients with cytogenetically normal AML. However, a recent retrospective analysis of 113 patients with CBF AML demonstrated that at diagnosis, patients with inv(16) karyotype are less likely to have any normal metaphases when compared with

patients showing t(8;21) karyotype. Moreover, an increasing number of cells with normal metaphases increased the risk for relapse and negatively affected survival of patients with inv(16); identifying at least one normal metaphase at diagnosis [as well as 19 with inv(16)] had a significant impact on 5-year survival (60% versus 14%, $P = 00005$). These factors, along with age, were the only independent variables associated with refractory disease and higher relapse.

Risk-adapted stratification based on the genomic makeup of each individual patient is used. Patients with CBF AML and mutations in KIT gene (exon 17) have a higher risk for relapse. KIT mutations represent not only a prognostic indicator but also a potential therapeutic target for tyrosine kinase inhibitors. RUNX1 mutations present in patients with AML, usually M0 in about 5% to 15%, are mutually exclusive when t(8;21) and inv(16) are present. As mentioned earlier, there are 39 recurrent abnormalities involving the 21q22 chromosomal site where RUNX1 is localized. Some of the more frequent rearrangements are discussed here.

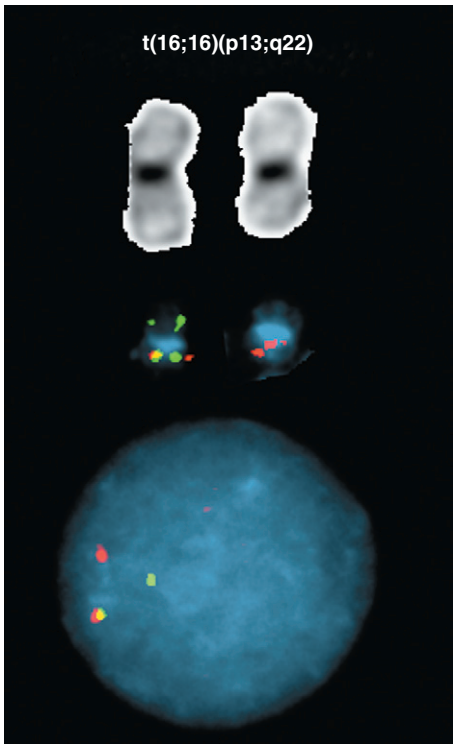

Figure 54-27 Partial G-banded karyotype from a patient with M4 acute myeloid leukemia showing t(16;16) *(top),* after FISH study using a breakapart CBFB probe (at 16q22), demonstrating that the 5′ end *(red)* of the gene remains on 16q of one chromosome 16, whereas the 3′ end *(green)* translocated to the short arms of the other chromosome 16. Separation of 5′ and 3′ ends as single signals is indicated in the bone marrow nucleus *(bottom).*

t(16;21)(q24;q22) is a rare but recurrent chromosomal abnormality associated with therapy-related AML. Studies using FISH and RT-PCR methods have demonstrated fusion of AML1 on 21q22 and MTG16 (myeloid translocation gene on chromosome 16) on chromosome 16, which produces an AML1-MTG16 fusion gene on chromosome 16. The breakpoints of both t(8;21) and t(16;21) occur within the same intron of the AML1/RUNX1 gene. AML1/RUNX1-MTG16 gene fusion results in the production of a protein that is very similar to the RUNX1/RUNX1T1 (AML1-ETO) protein in t(8;21).

(16;21)(p11;q22) is a rare chromosomal rearrangement associated with M1-M2 AML. A proportion of patients may have additional abnormalities. This translocation fuses the TLS/FUS gene on chromosome 16, band p11, to the ERG gene on chromosome 22, band q22. The ERG gene is a member of the ETS family of transcription factors and is a sequence-specific transcriptional activator. The presence of a fusion transcript is detected by RT-PCR, at the time of diagnosis, at relapse, and during remission. These observations are consistent with the impression that patients with t(16;21) have a poor prognosis and may benefit from early detection of this chimeric gene in order to determine the need for more aggressive therapy.

t(15;17)(q22;q21) involves the PML (promyelocytic leukemia) gene on chromosome 15, band q22, and RARA on chromosome 17, band q21. This abnormality constitutes the genetic basis for approximately 94% of all cases of acute promyelocytic leukemia (Fig. 54-28, *middle panels*).[16] The remaining 6% of cases include eight rare variant translocations: t(11;17)(q23;q21) (including two different genes on 11q23 MLL and ZBTB10), t(11;17)(q13;q21), t(5;17)(q35;q21), t(2;17)(p21;q21), dup(17)(q21.3-q21), t(4;17)(q12;q21), and t(X;17)(p11q21). Therefore acute promyelocytic leukemia is associated with several different genetic rearrangements fusing the RARA gene with a different partner gene in each case. Variant RARA fusion partners include PLZF (promyelocytic leukemia zinc finger) gene on 11q23, NPM gene on 5q35, NuMA (nuclear matrix-associated) gene on 11q13, STATb5 gene on 17q11, and BCOR (BCL6 corepressor) gene on Xp11. Based on these genomic rearrangements, a FISH assay, using a breakapart probe strategy with dual-color RARA, can identify two different clinical syndromes. These syndromes occur in patients who are not responsive to all-trans retinoic acid (ATRA) therapy and carry the RARA-PLZF fusion gene, as well as in patients whose promyelocytes have exquisite sensitivity to differentiate in response to ATRA treatment and have one of the other six RARA fusion rearrangements (Fig. 54-29). FISH study also identifies patients with cryptic translocations and unusual chromosomal variants (see Fig. 54-29). It is important to recognize patients who will or will not respond to ATRA so that appropriate therapy can be administered.

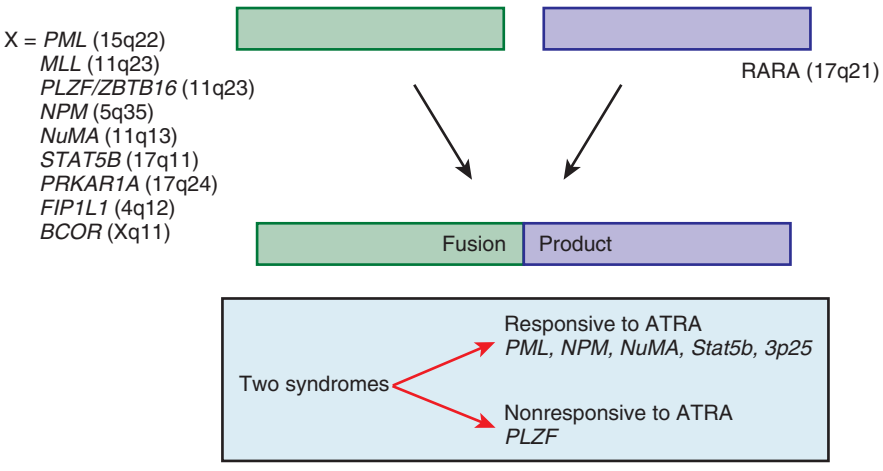

Figure 54-28 MOLECULAR CYTOGENETIC DEFECTS IN ACUTE PROMYELOCYTIC LEUKEMIA ARE RESPONSIBLE FOR DIFFERENT RESPONSE TO ALL-TRANS RETINOIC ACID DIFFERENTIATION THERAPY. Patients with t(11;17)(q23(q22) and PLZF(ZBTB16)-RARA fusion do not respond to all-trans retinoic acid differentiation therapy, whereas patients with classic t(15;17) and other four cytogenetic variants have exquisite sensitivity to differentiate in response to all-trans retinoic acid.

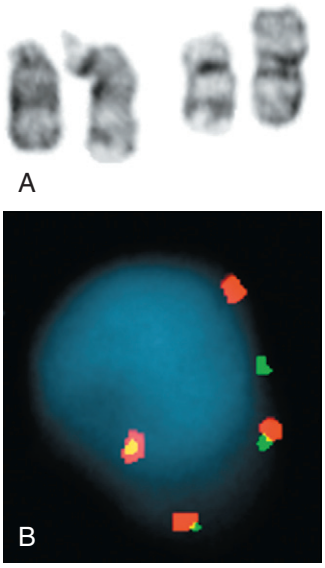

Figure 54-29 Partial karyotype from a patient with acute promyelocytic leukemia, showing ider(17)t(15;17)(q22;q21) *(top)*. The karyotype shows isochromosome for the long arms of chromosome 17 and deletion of the short arms. FISH studies revealed three copies of PML-RARA fusion in bone marrow nucleus *(bottom)*, confirming that the first event in the pathogenesis was PML-RARA fusion and the subsequent event was a structural rearrangement of isochromosome. *(From Cheng L, Zhang DY, editors:* Molecular genetic pathology, *Totowa, NJ, 2008, Humana Press, a part of Springer Science.)*

Acute promyelocytic leukemia is a disease characterized by accumulation of blasts blocked at the promyelocytic stage of granulocytic differentiation. APL accounts for only 5% to 8% of pediatric AML, and 95% of children with APL show a classic t(15;17). However, almost 35% of pediatric APL have FLT3-ITD mutations. The clinical impact of these mutations on relapse rate and overall survival is not yet clear.

Our current understanding of the molecular pathogenesis of acute promyelocytic leukemia is that PML-RARA behaves as a potent transcriptional repressor and that supraphysiologic doses of retinoic acid can overcome this repression. In the presence of retinoic acid, PML-RARA behaves as a transcriptional activator. In patients with variant PLZF-RARA, an additional corepressor complex binding site is present, and histone deacetylase inhibitors are used to restore sensitivity to retinoic acid. It appears that PML-RARA fusion-induced differentiation arrest of leukemic blasts and increased self-renewal of progenitors are two distinct features of APL and are probably driven by two different gene programs. Accurate identification of the acute promyelocytic leukemia-associated genomic lesion at diagnosis is important because acute promyelocytic leukemia is a medical emergency that frequently presents with abrupt onset, high risk for early death (10% to 20%), and potential for high cure rate (>80%) if appropriate treatment, based on genetic profile, is initiated. Initial workup may include conventional karyotyping, FISH studies, RT-PCR, and anti-PML antibodies. Longitudinal monitoring of disease with RQ-PCR is currently recommended to provide early intervention if relapse should occur.

Less than 1% of patients with AML have Ph (see Fig. 54-24, *bottom left*). In rare patients with AML, late appearance of Ph either as a sole abnormality or in a clone showing t(8;21) is taken as evidence that the Ph in these patients is a secondary event. The late-appearing Ph in AML is characterized by $P190^{BCR\text{-}ABL1}$ protein. The coexistence of Ph and inv(16) is a rare but recurrent finding in both CML and AML. In CML the fusion transcript is $P210^{BCR\text{-}ABL1}$, whereas in AML the fusion transcript is $P190^{BCR\text{-}ABL1}$. The presence of both Ph and inv(16) in AML seems to have a favorable prognosis, whereas in CML, the coexistence of BCR-ABL and CBFB-MYH11 suggests rapid transformation to blast crisis.

The MLL (also referred to as ALL1 or HRX) gene at 11q23 is responsible for 95% of all 11q23 translocations, including AML and ALL (Fig. 54-30 and Table 54-8). Approximately 20% of all translocations in human neoplasia involve the MLL gene. The MLL abnormalities are found in approximately 15% of patients with AML and ALL. To date, 88 partner genes participate in MLL translocations, and 74 of these are characterized at the molecular level. The most common translocation involving the MLL gene in AML (see Table 54-7) is t(9;11)(p23;q23), occurring in ≈2% of cases (see Fig. 54-30, *M*) and resulting in MLL-MLLT3 (AF9) fusion, and t(11;19)(q23;p13.1) (see Fig. 54-30, *E*), producing the MLL-ELL fusion. The t(9;11), which has been associated with a more favorable outcome in adult and pediatric studies, is distinguished as a separate entity in the latest WHO classification. Other frequent MLL translocations are t(6;11)(q27;q23) involving MLLT4(AF6) and t(11;19)(q23;p13.3) involving MLLT1 (ENL). A partial tandem duplication of the amino-terminus region of the MLL gene is associated in patients with or without trisomy 11 (see Figs. 54-24 and 54-30, *B, C, F,* and *G*). MLL is an epigenetic regulator that plays a critical role in hematopoiesis, modulating HOX gene expression. The MLL gene is encoded by 37 exons. The MLL-binding protein possesses multiple recognizable protein motifs, including DNA-binding domain, transcriptional and repression domains, and a COOH-terminal SET domain that contains histone H3 lysine 4 (H3K4) methyltransferase activity. Recent biochemical evidence has identified MLL as a member of a large multiprotein complex that contains protein involved in chromatin modification/remodeling. In addition, MLL is recruited to the promoters of select cell-cycle regulatory genes, suggesting its role in cell-cycle control. The current understanding is that MLL protein regulates gene expression and cell cycle control via chromatin modification. 11q23 translocations cluster within an 8.3-kb region that encompasses exons 8 to 14 of MLL and fuses the N-terminal portion of MLL, which contains the AT hook and methyltransferase domains, to numerous different proteins. In infant and in therapy-related AML, the MLL genomic breakpoints cluster in the 3′ end, near exon 12. In childhood and adult de novo AML, the breakpoints usually occur in the 5′ end, between exons 9 and 10. AML patients with MLL rearrangements have a poor prognosis despite treatment with aggressive multiagent chemotherapy. Identical MLL rearrangements have been detected in three pairs of infant monozygotic twins, raising the possibility of in utero MLL rearrangements.

The contribution of various MLL fusion partners to transformation was not previously known.[17] The partner genes in the translocations did not appear to have any unifying characteristics that would clarify their role in leukemogenesis. However, two observations suggest that MLL fusion partners are not randomly chosen. First, a precise localization of genomic MLL breakpoints in 414 samples with MLL rearrangements, using a novel long-distance inverse PCR method, showed that the most frequent translocation fusion partners (AF4, MLLT3, MLLT1, AF10) belong to the same nuclear protein network involved in histone methylation. Second, several chromatin structural elements, such as topoisomerase II cleavage sites, DNase I hypersensitive sites, and other chromatin sites, are associated with MLL rearrangements observed in infant and therapy-related AML. These characteristics of MLL suggest that specific chromatin sites are functionally selected in MLL rearrangements rather than being randomly chosen. More recently, a retrospective analysis demonstrated that the prognosis of MLL-rearranged leukemia may also be influenced by the fusion partner. Survival associated with the rare t(1;11)(q21;q23) translocation was good, in contrast to very poor outcomes with the more frequent t(4;11), t(10;11), and t(6;11) translocations.

Gene expression studies have demonstrated clear differences between MLL-rearranged AML and ALL in expression of lineage-associated genes, but there appears to be a core gene expression profile found in all MLL-rearranged leukemias, independent of the lineage markers.

t(6;9)(p23;q34) is a rare cytogenetic abnormality, found in approximately 1% of AML cases, and subsequently reported to be associated with AML and marrow basophilia. Basophilic leukemia is now recognized by the WHO classification as a separate entity. In addition to

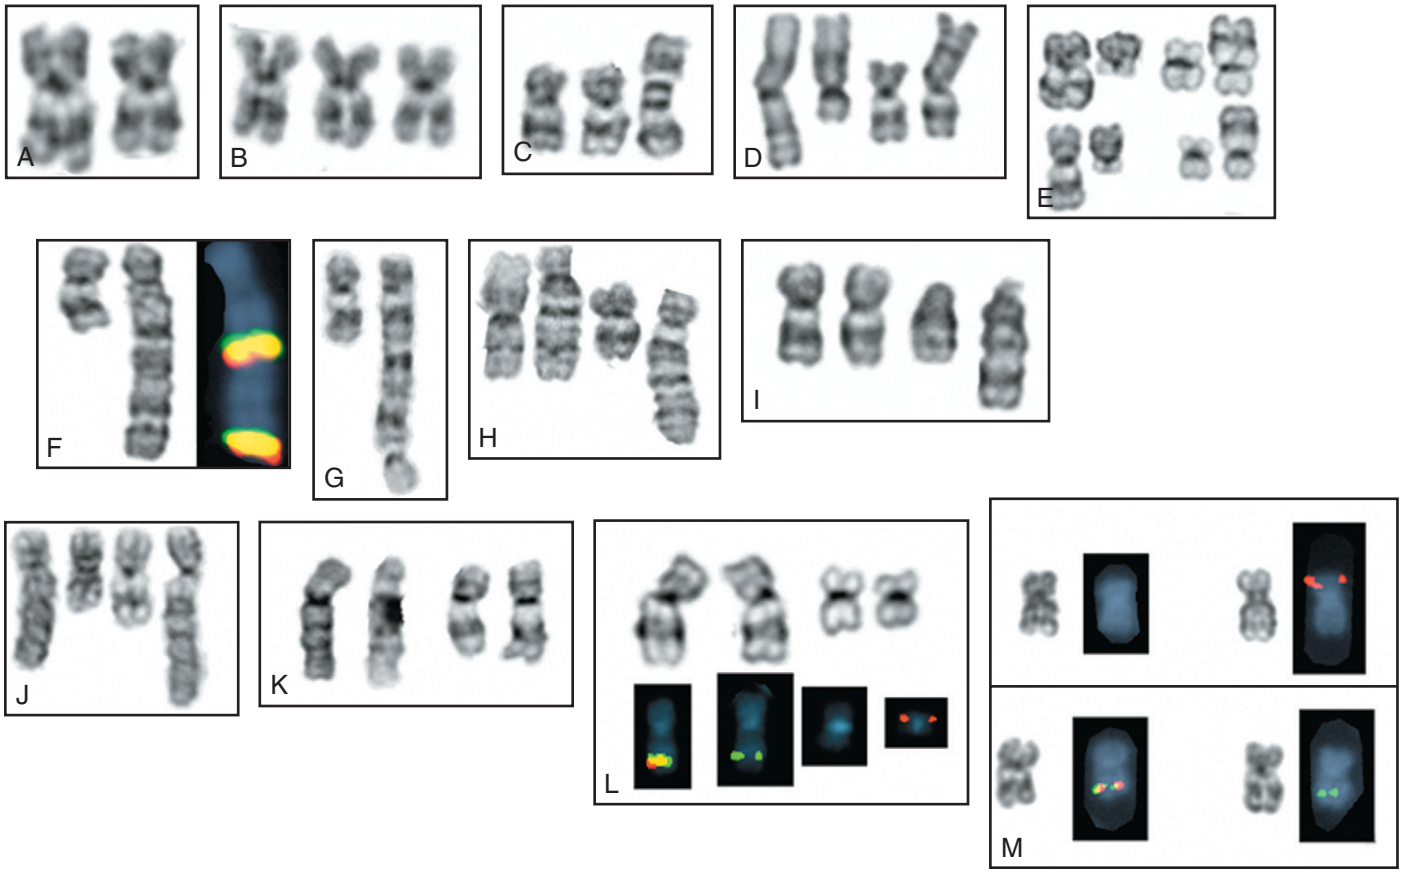

Figure 54-30 EXAMPLES OF CHROMOSOME 11 ABNORMALITIES. **A**, Deletion of chromosome 11 at band q23. **B**, Gain (trisomy) of chromosome 11. **C**, Gain of isodicentric, idic(q11) in myelodysplastic syndrome (MDS). **D**, Balanced t(1;11)(q13;p15) in MDS. **E**, t(11;19)(q13;p13) in a pediatric patient with acute myeloid leukemia. **F**, Duplication of the long arms of chromosome 11 and FISH image of MLL duplication. **G**, Duplication (11;22) in the form of dicder(11;22)dup(11)(q13q14)t(11;22)(q23;p11) in a patient with MDS. **H**, der(11)dic(1;11)(q12;q23) in a patient with myelofibrosis transforming to acute myeloid leukemia. **I**, der(14)t(11;14)(q23;q23), resulting in trisomy for part of the long arms of chromosome 11. **J**, t(4;11)(q23;q23) in pediatric acute lymphoblastic leukemia. **K**, t(6;11)(q27;q23) in pediatric acute lymphoblastic leukemia. **L**, t(11;19)(q23;p13) in pediatric acute lymphoblastic leukemia and after FISH study, showing separation of MLL breakapart probe where the 5′ end of the MLL *(green)* remains on der(11), and the 3′ end *(red)* is translocated to 19p. **M**, t(9;11)(p22;q23) in pediatric acute myeloid leukemia and after metaphase FISH study *(right),* showing that the 3′ end of the MLL *(red)* is translocated to 9p but the 5′ end *(green)* remains on der(11).

t(6;9), other chromosomal abnormalities [such as t(8;21)(q22;q22), del(12)(p11-13), t(X;6),(p11;q23), and t(2;6)(q23;p22)] may be found in basophilic leukemia. As a result of t(6;9), the 3′ part of the CAN (Nup214, nuclear pore complex protein 214 kd) gene located on chromosome 9, band q34, is fused to the 5′ part of the DEK gene located on chromosome 6, band p23. The resulting DEK-CAN/Nup214 fusion gene is a derivative of chromosome 6. The translocation breakpoints occur in a single intron of 8 kb in the CAN gene and in a single intron of 12 kb in the DEK gene. As a result, the presence of the DEK-CAN fusion can be identified in blood or marrow cells by Southern blot analysis and PCR methods. Dual-color commercial FISH probes are not available for this translocation.

The nuclear pore complex is a massive structure that extends across the nuclear envelope, forming a gateway that regulates the flow of macromolecules between the nucleus and the cytoplasm. Nup214 may serve as a docking site in the receptor-mediated import of substrates across the nuclear pore complex and plays a role in nuclear protein import, mRNA export, and cell cycle progression. The hybrid protein contains almost the entire DEK protein fused to the C-terminal two-thirds of the CAN protein. The role of DEK-CAN/Nup214 hybrid protein in leukemogenesis awaits elucidation.

inv(3)(q21q26.2) or t(3;3)(q21;q26.2) (see Fig. 54-20) occurs in ≈1% of AML; each is associated with upregulation of the zinc finger transcription factor EVI1. Both rearrangements may present de novo or secondary to prior MDS and are characterized by normal or increased platelet counts and abnormal megakaryopoiesis.

The presence of hyperdiploid karyotype in acute erythroleukemia is found in 47% to 56% of patients, along with a loss of genetic material occurring in chromosomes 5, 7, and 18. A monosomal karyotype was identified in 43% in one series. Balanced translocations are rare in erythroleukemia, although rare cases of MLL rearrangements have been reported. The frequent occurrence of complex karyotype and abnormalities of chromosomes 5 and 7 may be one reason for poor prognosis associated with acute erythroleukemia. Mutations frequently seen in other subgroups of AML (such as FLT3, KIT or RAS mutations) have not been reported in acute erythroleukemia. In pediatric patients acute erythroleukemia is very rare, present in 2.3% of all patients with AML. Congenital erythroleukemia is exceedingly rare with only six cases reported in the literature.

The M7 or megakaryocytic subtype of AML is a clonal disease, arising in a multipotent stem cell capable of differentiating along the megakaryocytic and granulocytic pathway.[18] This acute leukemia subtype has a variety of genetic and morphologic characteristics. The M7 subtype has an estimated frequency of 3% to 14% of all AML and is more frequent in children than in adults. In adults, megakaryocytic leukemia is frequently observed as a secondary leukemia after chemotherapy or leukemic transformation of several chronic MPDs, including CML. Approximately 65% of acute megakaryocytic leukemia is associated with myelofibrosis. No specific chromosomal abnormality is associated with the adult form of megakaryocytic leukemia. Approximately 50% of M7 AML patients have chromosomal

abnormalities at diagnosis. Observed diverse abnormalities include 3q21-3q26 rearrangements, partial or total deletion of chromosomes 5 and 7, gain of chromosomes 8 and 19, and t(9;22). In multivariate analysis, M7 diagnosis in adults is an independent adverse prognostic factor for overall survival. Three manifestations of childhood megakaryocytic leukemia are observed. First is the t(1;22)(p13;q13) with constitutional trisomy 21 associated with GATA1 mutation. Children with constitutional trisomy 21 have a 10- to 20-fold increased risk for developing leukemia. The incidence of developing M7 leukemia is up to 500 times higher in children with constitutional trisomy 21 than in children without it. However, children with constitutional trisomy 21 and megakaryocytic leukemia have a more favorable prognosis compared with patients without constitutional trisomy 21. Somatic mutation of transcription factor GATA1 in these patients leads to exclusive expression of a truncated form of GATA1. The second form of childhood acute megakaryocytic leukemia involves t(1;22)(p13;q13) encoding the OTT-MAL (RBM15-MKL1) fusion protein in infants without constitutional trisomy 21 (Fig. 54-31). It is a very rare abnormality, described in about 40 cases worldwide (≈5% of infant AML cases), and associated with infantile M7 and with children younger than 3 years of age. Detection of t(1;22) is diagnostic. Adults with t(1;22)(p13;q13) encoding the OTT-MAL fusion protein are not reported to date. Third, approximately 19% of infants with constitutional trisomy 21 (or mosaic trisomy 21C) and transient myeloproliferative disorder subsequently develop M7 leukemia at a mean age of 20 months. With development of leukemia, these children acquire diverse chromosomal abnormalities, most notably tetrasomy 21 and trisomy 8. The t(1;22) rearrangement has been observed in a set of monozygotic twins, suggesting an in utero origin in some cases.

Preliminary results using gene expression profiling (GEP) are providing the first insight into the molecular pathogenesis of M7 leukemia in children with and without constitutional trisomy 21. These two groups of patients have distinct molecular phenotypes, with increased expression of chromosome 21 genes in patients with constitutional trisomy 21 compared with M7 leukemia patients without constitutional trisomy 21. The AML1 (RUNX1) gene, localized on chromosome 21 and essential for normal megakaryopoiesis, is expressed at lower levels in children with constitutional trisomy 21 and M7 leukemia, indicating a mechanism that may contribute to a block in differentiation in megakaryocytic leukemia.

In a recent study of 1058 patients with AML and abnormal karyotype, 30% had monosomal karyotype (see Fig. 54-20, *bottom row*). AML with MK is frequently associated with other adverse risk cytogenetic abnormalities, such as inv(3), −5 or del(5q), −7 or del(7q), abnormal (12p), −18/del(18q), abnormal (17p), and complex karyotype. Response to induction therapy and overall survival of patients who have AML with MK is dismal—complete remission rates of 32% and a 4-year survival of 9%. Monosomal karyotype in a study of 248 patients with AML was found to be associated in more than 50% of these patients with deletion of P53, whereas in another study of newly diagnosed 369 patients with AML, MK predicted adverse treatment outcome and was associated with multidrug-resistance functional activity of leukemic blasts.

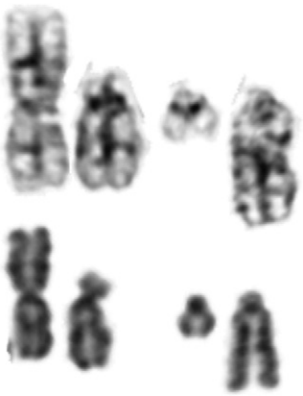

Figure 54-31 Partial bone marrow karyotype from two metaphase cells from a 4-week-old baby with M7 megakaryocytic leukemia showing a diagnostic t(1;22)(p13;q13) abnormality.

Approximately 15% to 20% of patients with AML have a numerical gain or loss of a single chromosome as the sole primary karyotypic abnormality. Each of the autosomes and sex chromosomes contributes to the numerical changes. The most common trisomies in decreasing order of frequency are gain of chromosome 8, 22, 13, 21, and 11. The gain of chromosome 8, the most frequent abnormality seen in AML, is found as a sole abnormality in 6.3% and overall in 16%. The incidence of +8 detected by FISH varies between 19% and 25%. The prognosis of AML with +8 depends on whether +8 occurs as an isolated abnormality or accompanies other cytogenetic aberrations. In the latter situations, +8 does not appear to adversely affect the favorable outcome of patients with t(15;17), inv(16)t(16;16), and t(8;21). In contrast, patients with +8 and a complex karyotype and/or an unfavorable aberration such as del(5q) or −7 usually have very poor outcome. Isolated +8 has been considered to be associated with either intermediate or unfavorable prognosis.

Deletion of 17p often results in the loss of tumor suppressor TP53 gene on band p13.1, which has been reported in 5% to 9% of adult AML. The abnormalities of 17p are often associated with other chromosomal aberrations such as del(5q), −5, −7, but it is also an independent poor-risk prognostic factor for disease-free survival, relapsed risk, and OS. Patients with p53 mutations are more common in older patients and those who have previously received alkylating agents. These patients were found to have an increase in the number of $CD34^+$ cells, suggesting that the loss of p53 function could cause cell cycle arrest at an immature stage.

Whether PCR-based molecular screening, conventional cytogenetics, or both, should be used at diagnosis of AML is an important question with major consequences for treatment strategy, monitoring therapy, and overall genetic risk assessment. A prospective comparison study demonstrated approximately 20% discrepancy between broad molecular screening using a multiplex RT-PCR system and cytogenetic testing. This discrepancy has the potential to influence treatment strategies. Cryptic translocations detected as submicroscopic genetic lesions detected by RT-PCR may have no influence on prognosis or treatment strategy. In contrast, cytogenetic results influence treatment decisions by conferring unfavorable risk assignment on patients with negative broad molecular screening. These methodologies provide complementary genetic information for diagnosis, treatment, and follow-up.

Cytogenetic studies are valuable in assessing the effectiveness of therapy (see box on Genetic Testing for Acute Myeloid Leukemia and Fig. 54-24). In most patients with AML, a clonal cell population cannot be detected during remission. However, in some cases, hematopoiesis remains clonal, with normal karyotype showing only a single G6PD enzyme type—hence the fourth aspect of AML heterogeneity. When disease relapses, cells with the original chromosome anomalies are observed. If an appropriate FISH or RT-PCR test is available, these are the genetic tests of choice for predicting relapse because these methods are less expensive and more sensitive than chromosome studies.

The striking clinical, cytogenetic, and biologic heterogeneity of AML is only partly explained by the known chromosomal or molecular rearrangements. DNA microarray technology (cytogenomics) provides a higher resolution and has been demonstrated to detect cryptic copy number alterations (CNA) and UPD (uniparental disomy) that occurs in commonly in AML. The clinical implications of array CGH and SNP microarray analyses in AML are still limited. However, it has been demonstrated that in cases with UPD, gene mutations precede mitotic recombination, resulting in loss of the remaining wild-type allele, which can act as a "second hit" mutation. Evidence suggests that the association of UPD with a more advanced disease is also reflected in clinical outcome because UPD has been shown to be predictive of poor event-free and overall survival. For example, SNP microarray analysis of AML patients with a normal karyotype

Genetic Testing for Acute Myeloid Leukemia

At diagnosis, the recommended general practice should be FISH studies using the panel of chromosomal probes for acute myeloid leukemia, including RUNX1-RUNXT1,PML-RARA, CBFB, BCR-ABL and MLL. Conventional cytogenetic studies must be also performed at diagnosis. Patients with CBF AML subtype should be tested for KIT exon 17 mutations because these mutations adversely affect the prognosis. These tests are performed at diagnosis to establish a benchmark for the percentage of neoplastic cells and are used in follow-up studies to help assess the effectiveness of therapy. In patients with a normal karyotype, mutation studies for the most common genes (NPM1, FLT3, CEBPA, and TET2) are recommended.

The impact of cytogenetics on outcome in a pediatric group of patients with AML (excluding APL) demonstrated ≈80% overall survival for 10 years in patients with CBF AML. In contrast, patients with MLL abnormalities had an intermediate prognosis (61% OS at 10 years) with no evidence of heterogeneity according to the translocation partner of MLL. Additional abnormalities among the 11q23 leukemia have diverse prognoses; trisomy 8 is an independent favorable, whereas trisomy 19 is considered an adverse prognostic factor in MLL rearranged group of pediatric patients.

demonstrated UPD of chromosome 13q, leading to duplication of a mutant FLT3 allele at band 13q12, which was associated with significantly inferior overall survival. Approximately 20% of patients with AML and a normal karyotype have UPD. The most common chromosomal regions of UPD are 1p, 2p, 2q, 4q (TET2), 6p, 7q (EZH2), 11p (WT1), 11q, 13q (FLT3), 14q, 16p, 17p (TP53), 19q (CEBPA), 21q (RUNX1), and Xq. Analysis of genes located within UPD chromosomal region showed a copy-neutral loss of heterozygosity with duplication of gene mutations that has been already implicated in AML pathogenesis and a loss of corresponding normal allele.

Numerous studies using cytogenomics have uncovered a broad range of cryptic CNAs in patients with AML and a normal karyotype, as well as in patients exhibiting balanced translocations or chromosomal imbalances. Not only did these studies reveal a tremendous genetic diversity of AML; they also showed that the estimated average number of CNAs per genome is 2 to 2.5. This finding implies either that most AML genomes are relatively stable or that at the current level of resolution provided by the modern cytogenomics (≈35 kb), more sensitive methods are required (e.g., complete genome sequences) to capture the whole spectrum of genetic alterations. Genomic imbalances (and their associated target genes) include gains of regions 4q25-26 (PRDM5), 8p11.21 (ZMAT4), 8q24.21 (CCDC26), 13q32 (ABCC4), 14q23.1 (PRKCH), 16q24.1 (USP10, CRISPLD2), and 21q22.3 (PRMT2), as well as losses of regions 6q27 (RPS6KA2), 7p22.3 (FAM20C), 8q24.12 (TRPS1), 9p21.2 (TISCI), 10q11,21 (HNRNPF), 15q21.3 (RFX7), Xp11.4 (BCOR), and XP25 (STAG2). The biologic consequences of these small genomic imbalances are not fully understood. In some cases submegabase-sized CNAs may uncover cryptic rearrangements, as has been shown for NSD1-Nup98 and MALT4 -MLL fusion genes. The systemic analysis of CNAs and regions of UPD in AML in future may fully uncover genomic changes that contribute to AML pathogenesis.

The biology of AML changes with age. The spectrum of cytogenetic abnormalities in older adults includes a higher percentage of patients with abnormalities involving −5/del(5q), −7/del(7q), and 17p and a lower incidence of translocations associated with favorable prognosis and treatment outcome. Older patients with a complex karyotype have an extremely poor prognosis, with 26% achieving CR because of high rates of resistant disease. Multidrug resistance is demonstrated in 57% of patients older than 75 years but in 33% of AML patients younger than 56 years. The overall survival rate in older adult patients with AML is only 2% at 5 years. The different biology of AML in older patients may be a consequence of the age of hematopoietic stem cells, shortened telomere length (associated with older cells), and presence of fewer normal stem cells to compete with malignant clones and repopulate marrow following chemotherapy.

Genetic Testing for Therapy-Related Neoplasms

The best genetic test for therapy-related myelodysplastic syndrome or acute myeloid leukemia is a conventional cytogenetic study. FISH studies with probes for loci on chromosomes 5 and 7, MLL, and RUNX1 should be performed if therapy-related leukemia is suspected. This approach is useful for t(8;21), t(9;22), t(11;var), t(15;17), inv(16), −5/del(5q), −7/del(7q), rearrangements of ETV6 on 12p, and some others.

Therapy-related AML and therapy-related MDS are distinct clinical syndromes occurring as late complications after high-dose chemotherapy, radiation therapy, or autologous HCT. A normal karyotype is observed in 8%, and abnormal karyotype is detected in 92%. From the cytogenetic point of view, two different categories of therapy-related AML and therapy-related MDS can be distinguished. The first is found in patients exposed to alkylating agents who developed therapy-related approximately 5 years after therapy. These leukemias are associated with the presence of monosomy 5/del(5q) or monosomy 7/del(7q). Many of these patients initially develop myelodysplastic features before transforming into a frank AML. Recurrent abnormalities of chromosomes 5, 7, or both account for 70% of all abnormalities observed in therapy-related leukemia. These patients have a poor response to therapy and poor overall survival. A second group of patients develop therapy-related AML without prior MDS. Leukemia cells in these patients often exhibit 11q23 (3%) and 21q22 (3%) balanced rearrangements, attributed to late effects of topoisomerase II inhibitors combined with alkylating agents and radiation. The leukemia may develop within a few months to 3 years after therapy. Polysomy (tetrasomy, pentasomy, hexasomy) of chromosome 8 defines a clinicocytogenetic entity associated with therapy-related myeloid malignancies and poor overall survival (see box on Genetic Testing for Therapy-Related Neoplasms).

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL (see Chapters 63, 64, and 65) is a clonally derived disease involving progenitor cells with differentiation expression detected only in the lymphoid lineage. ALL accounts for at least 85% of acute leukemias in children and 20% of acute leukemias in adults. Most published series of patients with acute ALL indicate that 70% to 75% have an abnormal clone by conventional cytogenetic studies (Fig. 54-32). Genomic rearrangements detected with intensive interphase FISH screening are found in up to 91% of cases. The application of contemporary genome-wide molecular analysis continues to reveal many additional genetic rearrangements that are not detectable by chromosome studies. At least one clonal aberration has been detected in 60% to 79% of adults and 57% to 82% of children with ALL. Today, cytogenetic analyses combined with FISH and/or RT-PCR investigations are mandatory in most ALL treatment trials, and genetic findings play a pivotal role in proper risk stratification and treatment options. Several of the ALL-specific chromosome aberrations and their molecular counterparts have been included in the 2008 WHO classification.

Pretreatment cytogenetics is an independent prognostic factor in children and adults presenting with ALL and is important in determining risk categories.[19] As shown in Fig. 54-32 and Tables 54-9 and 54-10, the risk categories in children include (a) low risk: high hyperdiploidy (trisomies for chromosomes 4, 10, and 17) and t(12;21)/TEL-AML1; (b) high risk: t(1;19)/E2X-PBX1; and (c) very high risk: t(9;22)/BCR-ABL and 11q23/MLL rearrangements. In

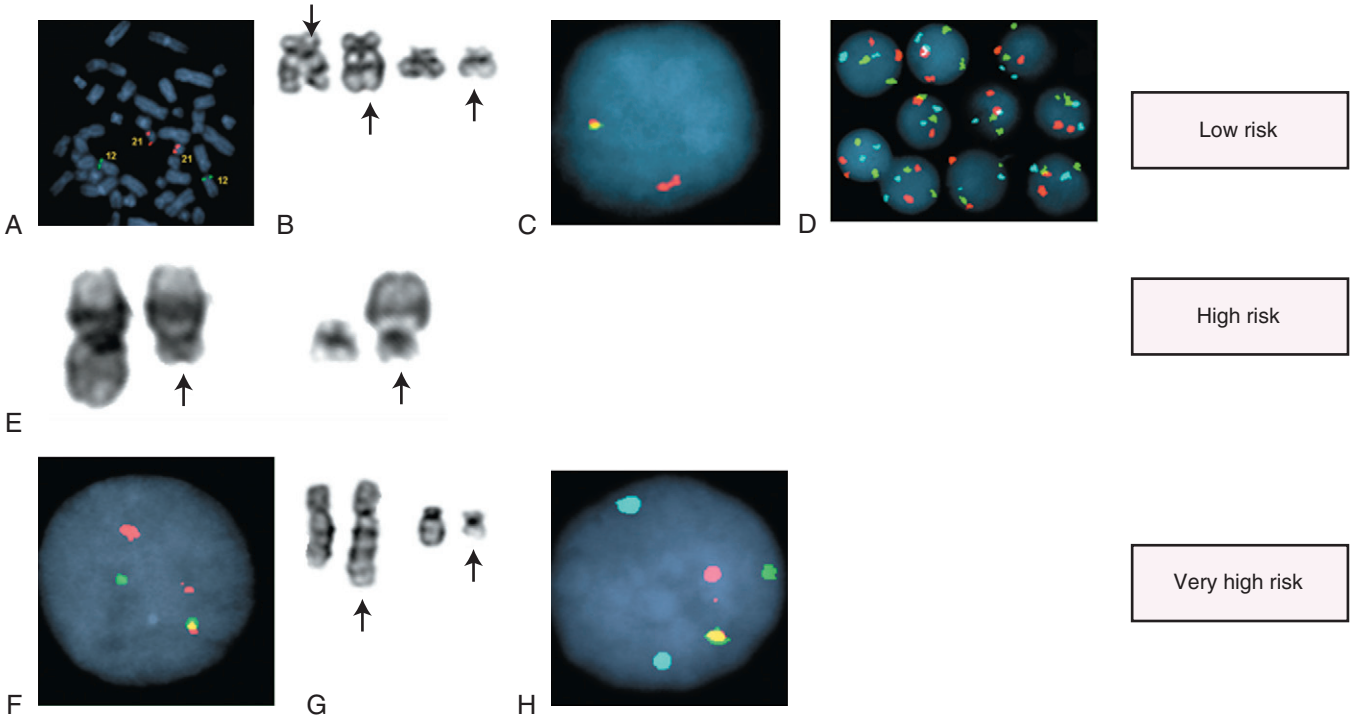

Figure 54-32 PROGNOSTIC CYTOGENETIC CATEGORIES IN ACUTE LYMPHOBLASTIC LEUKEMIA. **A,** Localization of TEL/ETV6 and AML1 fluorescence probes to chromosomes from a normal bone marrow metaphase cell. TEL/ETV6 is on 12p13 *(green)* and AML1 is on 21q *(red)*. **B,** Partial karyotype showing t(12;21)(p13;q22) *(arrows)*. The short arrow at 12p indicates a possible TEL deletion from normal chromosome 12. **C,** FISH study showing loss of TEL *(green)* from normal 12 homologue in interphase nucleus, a frequent subclonal evolution in patients with t(12;21). **D,** Hyperdiploidy [specifically trisomies for chromosomes 4 *(green)*, 10 *(red)*, and 17 *(aqua)*] is associated with low-risk cytogenetic category (see text for details) and is present in disomy in interphase cells *(top left)*. **E,** Partial G-banded karyotype showing t(1;19)(q23;p13.3), which occurs in approximately 6% of patients with B-cell precursor childhood acute lymphoblastic leukemia. **F,** FISH hybridization to bone marrow nucleus showing BCR-ABL fusion *(yellow)*. **G,** as a consequence of t(9;22), occurring in 5% of children and 20% to 25% of adults with acute lymphoblastic leukemia. **H,** Interphase nucleus after FISH study with tricolor probe. Dual-color/breakapart MLL shows separation of the 3′ end and the 5′ end as a result of 11q23 rearrangement. CEP11 *(aqua)* indicates disomy for chromosome 11, used as internal control. MLL rearrangements in acute lymphoblastic leukemia are associated with unfavorable prognosis.

Table 54-9 Frequencies of Cytogenetic Aberrations in Adult and Childhood ALL and Their Prognostic Relevance

		Adults		Children	
Cytogenetic Abnormality	**Genes Involved**	***Frequency (%)***	***Prognosis***	***Frequency (%)***	***Prognosis***
Normal karyotype	NA	15-34	Intermediate-good	31-42	Favorable
High hyperdiploidy (>55)	NA	7-8	Good-intermediate	23-30	Good
Low hyperdiploidy (>50)	NA	10-15	Poor	10-11	Intermediate
Near haploidy (<35)	NA	Rare	NA	1-4	Poor
Pseudodiploidy	NA	31-50	Poor	18-26	Intermediate

B-ALL	FLT3	3	Receptor tyrosine kinase	Activating ITD

adults the low-risk category includes high hyperdiploidy and del(9p), whereas the high-risk category includes hypodiploidy/near triploidy, t(9;22)(q34;q11), t(4;11)(q21;q23), t(8;14)(q24;q32), and complex karyotype (five or more chromosomal abnormalities).

Approximately 20% of children and 26% of adults with B-cell ALL have a hyperdiploid number of chromosomes. Two groups are distinguished based on cytogenetics: (a) those with 51 to 55 chromosomes whose prognosis is poorer, and (b) those with 56 to 67 chromosomes whose prognosis is excellent. Both groups have a more favorable prognosis than do children with hypodiploidy or near-haploid ALL. In a study of 1880 children with ALL, patients with 45 chromosomes have an outcome similar to that of ALL patients with pseudodiploid or low hyperdiploid (47-50 chromosomes).[20] Children and adolescents with ALL and hypodiploidy with fewer than 44 chromosomes have a poor outcome despite contemporary therapy. The distribution of specific chromosome gains is not random, with the most often gained chromosomes being 21, X, 14, 6, 18, 4, 17, and 10, each of which is gained in more than 50% of hyperdiploid ALL patients, followed by chromosomes 8, 5, 11 and 12, gains that occur more often in patients with 57 or more chromosomes. Prognosis of children with high hyperdiploidy is excellent with 5-year event-free survival rates of between 71% and 83% and a 5-year overall survival rate of approximately 90% being reported. Pretreatment cytogenetic analysis of more than 5400 children with ALL unequivocally shows that simultaneous trisomies for chromosomes 4, 10, and 17 are associated with long-term event-free survival (see Fig. 54-32, *D*). In contrast to children who have a favorable prognosis when a hyperdiploid karyotype is present, such a favorable constellation has not been found in patients with adult ALL. The reason for this discrepancy may be that adults often have poor-risk chromosomal translocations, such as the Ph. Approximately 50% of the high hyperdiploid patients harbor other structural abnormalities, such as gains of 1q, del(6q), which do not appear to influence prognosis, with a possible exception of prognostically adverse isochromosome for the long arms of chromosome 17. Frequently, hyperdiploid leukemic cells fail to proliferate in culture; therefore, in the face of unsuccessful chromosome analyses or in those with normal karyotype interphase FISH with an ALL panel of FISH, it is strongly recommended that probes be performed to determine cytogenetic risk category before initiation of therapy.[21]

Modal chromosome numbers of 45 or less occur in less than 1% of cases (specifically, the near-haploid numbers of 24-36) and confer a poor prognosis. Similarly, ALL in adults presenting with low hyperdiploid/near-triploidy is associated with poor outcome. Loss of chromosome 7 is frequent in adult ALL. The majority of these patients also have t(9;22).

In childhood ALL, t(12;21) was first reported in 1994 as a fortuitous FISH finding. This translocation is difficult to detect by conventional cytogenetics because the translocated portions of 12p13 and 21q22 have virtually identical G-banding patterns. In contrast, the ETV6-RUNX1(AML1) fusion product of t(12;21) is detected using PCR or FISH in 17% to 41% of pediatric patients with ALL (see Fig. 54-32, *A* to *C*). The ETV6-RUNX1 (AML1) fusion, found almost exclusively in children 1 to 15 years old with B-precursor ALL, represents the most frequent molecular rearrangement in childhood cancer. Children with the ETV6-RUNX1 (AML1) fusion gene have significantly lower rates of relapse than do ETV6-AML1–negative patients. ETV6-RUNX1 (AML1)–positive B-precursor ALL is characterized by a prolonged duration of first remission and excellent cure rates. Prospective analyses have demonstrated that the survival rate in t(12;21)–positive patients is significantly better when compared with negative cases; however, this abnormality in multivariate analysis is not found to be an independent predictor of outcome. The ETV6-RUNX1 (AML1) fusion is rare in adult ALL. t(12;21)(p13;q22) fuses the helix-loop-helix domain of the ETV6 gene, located on chromosome 12, band p13, to the DNA-binding and transactivation domain of the RUNX1 (AML1) gene, located on 21q22. FISH studies allow visualization of the fusion gene on 21q22. Fusion with ETV6 converts RUNX1 (AML1) from an activator to a repressor of transcription. The ETV6-RUNX1 fusion is accompanied in 55% to 70% patients by the loss of the other normal nonrearranged TEL/ETV6 allele. This deletion probably represents a subclonal evolution. ETV6-AML1 has been detected in utero, probably in a committed B-cell progenitor, and is present in normal cord blood and peripheral blood samples at frequencies 100-fold greater than the risk for corresponding leukemia. The current view of development of ETV6-RUNX1 (AML1)–positive leukemia is that these early events are followed by a long "preleukemic" phase followed by loss of the normal ETV6 homologue, which appears to be an important event in the multistep pathogenesis of this leukemia. Currently, of the 397 children with ETV6-RUNX1–positive leukemia reported, approximately 60% harbor additional karyotypic abnormalities that contribute to the pseudodiploid or near-diploid karyotype in these cases. The most common secondary change, which occurs in approximately 50% of cases with additional abnormalities, is trisomy 21.

A rare group of patients with B-precursor ALL lack fusion of TEL and AML1 but have 3 to 15 copies of the q22 band of chromosome 21, including the RUNX1 (AML1) locus. Amplification of the 21q22 band of chromosome 21 is a clonal marker of the leukemic cells (Fig. 54-33, *A*). Following this initial observation, the British Childhood Leukemia Working Party prospectively screened 1630 patients with childhood ALL and identified 28 children with

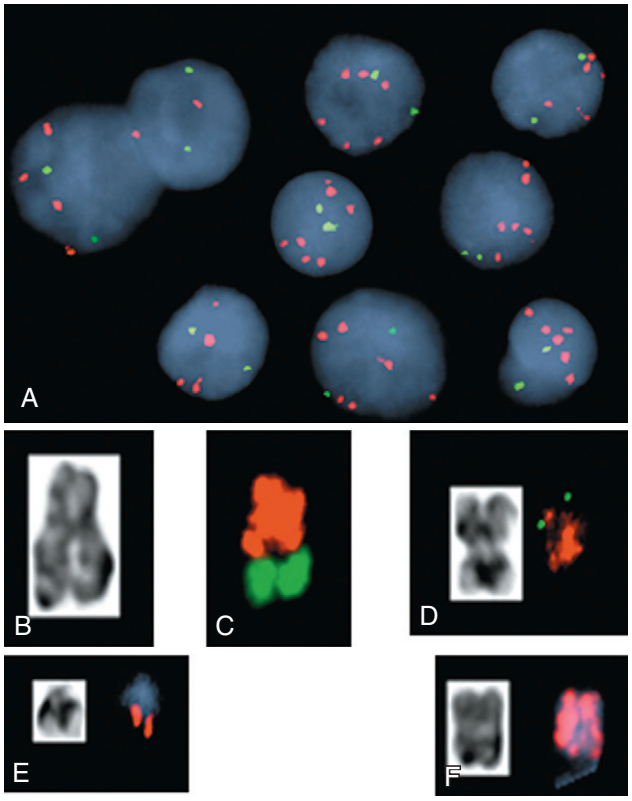

Figure 54-33 DETECTION OF AML1 AND 21q22 AMPLIFICATION. **A,** Intrachromosomal amplification of AML1 *(red)* (TEL *[green],* present in disomy) in a pediatric patient with pre–B-cell acute lymphoblastic leukemia. This finding is associated with poor prognosis. **B,** G banding of der(18) chromosome and after FISH study **(C)** with WCP 18 *(green)* and LSI 21q22.13 *(red),* documenting der(18)t(18;21) and amplification of 21q22 region in a patient with myelodysplastic syndrome/acute myeloid leukemia. **D,** Amplification of 21q22 region in myelodysplastic syndrome may be present in another formation: der(21) (G banding, *left*). FISH study shows amplification of 21q22.13 locus *(red)* and identified der(21) as t(5;21) with 5p15.2 probe *(green).* **E,** Localization of 21q22.13 LSI probe on normal chromosome 21. **F,** Homogeneous staining region (hsr)(21), G banding *(left),* and after FISH study *(right)* with locus-specific probe for 21q22.13 *(red)* consistent with 21q22.13 band amplification in a patient with myelodysplastic syndrome.

intrachromosomal amplification of chromosome 21 (iAMP21) (see Fig. 54-33, *D*). Approximately 2% of children and less than 0.5% of adults display iAMP21. Children with iAMP21 have a common or pre–B-cell immunophenotype, median age of 9 years, and significantly inferior event-free and overall survival at 5 years compared with children exhibiting other cytogenetic subgroups. Even children with Ph-positive ALL, known for its poor prognosis, have a better 5-year event-free survival compared with children with iAMP21. These children have a threefold increased risk for relapse and are twice as likely to die than are their counterparts without iAMP21.

ETV6 or TEL (for translocation, ETS, leukemia) transcription factor gene, most frequently found in translocations, was first identified as a part of a TEL–platelet-derived growth factor receptor β fusion (TEL-PDGFRB) created by t(5;12)(q33;p13) in chronic myelomonocytic leukemia. It was detected using FISH because, as mentioned earlier, of difficulties in detecting cytogenetic rearrangements at the 12p13 site. As a result of this translocation, the helix-loop-helix domain of TEL/ETV6 is fused in frame to the PDGFRB transmembrane and tyrosine kinase domain. Fusion of TEL/ETV6 to a tyrosine kinase also occurs as a result of t(9;12)(q34;p13), leading to the ABL-TEL(ETV6) fusion that has been observed in patients with ALL,

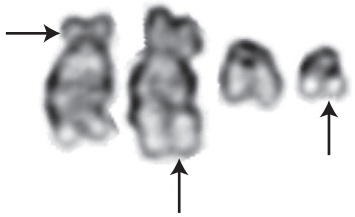

Figure 54-34 t(9;22)(q34;q11) *(arrows)* in a patient with acute lymphoblastic leukemia. Note that the first chromosome 9 has deletion of the short arms, a frequent finding in both adult and pediatric acute lymphoblastic leukemia patients.

AML, and atypical CML. More than 39 partner genes are known to participate in fusions with ETV6/TEL, primarily in ALL and less frequently in myeloid malignancies.

Other rearrangements involving 12p include deletions, duplications, and translocations and are observed most often as part of a complex karyotype, frequently associated with chromosome 5 and/or 7 abnormalities. Deletion of 12p13 is much more frequent in children than in adults with ALL and is observed in patients with myeloid disorders, specifically in adults with MDS. Two other genes residing on 12p also are rearranged: CCND2 is frequently amplified, and CDKN1B is often deleted.

Approximately 5% of children and 20% to 25% of adults with ALL have Ph, making it the most common structural rearrangement in adult ALL (Fig. 54-34). The breakpoint on Ph is more centromeric than in CML (see Chronic Myelogenous Leukemia section, earlier). It includes the 5′ breakpoint on chromosome 22, distal to the first exon (falling between exon e1 and e2) of the BCR gene, resulting in the $P190^{BCR\text{-}ABL1}$ variant, providing a diagnostic distinction between lymphoid blast crisis of CML and de novo ALL. Ph-positive ALL is characterized by the smallest BCR-ABL1 (P190) protein, containing less BCR than the P210 and P230 fusion proteins. Among Ph-positive patients with ALL, approximately 58% to 70% of adults and 80% of children have this genomic breakpoint variant. Up to 19% of Ph-positive ALL patients may express both the P190 and the P210 BCR-ABL1 fusions. A number of earlier studies indicated that the P190 type of the BCR-ABL1 breakpoint is associated with a more aggressive form of disease, with higher tyrosine kinase transforming ability than the P210 protein associated with CML. Ph-positive ALL has been classified as a stem cell disorder because of the presence of the BCR-ABL transcript in both the myeloid and lymphoid lineages. More recent reports suggest that the presence of the P190 protein does not confer a poorer prognosis.

The BCR-ABL1 fusion variants are easily detectable by FISH testing using the extrasensitive probe strategy, and BCR-ABL1 leukemia can be identified in up to 10% of Ph-negative cases. Moreover, FISH testing will identify ABL rearrangements in BCR-ABL1 fusion-negative ALL patients. The role of imatinib used alone or in combination with conventional chemotherapy in older adult patients with de novo Ph-positive ALL is being studied. Initial GEP studies have failed to identify specific genes associated with differences in overall survival of adult patients with P190 or P210 ALL.

Reactivation of BCR-ABL kinase activity is most commonly associated with the emergence of point mutation in the ABL kinase domain implicated in resistance to imatinib treatment (see Chronic Myelogenous Leukemia section, earlier). Retrospective analysis reveals that 40% of newly diagnosed and imatinib-naive Ph-positive ALL patients have kinase domain mutations, and 83% to 90% have identical mutation at relapse or at the time of hematologic or cytogenetic resistance to imatinib. The frequency of the mutant allele is always below the level of detectability by direct cDNA sequencing method at diagnosis, and use of more sensitive methods, such as denaturing high-performance liquid chromatography, is recommended.

More than 60% of adult patients with Ph-positive ALL show additional chromosomal abnormalities in the Ph-positive

clone. Most frequent are gain of Ph, monosomy 7, +8, +X, del(9p) (see Fig. 54-34), and high triploidy. The additional chromosomal abnormality has no effect on survival of Ph-positive patients. High hyperdiploidy is detected in approximately 15% of Ph-positive ALL. According to the WHO classification, 1% of all leukemia are mixed phenotype acute leukemia with t(9;22)(q34;q11.2) and leukemic blasts showing a B-cell and myeloid lineage. Occasional T-cell phenotype and trilineage BCR-ABL1 mixed phenotype leukemia have been rarely reported.

t(1;19)(q23;p13.3) occurs in 5% to 6% of patients with B-cell precursor childhood ALL. However, among patients with a pre-B (cytoplasmic immunoglobulin–positive) immunophenotype, t(1;19) is found in approximately 25%. t(1;19) occurs in 2% to 3% of adults (see Fig. 54-32, *E*). Cytogenetically, two forms of t(1;19) can be identified: 25% of cases have a balanced reciprocal t(1;19), whereas 75% of cases have a more common rearrangement of unbalanced der(19)t(1;19)(q23;p13.3). The unbalanced der(19)t(1;19) arises from the initial trisomy of chromosome 1 followed by the t(1;19) translocation, with subsequent loss of the derivative chromosome 1. More than 95% of t(1;19) is associated with the E2A (TCF3)–PBX1 fusion gene. The E2A gene (originally identified by binding of E2A proteins to the kE2DNA sequence motif contained in the Ig κ light-chain enhancer) on chromosome 19, band p13.3, is fused to the PBX1 (homeobox) gene on chromosome 1, band q23. Approximately 1% of pediatric B-ALL patients have a variant t(17;19)(q21-q22;p13) translocation resulting in two different genomic rearrangements. The first is the fusion between the HLF gene (breakpoint in intron 3) on chromosome 17 and the E2A gene (within intron 13) on chromosome 19, associated with disseminated intravascular coagulation. The second is the breakpoint in intron 12 of E2A and intron 3 of HLF associated with hypercalcemia. In contrast to ETV6-RUNX1 rearrangements, which have a prenatal origin, current evidence suggests a postnatal etiology for t(1;19) translocations.

Currently, it is thought that an unbalanced der(19) in pediatric patients with ALL is associated with significantly improved outcome compared with patients with balanced t(1;19), which remains an adverse prognostic factor. In adults the prognostic relevance of t(1;19) is unclear, and both favorable and unfavorable outcomes have been reported. In contrast, a variant t(17;19) rearrangement is associated with poor prognosis. A recent study of adult ALL has suggested that prognosis of patients with t(1;19) can be substantially improved by the hyper-CVAD regimen. Both t(1;19) and t(17;19) are easily identifiable by conventional cytogenetics, FISH, and RT-PCR, and the latter two methodologies are particularly useful in posttreatment specimens that are cytogenetically normal.

In ALL, the most frequent MLL translocations include t(4;11) (see Fig. 54-30, *J*) leading to MLL-AFF1(AF4) fusion and t(11;19)(q23;p13.3) (see Fig. 54-30, *L*) resulting in MLL-MLLT1(ENL) fusion. These abnormalities are present in more than 80% of infant leukemia and 10% of childhood and adult leukemia. MLL rearrangements are associated with poor outcome in both children and adults (see Acute Myelogenous Leukemia, earlier, and T-Cell Lymphoproliferative Diseases, later). t(4;11) is one of the most common 11q23 abnormalities, occurring in 2% of children and approximately two-thirds of adults with MLL-associated translocations. The outcome of patients with t(4;11) is generally poor. One-third of patients with t(4;11) have secondary abnormalities; the most frequent are +X, i(7q), abnormalities of 9p, including i(9q), and +8. The outcome of patients with t(11;19) is also generally poor, especially in children younger than 1 year of age. The most frequent additional abnormalities in patients with t(11;19) are +X, +8, and del(6q). Other less common MLL translocations include t(9;11)(p22;q23)/MLL-MLLT3,t(10;11)(p13-15;q23)/MLL-MLLT10 and others. A large multiinstitutional study has determined that secondary aberrations do not affect prognosis of children with ALL and t(4;11),t(11;19) or other MLL translocations.

t(8;14)(q24;q32) is seen in fewer than 5% of all ALL patients (children and adults). Variant translocations t(8;22)(q24;q11) and t(2;8)(p12;q24) are seen in less than 1% of children and adults. These patients have CD10, CD19, CD20, surface IgM immunophenotype, and extremely poor prognosis. The same translocation is found in Burkitt lymphoma, and both entities likely represent the same disease with different manifestations. It has been reported that the majority of adult patients with t(8;14) die within 1 year of diagnosis.

Approximately 2% of children and 8% of adult pre–B-cell precursor ALL show recurrent IGH translocations usually identified by FISH as t(8;14)(q11;q32), t(14;19)(q32;q13), inv(14), (q11q32/t(14;14)(q11;q32), and t(14;20)(q32;q13). These five recurrent IGH translocations have in common deregulated expression of unmutated CEBP genes (CCAAT enhancer–binding protein transcription factors), and approximately 1% of all B-cell precursor ALL are characterized by novel CEBP-IGH fusions.

Abnormalities of the short arms of chromosome 9 (p21-22) occur at a frequency of 7% to 13%. In adults the presence of del(9p) appears to be associated with improved outcome, whereas in children with ALL, del(9p) is associated with poor outcome. The most frequent abnormalities are codeletions of two genes, $p15^{INK4B}$ and $p16^{INK4A}$, as well as the interferon α and β genes found in many, but not all, cases. Among the structural rearrangements involving the short arms of chromosome 9, t/dic(9;12)(p11-12;p11-13) is a rare recurrent abnormality associated with L1 morphology (FAB classification), pre–B-cell phenotype, and excellent prognosis.

Other chromosomal abnormalities detected in nonrandom fashion in adult ALL include deletions, both terminal and interstitial, of the long arm of chromosome 6, and isochromosomes of 7q, 9q, 17q, and 21q. Adult patients with ALL showing t(9;22), t(4;11), t(8;14), –7, +8 chromosomal aberrations have a poorer prognosis and significantly lower probability of long-term complete remission and survival than do patients with a normal karyotype or patients with other chromosomal rearrangements.

Gene expression profiling in childhood ALL suggests that ALL segregates according to cell lineage and primary genomic defects. However, some clues about the genes that participate in drug resistance and influence treatment are provided by a comparison between GEP and response to therapy. In this study of 187 children with ALL, 14 functionally related genes with roles in regulation of cell proliferation were independently associated with risk for relapse. Retrospective studies have demonstrated that expression profiling can be effective in classifying ALL into recognized, prognostically important subtypes such as those mentioned earlier; these studies have also identified a new subtype of ALL without the BCR-ABL1 fusion, but with a similar expression profile to BCR-ABL1 leukemia. Moreover, GEP has shown that ALL with MLL rearrangements has a unique expression profile separate from other types of AML and ALL.

Epidemiologic and twin studies indicate a multistep pathogenesis of B-cell ALL in infants and children, with initial leukemogenic event(s) occurring in utero and subsequent genomic changes occurring postnatally. Twin studies provide insight into the pathogenesis of pediatric leukemia because most common chromosomal translocations and their resultant gene fusions can be documented by molecular analysis of neonatal blood spots or Guthrie cards. If a unique gene fusion sequence is present in at least one cell per 30,000 in peripheral blood, it will be detected by a sensitive PCR-based assay. The first observations of in utero origin of an acute leukemia were demonstrated for MLL rearrangements in three children with ALL, in monozygotic twins who shared the identical TEL(ETV6)–AML1 (RUNX1) fusion, and in a pair of twins diagnosed at age 3 with B-precursor ALL. The concordance rate of twins who share a monochorionic placenta and develop leukemia is probably 100%, whereas older twins have a discordance rate of 90%, indicating that additional postnatal leukemic events are needed. The frequency of in utero origin of B-cell precursor ALL in nontwins as measured by clonal IGH rearrangements is reported to be 71%, supporting the notion that in the majority of infants older than 1 year, the development of ALL occurs during fetal hematopoiesis. Subsequent physiologic postnatal switch may eliminate these abnormal clones in the vast majority of the cases; however, a small number of children have a "preleukemic" clone for some time, with later emergence of leukemia (see box on Genetic Testing for Acute Lymphoblastic Leukemia).

B-CELL CHRONIC LYMPHOCYTIC LEUKEMIA

Approximately 40% to 50% of CLL patients have clonal abnormalities identified by conventional cytogenetics (see Chapter 76). This may be an underestimation because chromosomal changes may occur in one or more cell subsets of the malignant clone. Classic cytogenetic analyses of B-CLL has remained difficult because of the low mitotic yield of neoplastic B cells despite the use of B-cell mitogens, such as 12-O-tetradecanoylphorbol-13-cetate (TPA) and stimulation with CD40 ligand and interleukin 4. Molecular cytogenetics, such as interphase FISH, CGH, and array CGH, have raised the detection rate to 80% to 90%. Analysis of clinically relevant chromosomal loci, combined with immunophenotyping, mutational analyses of the immunoglobulin heavy-chain variable region (IgV_H), and ZAP-70 overexpression, are of prognostic importance, even though oncogenic events that lead to the origin of B-CLL remain unknown (Table 54-11 and Fig. 54-35; see also box on Genetic Testing for B-Cell Chronic Lymphocytic Leukemia). Although microarray and high-density SNP array studies have not identified genes involved in the pathogenesis of CLL, they clarify that CLL, despite its heterogeneous nature, is one disease entity with a common genetic phenotype resembling memory B lymphocytes. Genetic testing is strongly recommended for all CLL patients, particularly in the context of novel therapeutic trials for CLL.

Genetic Testing for Acute Lymphoblastic Leukemia

At diagnosis, conventional cytogenetic studies should be performed, especially for pediatric patients in whom solely numerical anomalies occur in 25%. FISH and molecular genetic methods are valuable to detect certain cryptic chromosome anomalies, such as TEL/AML1 fusion associated with t(12;21)(p12;q22). The panel of FISH probe at the diagnosis of pediatric acute lymphoblastic leukemia includes TEL(ETV6)-AML1 (RUNX1), MLL, BCR-ABL, P21 at 9p, and centromeric probes for chromosomes 4, 10, and 17. In adults, the role of hyperdiploidy as it relates to prognosis is uncertain; thus FISH testing with centromeric probes is not useful. Establishing benchmarks with FISH and/or molecular testing is crucial for follow-up of patients during and after therapy.

Genetic Testing for B-Cell Chronic Lymphocytic Leukemia

Interphase FISH is used in lieu of chromosome studies because FISH detection of abnormalities in chronic lymphocytic leukemia correlates with clinical risk groups and prognosis. FISH studies should be performed on blood for detection of trisomy 12, deletions of 11q22.3, 13q14.3, and P53 loci, as well as rearrangement of 14q32.3, IGH locus. The FISH test can distinguish between patients with B-cell chronic lymphocytic leukemia and those with the leukemic phase of certain lymphomas, such as mantle cell lymphoma and follicular lymphoma.

ALL, Acute lymphoblastic leukemia; *B-CLL*, B-cell chronic lymphocytic leukemia; *LPL*, lymphoplasmacytoid lymphoma; *MALT*, mucosa-associated lymphoid tissue.

Chromosome abnormalities in CLL detected by FISH are of prognostic significance.[22] Four genomic aberrations, as well as normal findings, are independent predictors of disease progression and survival. Genomic aberrations of prognostic significance include 17p deletion, 11q deletion, trisomy 12, and 13q deletion. Survival in these groups was 32, 79, 114, and 133 months, respectively, and the treatment-free interval was 8, 12, 33, and 92 months, respectively (see Fig. 54-35). Survival of patients with a normal karyotype was 111 months, and the treatment-free interval was 49 months. The deletion of 17p13 affects the tumor suppressor gene TP53. In 80% to 90% of the cases, a deletion of 17p is associated with the mutated TP53 on the remaining copy. This is considered one reason why p53 pathway-based therapies such as fludarabine or its combinations are not effective in patients with 17p deletion. TP53 genes have been found in 4% to 15% of patients in early-stage CLL and are associated with poorer outcome. Deletion of 11q and deletion of the ATM gene on 11q23.1 are found in 18% of CLL patients. In about one-third of 11q-deleted patients, a simultaneous mutation of the ATM has been found. The overall survival of these patients is shorter.

A comparison of known prognostic features of B-CLL with interphase FISH results indicates that FISH-detected anomalies are frequent in B-CLL cases, even in Rai stages 0 to 1, but are more frequent among patients with progressive disease (88%) than in those with stable disease (66%). Two risk groups are recognized: (a) low risk includes patients with a normal karyotype or isolated del(13q); (b) high risk includes patients with del(11q) and del(17p). Patients with +12 are high risk, but in contrast to del(11q) and del(17p), they respond to fludarabine-based therapies (Fig. 54-36). Comparison of a quantitative PCR method with FISH for assessment of the four most frequent aneuploidies revealed a tight correlation in 103 of 110 patients examined, with FISH being more sensitive in detecting subclonal genetic evolution.

The frequency of abnormalities of chromosome 13 in CLL detected by conventional cytogenetics is 10% to 15%. However, with the application of FISH, smaller or larger deletions of band q14.3 are detected in up to 60% of patients over time. When multiple DNA probes are used, D13S319 and D13S25 DNA markers are deleted more frequently in B-CLL than is RB1. Molecular analyses have detected deletions of 13q in cells that are cytogenetically normal as well as abnormal. Homozygous deletion of D13S25 and/or D13S319 DNA segments from the 13q14.3 band region is a rare but consistent finding in a subset of patients with B-cell CLL. In a study examining loss of heterozygosity and subchromosomal copy losses on chromosome 13, two types of deletions were defined: type 1 aberrations occurred in 60% of del(13)(q14) cases and had loss of Rb1 and breaks close to the miR16/15a locus; and type 2 aberrations that included Rb1 occurred in 40%. As mentioned earlier, the 13q14.3-deleted segment contains micro-RNA (miRNA) genes. Micro-RNAs are normally made by cells, including B lymphocytes, and they regulate the function of many genes. Preliminary findings demonstrate that all patients with homozygous 13q deletion have dramatic miRNA15a downregulation, whereas patients with hemizygous 13q deletions are indistinguishable from controls, providing the first molecular clues for the genetic basis and pathogenesis of CLL.

Trisomy 12 or 13q rearrangements are found separately in a substantial proportion of patients with CLL. They coexist in only 2% to 5% of patients, suggesting that each change may have a distinct pathogenetic route. The presence of del(13q) as the sole abnormality in CLL is associated with the most favorable prognosis, with a median survival of 11 years.

Among the first-degree relatives of patients with familial CLL, population studies have demonstrated a sevenfold increased risk for developing CLL and a twofold increased risk for developing lymphoproliferative disorders. More than 80 families with CLL affecting multiple family members have been reported. Linkage studies suggest a region of interest in band q22.1 of chromosome 13 (marker D13S156). Fine FISH mapping of six CLL-prone families (63 individuals) reveals deletion of 13q14 in 85% of patients with familial CLL, and four CLL families shared a 3.6-Mb minimal region in 13q21.33-q22.2. This region included 12 candidate genes, but thus far informative candidates have not been identified.

Trisomy 12 was the first reported recurrent abnormality in CLL. It is detected by classic cytogenetics in 7% to 15% of all cases. FISH assessment detects +12 in 15% to 20% of patients with CLL. FISH studies are more representative of the true incidence of trisomy 12 because the interphase FISH methodology provides information on cells independent of their cycling status. Trisomy 12 may be present as the sole abnormality or in combination with other chromosomal rearrangements. Because only a proportion of cells are trisomic, normal cells or disomic neoplastic cells also may be present. Follow-up analysis over a 4-year period demonstrates clonal expansion of cells with trisomy 12 as the disease progresses. These observations suggest that trisomy 12 might be relevant in the cell activation process in CLL. The observation that trisomy 12 is documented in B cells and is absent from T lymphocytes and CD34 cells in the majority of patients is consistent with the original hypothesis that CLL has a clonal origin and that trisomy 12 arises in a progenitor cell already committed to the B-cell pathway. Routine FISH testing identifies patients with trisomy 12 because it uses the probe that is hybridized only to the centromeric area of chromosome 12. More sophisticated molecular cytogenetic methods may be useful. Increased expression of the CLLU1 gene on 12q22 has been observed in CLL samples from patients with or without trisomy 12. Overexpression of CLLU1 in CLL patients without IgV_H hypermutation combined with restricted and CLL-unique expression pattern suggests that CLLU1 is among the first disease-specific genes identified in CLL.

Three recent studies utilizing whole genome sequencing detected NOTCH1 mutations in 42% of patients with trisomy 12. Almost all

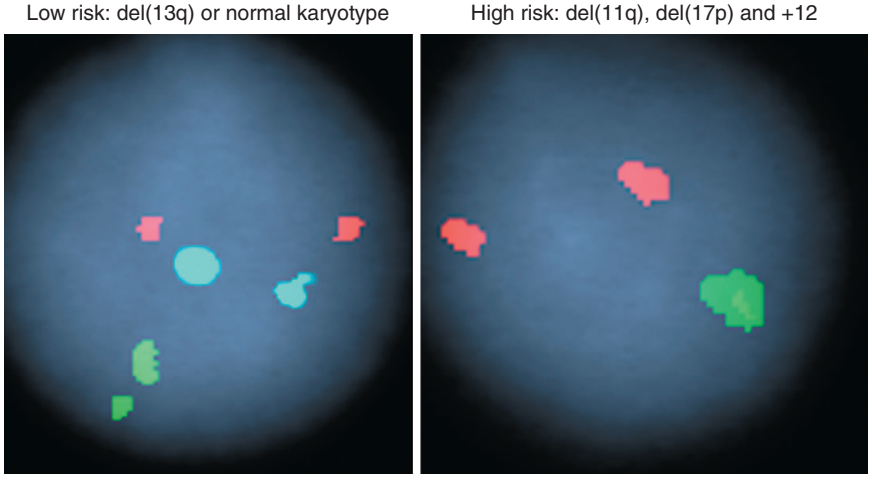

Figure 54-36 PANEL OF CHROMOSOMAL PROBES USED FOR DETECTION OF GENOMIC DEFECTS IN CHRONIC LYMPHOCYTIC LEUKEMIA. They include 13q14.3 *(red),* 13q34 *(aqua),* and CEP12 (all present in disomy; *left*) and 11q22.3 (ATM, *green*) and 17p13.1 (P53*; red, right*). Note only one copy of the ATM gene *(green, right)* consistent with deletion of sequences from the 11q22.3 band region, which is associated with unfavorable prognosis.

NOTCH1 mutations resulted in a truncated protein, lacking the C-terminal PEST degradation domain, rendering it constitutively active. Deletions of the long arm of chromosome 11 in CLL as detected by conventional cytogenetics have been reported in 5% to 8% of cases. An interphase FISH study identified a clinical subset of B-cell CLL defined by deletion of 11q22.3-23.1 in 7% to 10% of these cases. FISH characterization of aberrations involved in 11q21-q23 demonstrate a minimal consensus deletion segment of 2 to 3 Mb, containing a number of genes including ATM at 11q22.3 (see Fig. 54-36, *right*). Up to 12% of patients have simultaneous deletions of ATM and MLL at 11q23. The ATM gene is responsible for ataxia-telangiectasia and functions as a cell-cycle checkpoint regulator. Somatic disruptions of both alleles of the ATM gene by deletion or point mutation are detected in 25% to 34% of cases. This finding strongly suggests the pathologic role of ATM in some patients with B-CLL. A study revealed discontinuous deletions at 11q23.1-q23.3, indicating that genes in this region may have pathogenic significance because they constitute independent targets for amplification or deletion in cases of B-CLL. Patients with 11q deletion exhibit extensive lymphadenopathy, more rapid disease progression, a shorter treatment-free interval, inferior molecular remission, and reduced overall survival. Structural aberrations of chromosome 17 are observed in 4% of cytogenetically evaluable B-CLL cases. This abnormality frequently affects the short arm of chromosome 17, the site of the P53 tumor suppressor gene. Monoallelic deletions of P53, detected by FISH, are present in 7% to 20% of patients and represent the strongest predictor of survival in B-cell CLL. The median survival time of these patients is only 32 months. A novel recurrent dic(8;17)(p11;p11) abnormality also leads to loss of TP53, and low copy repeats in 17p12 and 8p11 may the origin of the translocation by nonallelic homologous recombination on one chromosome 17. B-CLL in patients with deletion of the P53 gene is associated with refractory advanced disease, resistance to treatment, and shorter survival. A comprehensive assessment of genetic and molecular features predicting outcome in previously untreated CLL patients receiving either fludarabine or fludarabine plus cyclophosphamide identified del(17)(p13) along with del(11q), but not IgV_H, CD38 expression, or ZAP-70 status, as significant risk factors for early relapse. Because the leukemic phase of certain lymphomas can clinically mimic B-CLL, FISH testing for translocation using an IgH probe is important. Fewer than 5% of patients with CLL/prolymphocytic leukemia have t(11;14)(q13;q32), and these conditions usually transform into prolymphocytic leukemia. Moreover, IGH testing in CLL is important for detecting patients with recurrent del(14)(q24.1) associated with unmutated IgV_H status (66%) and trisomy 12 (47%).[23]

Solid evidence exists that chromosomal translocations detected by conventional cytogenetics independently predict treatment failure, treatment-free survival, and overall survival in untreated and cladribine-treated B-cell CLL patients. When CLL-derived metaphase cells are obtained with systematic stimulation using B-cell mitogens and activators, balanced and unbalanced translocations are seen in 34% to 42% of patients. In multivariate analysis, unbalanced translocations are independently associated with risk for treatment failure. Because del(13q) usually is cryptic by conventional cytogenetics but easily detected with FISH studies, both conventional cytogenetics and interphase FISH should be performed at baseline in patients with advanced CLL. Comparison of the performance between the custom made 44K oligonucleotide array platform with results obtained by FISH panel (including ATM at 11q22.3, D13S319 at 13q14,3 TP53 at 17p13.1 chromosomal site, and centromere 12 in 100 CLL samples) showed 89% concordance rate. The genomic imbalances and LOH, investigated by different resolution SNP arrays, showed 66% to 82% of genomic lesions including uniparental disomy. Currently, the 250K NSP array was validated for routine clinical use in the diagnosis of CLL and demonstrated 98.5% concordance with the standard CLL FISH panel.

The most novel gene mutation implicated in more rapid disease progression and poorer overall survival is a somatic mutation of SF3B1. The somatic mutations of SF3B1 gene, encoding a small nuclear RNA-splicing protein, were uncovered using the whole-exome sequencing of matched tumor and normal samples from 105 patients at a frequency of ≈10%. SF3B1 mutations were associated with more rapid disease progression and poor overall survival.

The validity of hierarchical interphase FISH categories at diagnosis in predicting overall survival of CLL patients is confirmed by long-term follow-up studies. Interphase FISH testing can identify approximately 27% of patients with clonal chromosomal evolution occurring after 5 or more years of follow-up, with approximately two-thirds of patients acquiring del(13q) and del(17p). These observations have important clinical implications for management of patients with highest-risk early-stage CLL.

In 2011, using next generation sequencing technique, a new phenomenon called *chromothripsis* (from the Greek *chromos,* meaning "chromosomes," and *thripsis,* meaning "shattering into pieces") was described for the first time and was identified in CLL. Chromothripsis describes a process whereby hundreds of genomic rearrangements have been acquired in a single catastrophic event. A chromosomal region or a chromosome or telomere of other chromosomes gets shattered into hundreds of pieces, some but not all are stitched together by the DNA repair machinery in a mosaic patchwork of genomic fragments. Cells not only survive this crisis but emerge with a genomic landscape that confers selective advantage, thereby promoting further malignant evolution. Subsequent evidence of chromothripsis has been described in other types of malignancies, including multiple myeloma, where it is accompanied by a poor outcome.

MULTIPLE MYELOMA

Multiple myeloma (MM) is a malignancy of terminally differentiated B cells (see Chapter 85). These plasma cells have a very low proliferative rate, a characteristic that has limited their application in cytogenetic studies. Conventional karyotyping reveals chromosome abnormalities in 25% to 30% of newly diagnosed patients, especially in cases with exceptionally high plasma cell proliferative rates. Karyotypes obtained from these cells usually are complex and exhibit more than 20 aberrations in approximately 10% of cases.

When reassessed by FISH, CGH, and multicolor karyotyping using a large panel of centromere-specific and translocation-specific probes, interphase plasma cell nuclei revealed chromosomal aneuploidy in almost all patients with MM or monoclonal gammopathy of unknown significance. Even during complete clinical remission, 12% to 71% of cells still show a numerical gain or loss of chromosomes 3, 7, 8, 9, 11, 13, 15, 21, and X.

Analysis of numerical abnormalities reveals two broad groups of MM patients: hyperdiploid and nonhyperdiploid. Approximately 55% to 60% of newly diagnosed MM patients are characterized by a hyperdiploid karyotype with a number of chromosomes ranging from 48 to 74 and trisomies of odd-numbered chromosomes including 3, 5, 7, 9, 11, 15, 19, and 21 and fewer IGH translocations (Fig. 54-37). The remaining patients are cases of hyperdiploid MMs that include tumors with hypodiploid, near diploid, pseudodiploid, or near-tetraploid chromosome numbers (fewer than 48 or more than 74 chromosomes), which are characterized by a high frequency of IGH translocations (>85%). Both these groups are also present in monoclonal gammopathy of unknown significance, suggesting that they occur early in the evolution of disease. The prognostic relevance of numerical abnormalities is difficult to ascertain because frequently, other adverse genetic changes are present in the same clone.

Nevertheless, patients with hyperdiploid MM tend to have a better prognosis than do those with nonhyperdiploid disease. A recent array-comparative genomic hybridization-based classification schema has identified a subset of patients who present with additional gains of 1q and/or losses of chromosome 13. These patients have a worse prognosis than do patients in the nonhyperdiploid group. More detailed analysis using genome-wide CNAs revealed numerical aberrations in 98% of cases and identified amplification of 1q and deletions of 1p, 12p, 14q, 16q, and 20p to be associated with poor

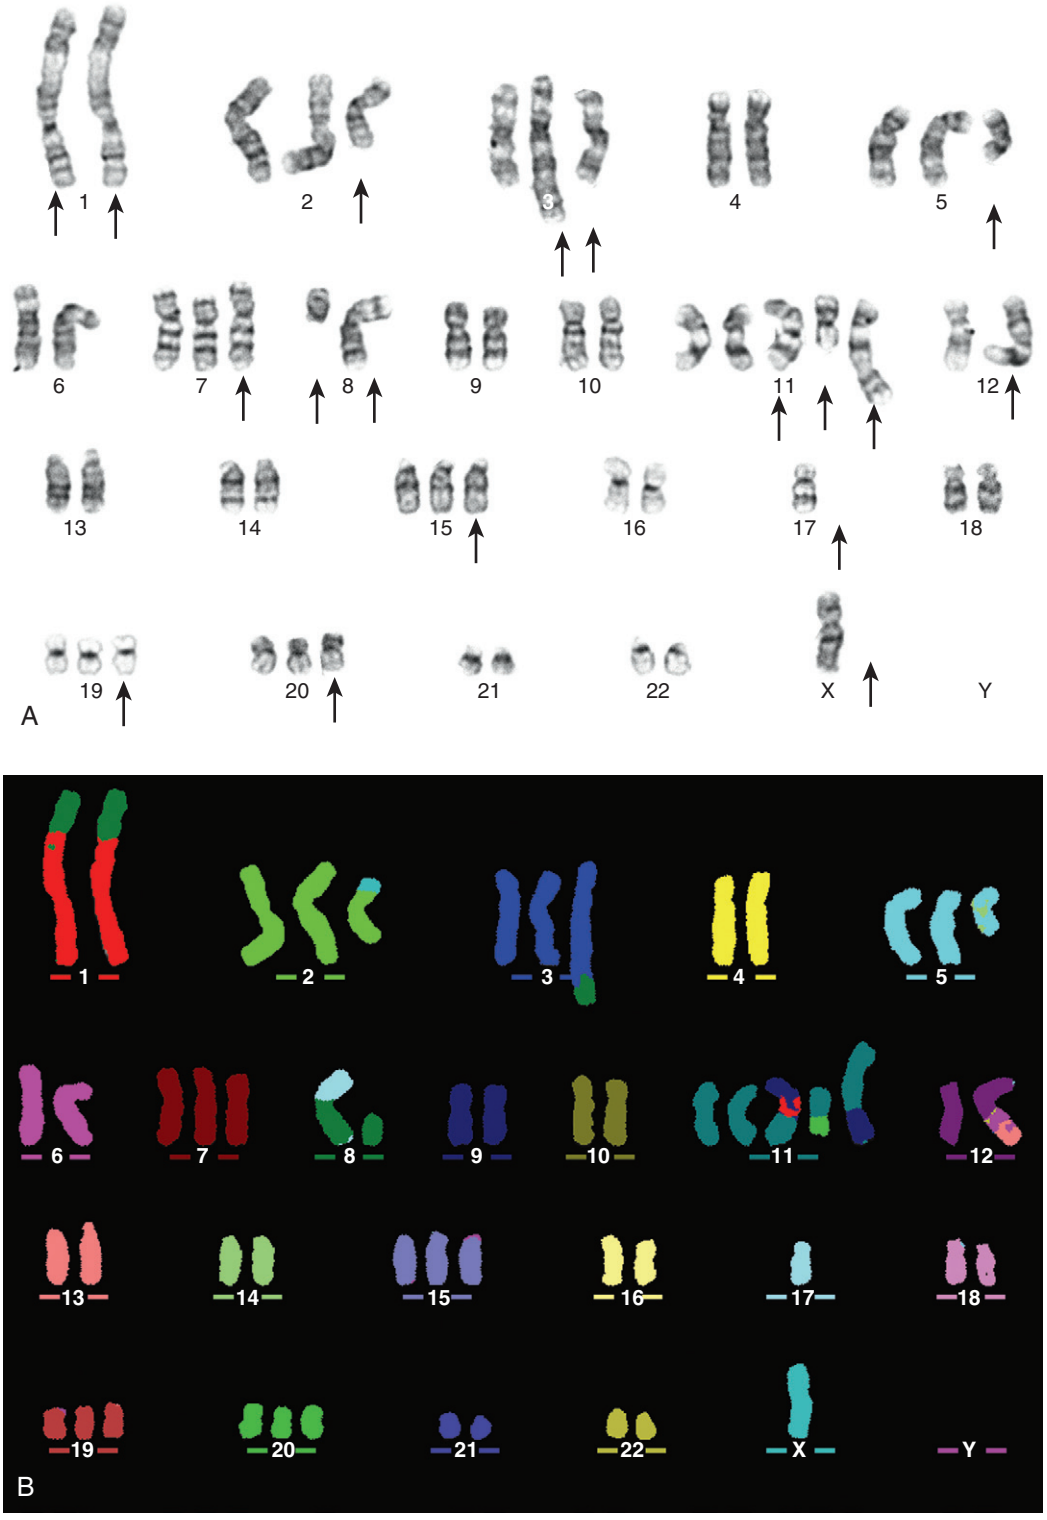

Figure 54-37 A complex hyperdiploid karyotype from a patient with multiple myeloma **(A)** and after multicolor FISH **(B)**, which was used to resolve a number of complex derivative chromosomes: 54, X, −X, der(1)t(1;8)(q34;q21q24)×2, der(2)del(2)(p13p25)t(X;2)(p21p22.3;p13), t(3;8)(q27;q22q24), +i(5)(p13p15), +7, der(8;17)(p23;q11.2q25), +der(11)t(1;9;11(?p36;q21q31;p15), t(11;20)(q13;q11.2, der(11)t(9;11)(q13q34;q25), t(12;13)9(p13;q14q34), +15, +19, +20.

prognosis, whereas amplification of chromosomes 5, 9, 11, 15, and 19 conferred a superior outcome. The Arkansas Multiple Myeloma Group pioneered the use of GEP as a highly sensitive method to stratify multiple myeloma patients in terms of outcome and to more fully characterize an individual's tumor at the molecular level. This group identified a distinctive 70-gene molecular signature (GEP70) for high-risk myeloma that correlated with a strong probability of early recurrence and shorter overall survival compared with patients with low-risk MM who had much greater probability of maintaining a longer-term remission[24] (Fig. 54-38). These 70 genes have overlapping functions and are involved in cell-cycle regulation, angiogenesis, cell adhesion, cell migration, and proliferation. When compared with standard metaphase and interphase FISH, the GEP70 gene signature significantly reduces the number of patients traditionally classified with a poor prognosis, while at the same time identifying those patients who may be at increased risk for relapse. The marked increase of GEP70 high-risk patients from 13% at diagnosis to 76% at relapse provides strong molecular evidence of disease evolution. GEP studies require plasma cell purifications and highly specific dedicated platforms (including very sophisticated bioinformatics), which are presently not widely available to the majority of physicians. However, GEP70 analysis and numerous other reports have demonstrated

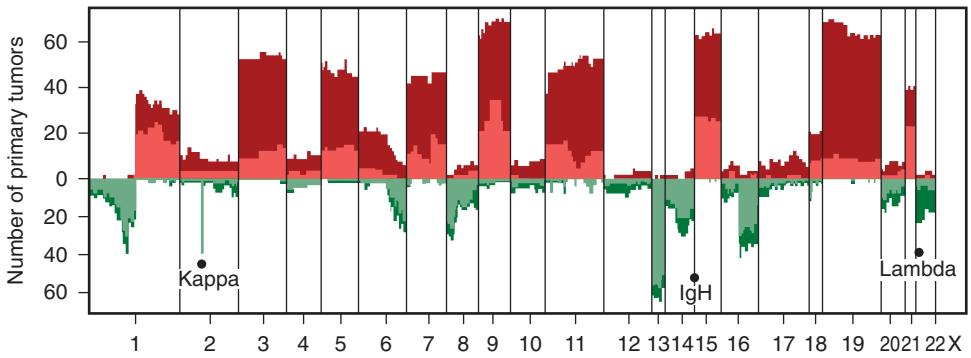

Figure 54-38 Summary of genomic profiles and recurrence of chromosomal alterations in primary tumors demonstrated by array comparative genomic hybridization. The recurrence plot mirrors the frequencies of previously reported chromosomal gains and losses, including the deletions of 1p and amplifications of 1q. Integer-value recurrence of copy number aberrations across the samples in segmented data is plotted on the y-axis. The x-axis is in chromosomal order. *Dark red* or *green* bands denote the number of samples with gain or loss of chromosome material, and *bright red* or *green* bars represent the number of samples showing amplification or deletion. *Black dots* show focal deletions of the kappa (2p12), IgH (14q32), and lambda (22q11) loci physiologic in B-cell postgerminal center neoplasms. *(Reprinted with permission from Carasco DR, Tonon G, Huang Y, et al: High resolution genomic profiles define distinct clinic pathogenic subgroups of multiple myeloma patients.* Cancer Cell *4:313, 2006.)*

that gains of 1q12-q44 are an independent marker associated with disease progression and that deletion of TP53 defines a group of patients with ultra high-risk MM (Figs. 54-39 and 54-40). Hence testing with FISH for 1q21 and/or 1q25 loci, as well for deletion of 17p13.1 chromosomal region, will identify patients with unfavorable prognoses (Fig. 54-41).[25]

Even with the application of GEP and SNP arrays, MM-specific oncogenes associated with hyperdiploidy have not been identified. However, in such a genetically heterogeneous group, it is anticipated that the application of novel cytogenomic technologies for detection of copy number aberrations may provide more precise and predictive tools.

It is believed that primary translocations occur early in the pathogenesis of MM, whereas secondary translocations occur late and are involved in tumor progression.[26,27] Most primary translocations are simple balanced translocations and juxtapose an oncogene and one of the immunoglobulin enhancers. An IGH rearrangement on 14q32.3 is found in most patients with MM. The rearrangement consists of complex and heterogeneous translocations with the breakpoint involving either the switch region of IGH or the V, D, or J gene (see Table 54-10). The primary translocations are due to somatic hypermutation or errors in the VDJ portion of the switch region recombination. The translocations include a promiscuous array of at least 20 nonrandom chromosomal partners, and the characterization of these translocations has led to the identification of critical dysregulated oncogenes (e.g., BCL2, cyclin D). In each translocation, a potent enhancer is juxtaposed to dysregulated oncogenes. The five most frequent IGH translocations are t(4;14)(p16.3;q32.3), t(6;14)(p21;q32.3), t(11;14)(q13;q32.3), t(14;16)(q32.3;q23), and t(14;20)(q32.3;q12) (Table 54-12 and Fig. 54-42).

Patients with a recurrent CCND1-IGH have an overexpression of cyclin D1. In contrast to mantle cell lymphoma, breakpoints on 11q13 in MM are not clustered but are scattered over a relatively large genomic region. Virtually all MM and MGUS tissues have cyclin D dysregulation, suggesting an early and unifying pathogenetic event. (see Fig. 54-40, *bottom left*). In contrast to other abnormalities involving the IGH locus, clonal t(11;14) MM cells, which occur in 15% to 20% of MM patients, tend to be diploid. There appears to be an association of the t(11;14) with oligosecretory or light chain only, CD20 expression, and lymphoplasmacytic morphology.

Approximately 15% of patients have a recurrent t(4;14)(p16.3;q32.3) abnormality. This cytogenetic abnormality is associated with IgA subtype, λ light chain, immature plasma cell morphology, and poor response to therapy. This abnormality is cytogenetically cryptic

Table 54-12 Most Frequent Chromosomal Abnormalities in Multiple Myeloma and Their Frequencies

Genetic Lesion	Frequency (%)	Oncogenes/Fusion Genes
TRANSLOCATIONS		
t(4;14)(p16.3;q32.3)	15	FGFR3, MMSET-IGH
t(11;14)(q13;q32.3)	15-20	CCND1-IGH
t(14;16)(q13;q23)	5-10	MAF-IGH
t(8;14)(q24;q32.3)	<10	MYC-IGH
t(14;20)(q32.3;q11)	5	IGH-MAFB
GAIN OF CHROMOSOMAL REGION		**CANDIDATE ONCOGENES**
1q21-q22	55	BCL9, IL6R
3q27.1-3q27.2	47	POLR2H, EIF4G1
5p12	44	?
7p11.2	44	?
9q34.11-9q34.3	54	ABL1, ANAPC2
11q13.4-11q14.1	52	SPCS2
15q24.2	44	IMP3
19q13.1	47	PDCD5
21q22.3	37	MCM3AP, HRMT1L1
LOSS OF CHROMOSOMAL REGION		**CANDIDATE TUMOR SUPPRESSOR GENE**
1p13.1-1p12	41	DENND2D
8p23.3-8p21.3	28	DLC1
10q26,2-10q26.3	18	PTPRE
13q34	49	RFP2, micro RNA 15/16
1432.13-13q32.2	33	?
16q11.2-16q12.3	31	CYLD

Modified from Anderson KC, Carrasco RD: Pathogenesis of myeloma. *Ann Rev Pathol* 6:249, 2011.

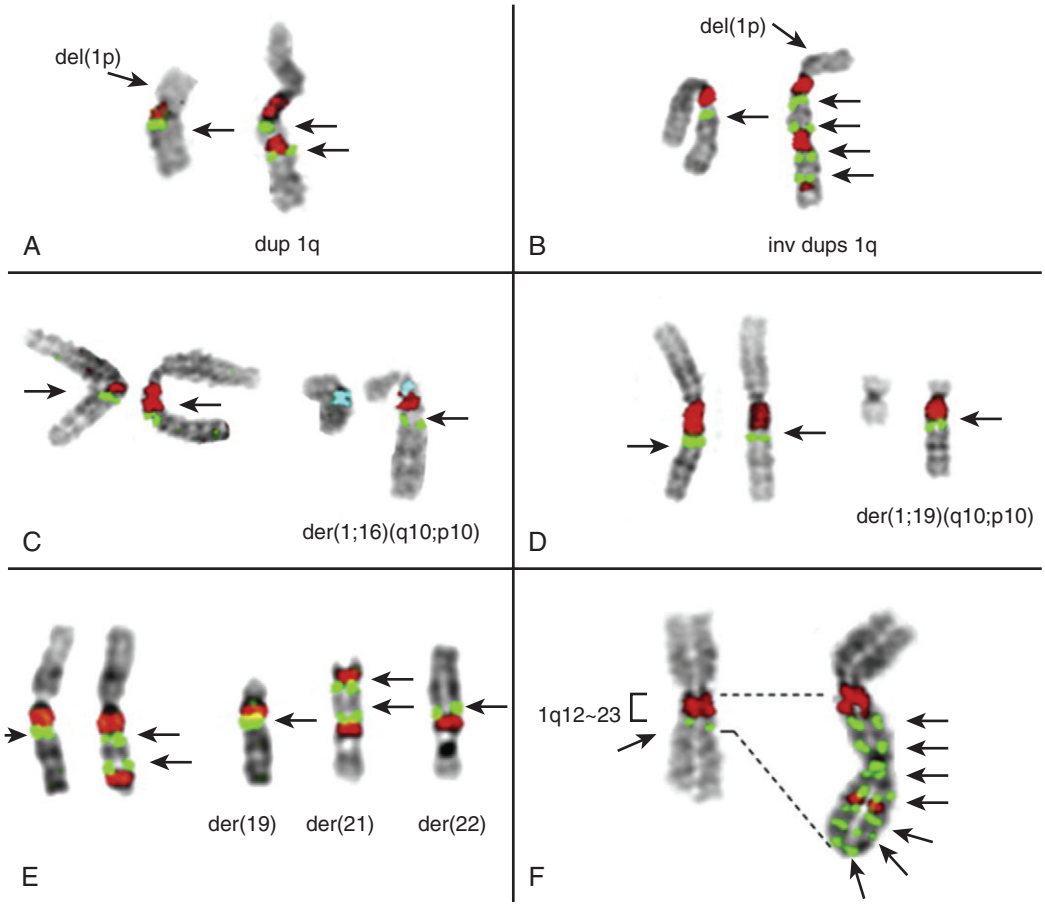

Figure 54-39 REPRESENTATIVE PARTIAL KARYOTYPES OF METAPHASE CHROMOSOMES DEMONSTRATING THE DIFFERENT TYPES AND DEGREE OF AMPLIFICATION OF CHROMOSOME 1. FISH probes for 1q12 *(red),* 1q21 *(green),* and 16q11 *(aqua)* are shown on inverted DAPI images of chromosomes. **A**, Interstitial deletion of 1p *(arrow)* in the homolog on the left and a direct dup1q12-q23 on chromosome on the right. **B**, Normal homolog 1 on the left and the abnormal homolog on the right, demonstrating both an interstitial deletion of 1p and the amplification of 1q in the same chromosome. Note four copies of 1q21 *(arrows)* in an inverted duplication pattern. **C**, Examples of an unbalanced whole-arm translocation of 1q to chromosome 16q. Chromosomes 1 are on the left, and chromosomes 16 are on the right. Aqua probe denotes 16q11 heterochromatin. Note the loss of 16q distal to the aqua probe on the der(1;16)(q10;p10). The entire long arm 1q is translocated to the pericentromeric region of 16q, and a total of three copies of 1q21 *(arrows)* are present. **D**, Examples of an unbalanced whole-arm translocation of 1q to 19q. Note that the result of this translocation is the der(1;19)(q10;p10) chromosome, which shows an extra copy of 1q21 *(arrows)* and loss of the entire 19q. **E**, Examples of jumping 1q, in which all or a part of 1q is translocated to three copies of 1q *(arrows)* on the three different nonhomologous chromosomes. The whole-arm der(19)(q10;p10) in this case is the same type seen in patient in **D.** The der(21) results from the segmental translocation of the inverted dup of 1q to the short arm of 21. The der(22) results from the whole-arm 1q translocated to the short arm of 22. **F,** Homologous of chromosome 1 demonstrating amplification of 1q12-q23 by breakage-fusion-bridge (BFB) cycles. Note multiple copies of 1q21 *(arrows)* on the abnormal homologue on the right. The copies of the 1q12-q23 amplicon occur in an inverted repeated pattern, with a deletion of the 1q distal to the amplified region. Dotted lines between normal homologue 1 *(left)* and abnormal homologue denote the size of expansion of the 1q12-q23 region by BFB cycles. *(Reprinted from Sawyer JR: The prognostic significance of cytogenetics and molecular profiling in multiple myeloma.* Cancer Genetics *204:3, 2011; with permission.)*

and is detected by FISH and other molecular cytogenetic methods. Two genes on chromosome 4p16.3 and the IGH switch region on 14q32.3 are involved. The fibroblast growth factor receptor 3 gene (FGFR3) is detected on der(14), where it is overexpressed along with a fusion of the multiple myeloma set domain (MMSET) gene, located on 4p16.3. This is the first example of a translocation that simultaneously deregulates two genes with oncogenic potential: the FGFR3 gene detected on der(14) and the MMSET gene detected on der(4). FGFR3 is 50 to 100 kb telomeric to MMSET. Loss of FGFR3 on der(14) is detected in approximately 20% of cases. A significant number of these patients display del(13q) in the same clone and are hypodiploid.

Translocation (14;16)(q32.3;q23) had never been cytogenetically detected because of the telomeric positions of both loci. However, with FISH studies the incidence of t(14;16) has been estimated to be approximately 2% to 8% of cases. In this translocation, the MAF protooncogene is translocated from its normal position on 16q23 to chromosome 14, band q32.3, and it is overexpressed. Rare variants t(14;20) and t(8;20) are included in this group because they share a similar gene expression signature and clinical outcome. The clinical outcome of patients with t(14;16) is significantly shorter compared with a t(14;16)-negative cohort.

A large number of secondary chromosomal aberrations are found during tumor progression, but four main aberrations include

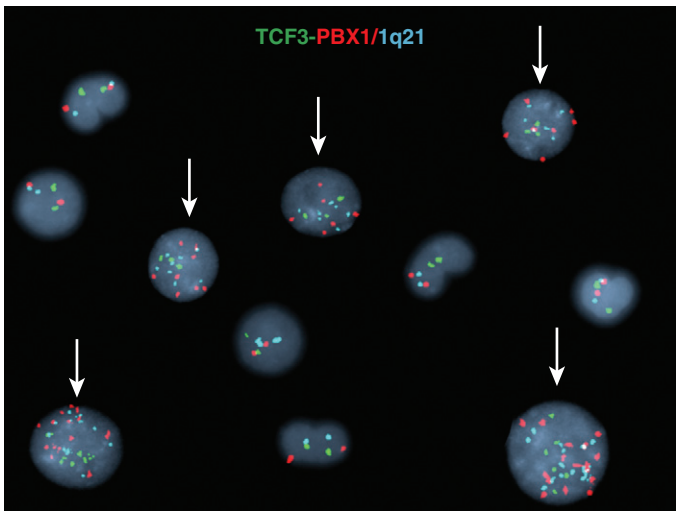

Figure 54-40 Bone marrow nuclei from a patient with multiple myeloma after hybridization using three probes 1q21 *(aqua),* PBX1 *(red)* localized on 1q25 and TCF3 *(green)* localized on 19q13. Note amplification (up to 17 copies) of 1q21 an2 1q25 *(white arrows),* as well as multiple copies of 19q loci. Amplification of 1q21-q25 is associated with disease progression and very poor prognosis in multiple myeloma despite novel therapies.

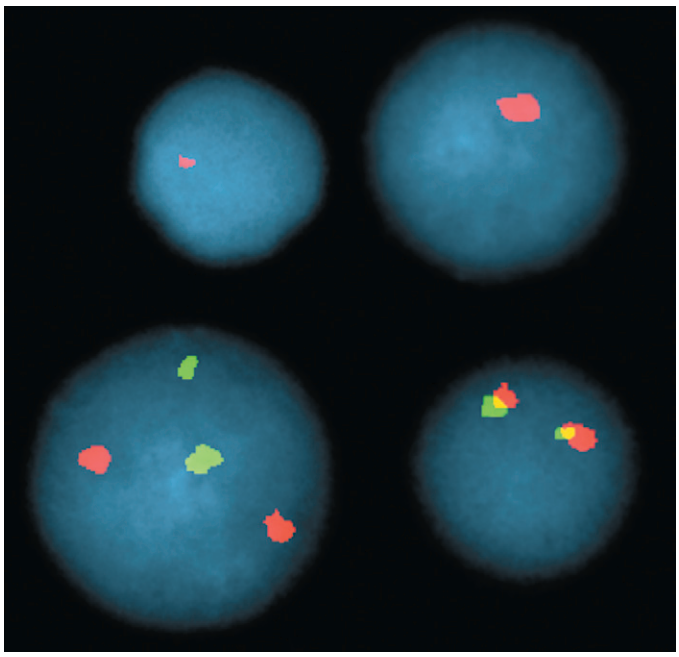

Figure 54-41 COMPOSITE IMAGE OF MARROW NUCLEI FROM A PATIENT WITH MULTIPLE MYELOMA AFTER HYBRIDIZATION WITH FIVE PROBES. The following probes are the most frequently used for detection of genomic structural rearrangements in clinical testing of multiple myeloma. *Top left cell* has 17p13.1 deletion (one red signal). *Top right nucleus* also shows a single red signal after hybridization with D13S319 probe, consistent with deletion of 13q14.3 locus. The patient had co-deletion of both loci, which is associated with unfavorable prognosis. *Bottom left cell* shows two green and two red signals after FISH study with CCND1 and IGH, indicating disomy for both probes and lack of CCND1-IGH fusion. Also shown are confirmatory results *(bottom right)* obtained after application of breakapart IGH probe, showing lack of separation of green and red signals, consistent with intact IGH gene.

translocations of MYC, the loss or deletion of chromosome 13, deletions of short arms and amplification of long arms of chromosome 1, and deletion of short arms of chromosome 17 predominates.

Translocations and/or amplification of MYC (8q24) may involve up to 45% of patients with an advanced MM, and they are frequently very complex and involve nonreciprocal rearrangements, duplications, and amplifications.

Deletion of either band q14 or q14.3 (RB1, DNA marker D13S319) on chromosome 13 is detected in 10% to 20% of patients by conventional cytogenetics and in 50% by FISH (see Fig. 54-40, *top right*). Microarray CGH data of the critical region on chromosome 13 are consistent with previous findings. Loss of the entire chromosome 13 (82%) is more frequent than is deletion of the long arms of chromosome 13. The most commonly deleted region has not been delineated. The median percentage of plasma cells carrying del(13q), identified by FISH, ranges from 75% and 90%. Deletion of 13q is associated with specific clinicopathologic features, including a higher frequency of λ-type MM, high plasma cell-labeling index, female predominance, and inferior survival after standard chemotherapy.

Numerous earlier studies have demonstrated that del(13q) represents an adverse prognostic marker in patients with MM treated with conventional low- and high-dose chemotherapy. However, more recent studies have demonstrated that del(13q) no longer has adverse prognostic significance in patients treated with bortezumib. However, molecular cytogenetics analyses revealed that del(13q) is present in 90% of patients showing t(4;14) or t(14;16); therefore the apparent adverse impact of del(13q) may not be the only genomic defect influencing unfavorable prognosis in these patients.

Deletion of TP53 at 17p13.1, which occurs in 10% of MM patients, is a powerful independent predictor of shortened survival and is associated with clonal evolution, drug resistance, and genetic instability (see Fig. 54-41, *top left*). This deletion is not found in patients with other high-risk abnormalities such as t(4;14) or t(14;16), and it appears mutually exclusive. Patients characterized by P53 deletion have significantly shorter overall survival regardless of therapy. The 17p deletion, identified by FISH as deletion of P53, is considered the most important molecular cytogenetic factor for prognosis.

The gain of 1q21 locus is identified in 45% of cases of monoclonal gammopathy of unknown significance, 43% of newly diagnosed MM, and 72% of relapsed MM, and it represents one of the most frequent recurrent chromosomal abnormalities in MM (see Figs. 54-40 and 54-41). Gain of 1q can be detected cytogenetically as isochromosome, duplications, or jumping translocations or detected with a 1q21-specific FISH probe. Among 479 patients with newly diagnosed MM, 43% with amplq21 also have either a hypodiploid and hyperdiploid karyotype, del(13q) by FISH, immunoglobulin A predominance, and poor prognosis compared with patients lacking amp1q21. A recent study of 92 patients treated with lenalidomide and dexamethasone demonstrated that del(17p) and gain of 1q21 are associated with a dismal overall survival, whereas the presence of t(11;14) or del(13q) as exclusive abnormalities had no impact on outcome. In the most comprehensive expression profiling survey of MM, reported by the Arkansas Multiple Myeloma Group using the previously mentioned GEP70, 30% of these genes were located on chromosome 1, with most of the downregulated genes located on the short arms of chromosome 1 and most of the upregulated genes on 1q. The clinical implication and significance of this finding is difficult to determine because of the lack of highly focal lesions and the lack of consensus of any critical genes on 1q21-q23. The mechanism for the amplification of 1q is believed to involve 1q12 pericentromeric instability, which most commonly increases the copy number of 1q by a direct and/or inverted duplication. Further instability can result in adding a whole-arm segment of 1q to nonhomologous chromosomes by jumping translocations of 1q. Two recurrent whole-arm unbalanced pericentromeric translocations are der(1;16)(q10;p10) and the der(1;19)(q10;p10). The 1q12-q23 amplicon has been reported to be formed by breakage-fusion-bridge (BFB) cycles of the 1q12 pericentromeric heterochromatin and the adjacent bands of 1q, resulting in an inverted repeat pattern of amplification of the

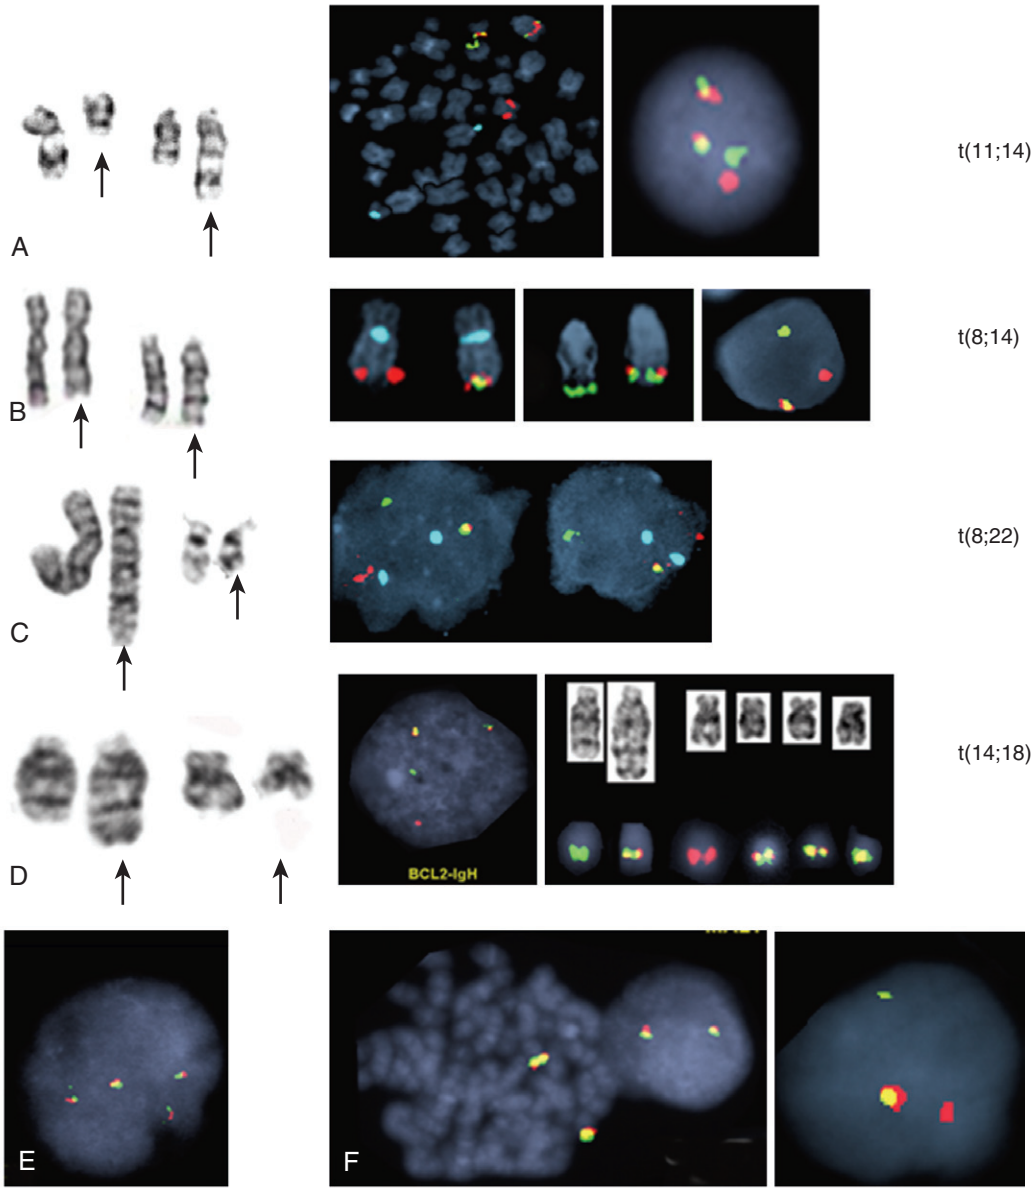

Figure 54-42 MOST FREQUENT CHROMOSOMAL ABNORMALITIES IN NON-HODGKIN LYMPHOMA. **A,** Partial G-banded karyotype of t(11;14)(q13;q32.3) *(left),* resulting in CCND1-IGH fusion *(yellow)* on metaphase *(middle)* and in interphase cell *(right)* present in the majority of patients with mantle cell lymphoma. **B,** Partial G-banded karyotype of t(8;14)(q24;q32.3) *(left),* resulting in MYC-IGH fusion [*yellow* on der(8) on isolated chromosomes]. Application of *MYC* breakapart probe shows separation of red and green signals consistent with MYC rearrangement. Approximately 80% of Burkitt lymphomas are characterized by t(8;14); **C,** Partial G-banded karyotype of t(8;22)(q24;q11), a variant of Burkitt lymphoma *(left).* Two interphase lymph node cells after hybridization with MYC breakapart probe and CEP8 *(aqua).* Separation of green and red signals is consistent with MYC relocation from 8q24 to 22q11: **D,** Partial G-banded karyotype of t(14;18)(q32.3;q21.3) *(left),* resulting in IGH-BCL fusion (two yellow signals, *middle*). A composite image on the right shows both a partial karyotype and FISH study of triplicated der(18) t(14;18) and three copies of *IGH-BCL2* fusion *(yellow),* as well as normal chromosome 14 and 18. Multiple copies of abnormal der(18) chromosome are associated with progressive disease similar to a duplication of the Philadelphia chromosome in the blast crisis of chronic myelogenous leukemia. **E,** Lymph node cell from a patient with diffuse large B-cell lymphoma (DLBCL), showing four copies of *BCL6* (breakapart probe). BCL6 is localized at 3q27 and is numerically or structurally rearranged in 35% of DLBCL. **F,** Bone marrow metaphase and interphase cell hybridized with breakapart MALT1 gene at 18q21 *(left)* indicating two fusion *(yellow)* signals when MALT1 gene is intact. In contrast, rearrangement of the MALT1 gene in MALT lymphoma usually is the consequence of t(11;18)(q21;q21.1)m as shown in the cell *(right)* with clear separation of the 3′ end *(green)* and the 5′ end *(red).*

1q12-q23 region. Copies of the 1q12-q23 amplicon can become integrated in complex multichromosome translocations during tumor progression.

The molecular basis of MM is slowly emerging, but the precise role of oncogenes is not yet defined. In order to address this issue and to understand the molecular basis of aneuploidy, work has evaluated the role of centrosome amplification in plasma cell neoplasms. Preliminary evidence indicates that centrosome amplification is common in all stages of plasma cell neoplasms, including monoclonal gammopathy of unknown significance, and probably is integral to disease

Genetic Testing for Multiple Myeloma

Chromosome studies of isolated plasma cells from the marrow are very useful at diagnosis. Perform interphase FISH and molecular genetic studies for detection of CCND1-IGH [t(11;14)], del(13)(q14.3)/D13S319, del(17)(p13.1)/P53, IGH/14q32.3, and 1q21 locus. If IGH rearrangements are detected using a breakapart IGH locus and CCND-IGH fusion is not identified, refine the partner and use the following set of probes: MAF-IGH for detection of t(14;16) and FGFR3-IGH for detection of t(4;14).

Genetic Testing for Non-Hodgkin Lymphoma

FISH testing can be performed on touch preparations, paraffin-embedded tissue, or bone marrow cells if bone marrow is involved. Peripheral blood cells are not appropriate for genetic testing of non-Hodgkin lymphoma. Bone marrow cytogenetics at diagnosis is not useful but may be important for staging in some cases. Fig. 54-42 lists the most useful FISH probes for detection of genomic defects in non-Hodgkin lymphoma. They include CCND1-IGH, IGH-BCL2, MYC-IGH, BCL6, MYC breakapart for detection of Burkitt variant not associated with t(8;14), and MALT1 breakapart for detection of t(11;18). For patients with suspected anaplastic large cell lymphoma, ALK breakapart probe should be informative.

pathogenesis and genomic instability of MM. Dickkopf-1 (DKK1) may be associated with the presence of lytic bone lesions in patients with MM.

Molecular abnormalities such as CCND1-IGH, IGH-MAF, and FGHR3-IGH are found in approximately 40% of patients presenting with MM. In the remaining 60% of cases, chromosomal translocations cannot be identified, but hyperdiploidy is present. These presenting features are followed by further karyotypic instability and often include deletions/monosomy of chromosome 13 or chromosome 17, band region p13.1 (P53) (see Fig. 54-41). Amplification of 1q21 represents a late event in this multistep process and is associated with a malignant phenotype. From a practical point of view (see box on Genetic Testing in Multiple Myeloma and Fig. 54-40), the report of the International Myeloma Workshop Consensus Panel 3 provided recommendations for standard investigative workup at diagnosis of MM. These recommendations included the standard metaphase cytogenetics, despite the low mitotic yield (<20%), in order to separate hyperdiploid from nonhyperdiploid patients and to capture uncommon structural chromosomal rearrangements. Patients should undergo FISH testing, preferably after sorting of plasma cells, with probes that include 1q21, 17p13, t(4;14), and t(14;16).

LYMPHOMA

Non-Hodgkin lymphoma (NHL) is a heterogeneous group of disorders characterized by localized proliferation of lymphocytes (see Chapters 78 through 84). Analogous to other hematopoietic disorders, the pathogenesis of these malignancies is attributable to a multistep process involving progressive and clonal accumulation of genetic lesions. The majority of NHLs are of B-cell origin and involve translocations of immunoglobulin loci (see Table 54-10 and Fig. 54-42). IGH translocations usually are detected by cytogenetics, often in conjunction with FISH probes that span the IGH loci and/or PCR-based technologies. These molecular abnormalities exhibit enormous complexity with multiple and complex translocations, deletions, and amplifications within one clone. The WHO recognizes that genetic anomalies represent one of the most reliable criteria for classification of malignant lymphomas. The most common associations between chromosome anomalies and specific lymphomas include t(14;18)(q32;q21) and follicular lymphoma; t(8;14)(q24;q32) and Burkitt lymphoma; t(11;14)(q13;q32) and mantle cell lymphoma; and t(11;18)(q21;q21) and mucosa-associated lymphoid tissue (MALT) lymphoma (see box on Genetic Testing for Non-Hodgkin Lymphoma and Fig. 54-42). However, identification of a specific translocation is not diagnostic of a specific lymphoma subtype. Chromosome studies are difficult and expensive for the study of lymphomas. Thus many investigators use FISH and/or molecular genetic methods to study touch preparations or paraffin-embedded lymphoid tissue to detect important genetic anomalies in lymphomas.

Approximately 85% to 90% of patients with follicular lymphoma and some patients with large cell lymphoma exhibit t(14;18)(q32.3;q21.3), which results in fusion of BCL2 on 18q21 and IGH on 14q32 and represents one of the most common abnormalities in NHL (Fig. 54-43, *D*). Although the exact underlying mechanism is not known, t(14;18) results from a mistake of VDJ recombination and juxtaposes the BCL2 oncogene with the nonexpressed IGH allele. As a consequence, the BCL2 gene comes under the control of IGH enhancer, causing dysregulated expression of BCL2 protein, one of the proteins involved in regulation of apoptosis. The breakpoints within BCL2 occur mostly within the 3′ region of the gene, whereas the breakpoints in IGH fall within the D_H and J_H regions. Although 75% of breakpoints are clustered within a remarkably narrow region of 15 to 20 bp at the 3′ end of the BCL2 gene, they are frequently missed by standard PCR. With regular and fiber FISH methods using BCL2 breakpoint flanking probes, individual 5′ and 3′ breakpoints can be detected. BCL2 rearrangements are detected with immunohistochemical staining for BCL2 protein. With disease progression, 100% of patients have BCL2 overexpression. Variant translocations, such as t(2;18)(p12;q21) and t(18;22)(q21;q11) involving the IGK or IGL gene, respectively, rather than IGH, also show overexpression of BCL2.[28]

Numerous secondary chromosomal abnormalities are identified by conventional cytogenetics, and at least five recurrent anomalies, each occurring in at least 20% of follicular lymphomas, may distinguish two subgroups of follicular lymphoma patients. Patients with t(14;18) showing additional trisomy for chromosome 2, 7, or 8 are associated with a more favorable course of disease compared with patients with additional del(1p), del(1q), del(6q), der(18), del(22q), or gain of chromosome 12 and X, which are associated with inferior outcome. Unfavorable outcome of patients with loss of X chromosome is confirmed by CGH, and del(6)(q25-q27) is identified as the strongest predictor of poor prognosis and shorter survival time. Rearrangements of chromosome 1, such as del(1)(p32-36), +1(p11-q44), and unbalanced translocations of der(1)(1;1)(p36;q11-23) regions are among the most frequent secondary chromosomal abnormalities in follicular lymphoma. Progression of follicular lymphoma to diffuse large B-cell lymphoma (DLBCL) occurs in 60% to 80% and is accompanied by accumulation of secondary abnormalities, of which homozygous del(9p) might be associated with histologic progression.

The combination of BCL-2 and MYC rearrangements resulting from t(8;14)(q24;q32) and t(14;18)(q32;q21) or variants in the same karyotype is characteristic of high-grade B-cell lymphoma/leukemia, which occurs in fewer than 2% of patients and is associated with aggressive histology and poor prognosis. In these cases, a translocation within a single IGH allele separates the 3′ from the 5′ IGH enhancer element, with relocation of the BCL2 5′ IGH enhancer fusion to the der(8) and translocation of MYC adjacent to the 3′ IGH enhancer element that is retained on the der(14). The ISCN cytogenetic description der(8)t(8;14)(q24;q32)t(14;18)(q32;q21), der(14)t(8;14)(q24;q32), der(18)t(14;18)(q32;q21) does not reflect the complexity of the underlying molecular rearrangements (see Fig. 54-43). Because one of the translocation may be cryptic, a combination of three FISH probes, labeled in three colors, is especially useful in identifying these complex translocations.

The IGH-BCL formation is believed to represent a very early event in the pathogenesis of follicular lymphoma. This notion is

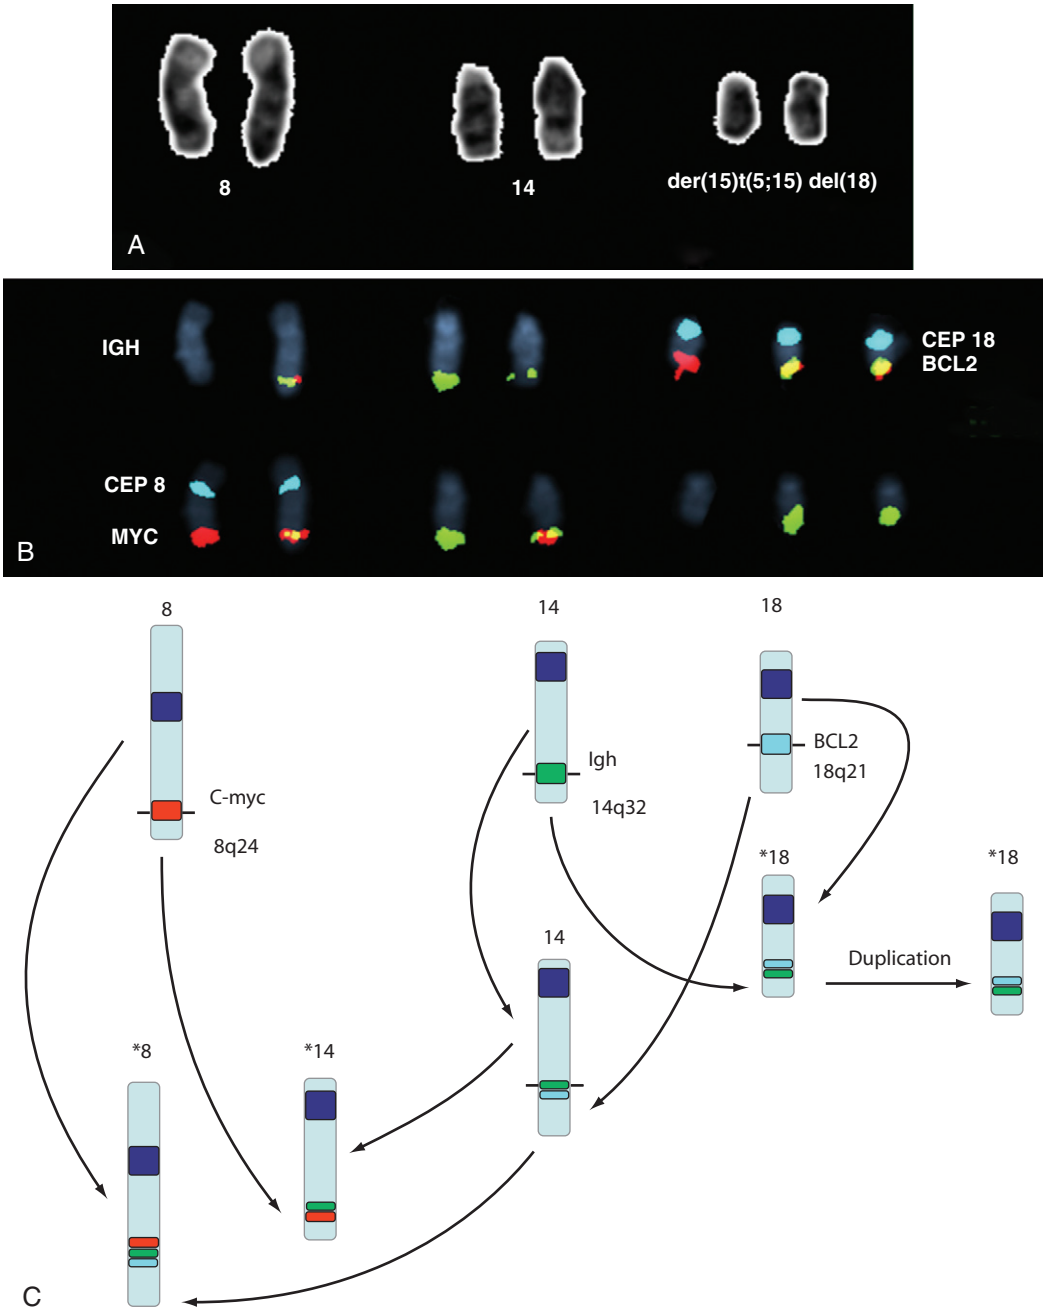

Figure 54-43 IDENTIFICATION OF SIMULTANEOUS BCL2 AND MYC REARRANGEMENTS IN HIGH-GRADE B-CELL LYMPHOMA LEUKEMIA (SEE TEXT FOR DETAILS). Partial G-banded karyotype **(A)** of chromosomes 8 and 14 and what is initially identified as der(15)t(5;15) and der(18). Partial karyotype of the same chromosomes after FISH study **(B)** with probes for IGH *(green),* CEP8 *(aqua),* and MYC *(red)* indicating IGH-MYC fusions *(yellow)* on both chromosomes 8 and 14. Sequential hybridization with CEP18 *(aqua),* BCL2 *(red),* and IGH *(green)* also revealed IGH-BCL2 fusion *(yellow)* on both der(15) and der(18), indicating that der(15) actually is a duplication of rearranged chromosome 18. **C,** Schematic representation of genomic events leading to duplication 18. Rearrangements of both *MYC* and *BCL2* show a complex molecular array.

supported by the observation that t(14;18) is also found in peripheral blood in more than 50% of healthy individuals and may persist for at least 3 years without overt disease. Because the incidence of follicular lymphoma in the United States is approximately 1 case per 24,000 persons per year, the occurrence of follicular lymphoma is relatively rare. GEP shows a distinct pattern associated with an indolent form of disease (median survival 11.1 years) and a more aggressive form (median survival 3.9 years), indicating that these different conditions may represent distinct stages in the evolution of follicular lymphoma. These and other observations point to an immune response that may regulate the pace of the malignant process and may restrain the proliferation of t(14;18)-positive B cells in healthy individuals. The molecular pathogenesis of follicular lymphoma may include formation of t(14;18) in a naive B cell. If stimulated by an exogenous agent such as a virus or autoantigen, a germinal center reaction may occur. Upon further stimulation by an antigen on the surface of a follicular dendritic cell, together with the T cell, a memory cell may form. This type of cell represents the majority of t(14;18)-positive cells identified

in the peripheral blood of normal individuals. Further oncogenic events and accumulation of different, recurrent chromosomal abnormalities in a stepwise pathogenesis may transform this cell into clinically recognizable follicular lymphoma.

Three translocations, all affecting the MYC gene at 8q24, have been recognized in Burkitt lymphoma. In 80% of patients a reciprocal translocation t(8;14)(q24; q32) is observed between the MYC gene and the IGH locus (Fig. 54-44). In the remainder of patients, the reciprocal translocation t(8;22)(q24;q11) or t(2;8)(p12;q24) is observed juxtaposing MYC to one of the light-chain loci (κ on 2p12 and λ on 22q11). The t(8;14) translocation originally was described in Epstein-Barr virus (EBV) tumor cells obtained from

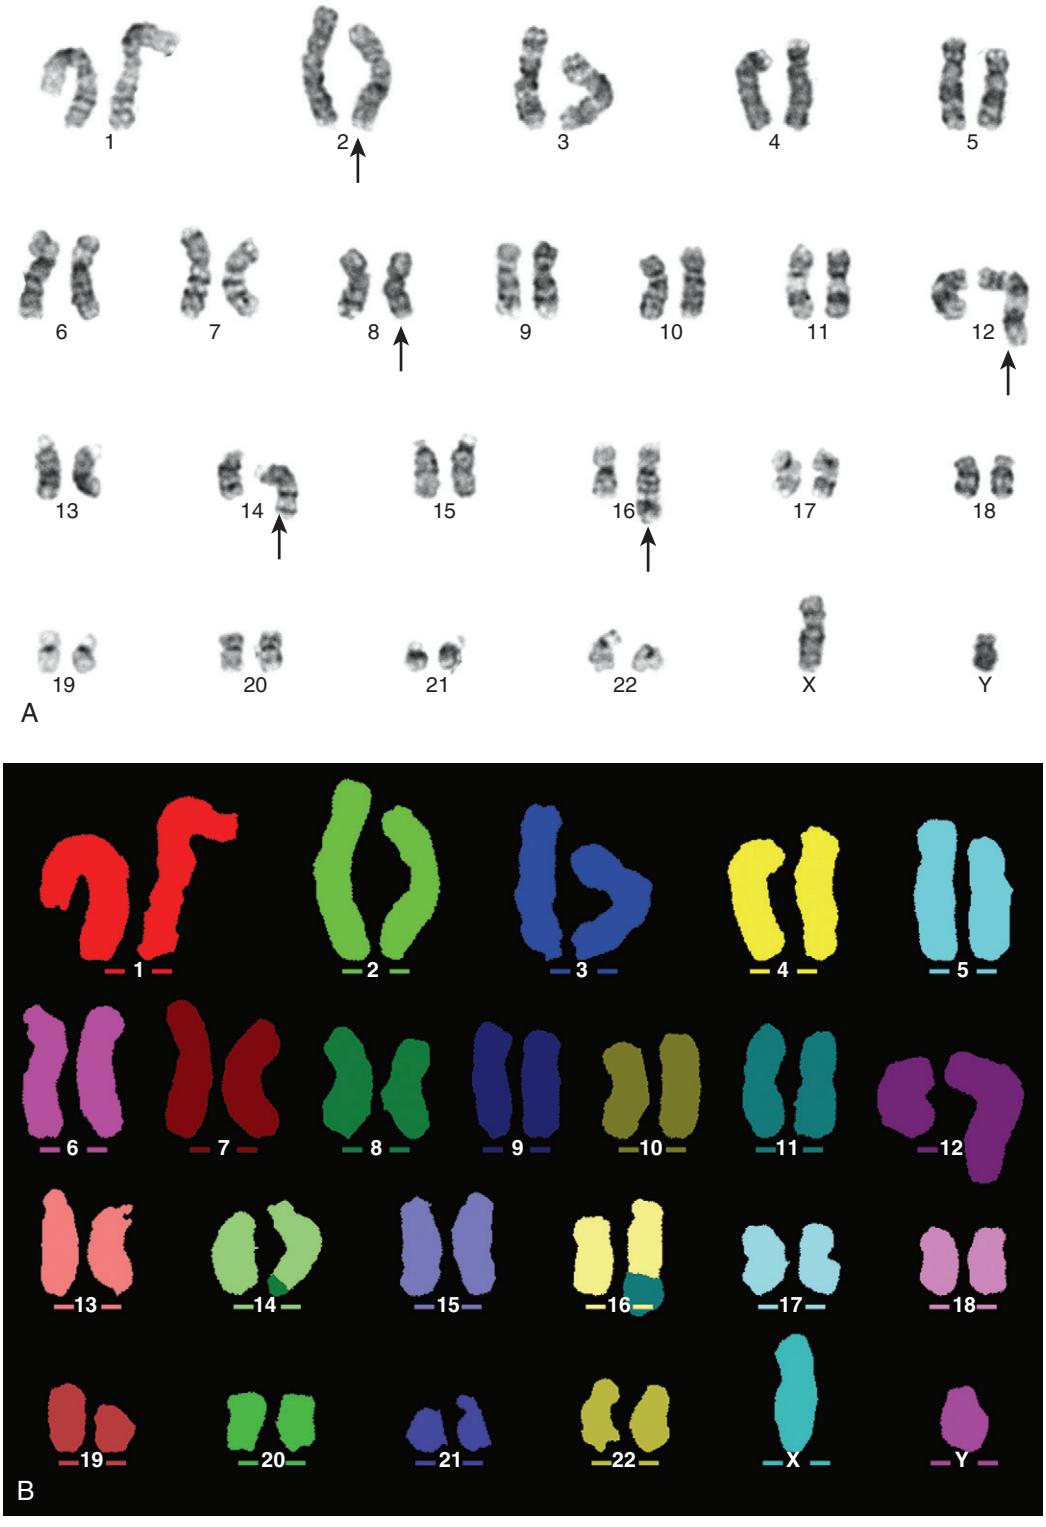

Figure 54-44 Bone marrow karyotype of a patient diagnosed in an advanced stage of Burkitt lymphoma **(A)** and after application of the multicolor FISH **(B)** to resolve complex derivative chromosomes, showing 46,XY, del(2)(p21p23), t(8;14)(q24;q32), dup(12)(q13q24.3), der(16)(t(11;16)(p11.2;q24) karyotype. *Arrows* indicate abnormal chromosomes. In addition to the classic t(8;14), both duplications of 11q and 12q were identified with multicolor FISH technology.

patients in Africa (see Fig. 54-44, *B* and *C*). Variant translocations involving MYC with a variety of other non-IG loci subsequently have been reported. In most patients with sporadic Burkitt lymphoma, the breakpoints on 8q24.1 are located on 5′ of the coding region of the MYC gene. In contrast, in most cases of endemic Burkitt lymphoma and in variant translocations, the MYC breakpoints are a considerable distance centromeric or telomeric from the MYC coding exons. As a result of the translocation, control of normal MYC is lost, and the intact protein is constitutively expressed throughout the cell cycle.

The MYC gene can function as both a transcriptional activator and a transcriptional repressor. As a result of t(8;14), there is transcription of a truncated MYC protein, whereas in t(2;8) and t(8;22) the rearrangement of the MYC gene can occur within sequences downstream of the transcribed region. The exact molecular mechanism by which the rearranged MYC is activated is not fully elucidated, but its activation constitutes an important step in malignant transformation. An increased level of MYC constitutive synthesis in leukemic disorders is found not only as a result of translocation but also as a result of MYC mutations and amplification. Approximately 65% of Burkitt lymphomas demonstrate MYC point mutations. Overexpression of MYC is linked to amplification of MYC genes reported in plasma cell leukemia, AML, CML, and T-cell lymphoma.

The most common secondary change associated with t(8;14) is duplication of the long arms of chromosome 1, and these rearrangements are associated with disease progression. A common duplicated region of 93 kb at 1q21.2 is defined by FISH studies. This section of chromosome contains at least three putative oncogenes, including the OTUD7B gene. This gene encodes a cytoplasmic protein and functions as a negative regulator of the nuclear factor (NF)-κB transcription factor, known to be implicated as a critical pathogenic factor in lymphoma.

Rearrangements of MYC can now be detected in nondividing cells as well as in paraffin-embedded lymph node biopsies using a very sensitive interphase FISH assay for t(8;14), with less than 2% false-positive results. Genomic profiling studies unequivocally demonstrated that the majority of patients with MYC rearrangements should be classified as Burkitt lymphoma, even though pathologists called some of the cases *diffuse large cell lymphoma*. However, these studies also indicate that rare cases with the Burkitt signature gene expression lack MYC rearrangements and have BCL2 rearrangements, suggesting that in rare cases MYC rearrangement alone may not be sufficient for diagnosis of Burkitt lymphoma.

According to the WHO classification, a Burkitt-like lymphoma is a separate entity characterized by one of the Burkitt lymphoma translocations. However, many such cases fail to show Burkitt lymphoma translocations but do exhibit increased MYC expression.

Approximately 35% of patients with diffuse DLBC and approximately 5% to 10% of patients with follicular lymphoma have rearrangements in the BCL6 gene normally residing at 3q27. Translocation of 3q27 is the third most frequent translocation in NHL, and at least 33 different partners have been described as participating in these rearrangements (see Fig. 54-42, *E*). The most frequent chromosomal band partners are 2p13, 4p13, 6p22, 7p12, 8q24, 13q14, 14q32, 18p11.2, and 22q11. These translocations juxtapose different promoters derived from other chromosomes, with the BCL6 coding domain causing persistent expression of BCL6.

Most of the breakpoints in 3q27 occur within a 10-kb region. The fact that the 3q27 region is affected in different lymphomas, irrespective of the translocation partner chromosomes, strongly suggests that alterations of BCL6, and not the reciprocal loci, are important in the pathogenesis. The alterations in 3q27 are too small for microscopic detection, so most of these rearrangements are detected by Southern blot analysis, PCR-based assay, or FISH. BCL6 functions as a transcriptional repressor of genes containing its binding sites; therefore the mechanism responsible for the malignant phenotype is transcriptional deregulation. The prognostic significance of BCL6 rearrangements is not clear, and different outcomes have been reported.

Approximately 3% to 4% of DLBCLs have t(14;15)(q32;q11-13), which results in fusion of the BCL8 gene on chromosome 15 to the V_H segment of the IGH locus. The most common secondary abnormalities are trisomies of chromosomes 3, 5, 7q, 11, 12p, 18q, and Xq, which are observed in greater than 10% of cases. Amplification of REL (2p12-16), MYC (8q24), BCL2 (18q21), GLI, CDK4, and MDM2 (12q13-14) genes, identified by a combination of molecular cytogenetic methods, are most frequently associated with advanced-stage disease. The most frequent monosomies include chromosomes 13, 14, and 15. A complex karyotype may have an adverse impact on prognosis.

Modern molecular cytogenetic methods such as CGH identify three major subgroups in DCLBC. Patients with activated B cell–like DLBCL (ABC-DCLBC) exhibit frequent trisomy 3, gains of 3q and 18q21-23, and loss of the 6q21-23 region. Patients with germinal center B (GCB)–like DLBCL have frequent gains of the 12q12 chromosomal region. Patients with primary mediastinal lymphoma (PMBCL) have gains of 2p14-p16 and 9p21-pter. Apparently, only gains in several regions of chromosome 3 are significantly associated with inferior survival. Moreover, genomic gains involving the 3p11-p12 region have an independent prognostic power for survival based on previously defined optimal gene expression–based models.

All patients with mantle cell lymphoma exhibit the t(11;14)(q13;q32) abnormality by FISH. t(11;14)(q13;q32) is also found in a variety of other B-cell malignancies, including MM, splenic lymphoma with villous lymphocytes, and B-cell prolymphocytic leukemia. Most breakpoints on chromosome 11, band q13, are dispersed over a region approximately 130 kb centromeric to the cyclin D1 (CCND1) gene. At the molecular level, the BCL1 locus (CCND1) on chromosome 11q13 is juxtaposed to an enhancer sequence within the immunoglobulin heavy-chain (IGH) gene on 14q32, leading to overexpression of the cyclin D gene, which is not expressed in normal B and T cells or in other malignant lymphomas. The consequence of this translocation is overexpression of cyclin D1, a gene involved in cell cycle control.

Each method for detection of t(11;14), including cytogenetics, Southern blot, and PCR-based analyses, has limitations. Cytogenetics is hampered by a low mitotic index of neoplastic B cells. Southern blot and PCR-based analyses for 11q13 rearrangements are positive in only 50% to 60% of patients with mantle cell lymphoma because the breakpoints within 11q13 are scattered along a 130-kb distance. In practical terms, dual-color FISH has proved to be the most sensitive assay for detection of IGH-CCND1 fusion, which is found in 100% of cases. Furthermore, the CCND1 fusion rearrangement can be detected in formalin-fixed, paraffin-embedded samples, making this method rapid, reliable, independent of cell cycle, and applicable to all cases of mantle cell lymphoma (see Fig. 54-42, *A*).

Gene expression studies have identified a subset of patients with D1-negative mantle cell lymphoma, so called because of the lack of cyclin D1 expression and t(11;14). However, both cyclin D1–positive and cyclin D1–negative patients have the same secondary genomic alterations when assessed with conventional cytogenetics, CGH, and array-based CGH. These secondary chromosomal alterations include gains of 3q, 8q, and 15q and losses of 1p, 8p23-pter, 9p21-pter, 11q21-23, and 13q. Some of the genes residing in these chromosomal regions are dysregulated and involved in cell proliferation, DNA repair mechanism of chromosome stability, and cellular homeostasis and apoptosis mechanisms. Unlike other lymphomas, in mantle cell lymphoma, DNA amplifications of several chromosomal regions appear to be associated with a blastoid variant. Loss of 9p21-pter, inactivation of TP53, gain of 3q, and high cyclin D expression are reported molecular and cytogenetic markers of shorter survival and a more aggressive clinical evolution. The prognostic value of 3q27-qer gains and loss of 9q21-32 region is determined to be independent of the gene expression-based signature. Extra copies of 3q are prognostic in patients with low proliferation, whereas loss of 9q has improved clinical value in a subgroup of patients with high proliferation.

Marginal zone lymphoma and MALT lymphoma are considered the third most frequent NHL subtype. According to the WHO classification, they are subdivided into splenic marginal zone lymphoma,

nodal marginal zone lymphoma, and MALT lymphoma. An etiologic link between low-grade gastric MALT lymphoma and the lymphoid reaction associated with *Helicobacter pylori* infection is well established. Growing evidence suggests that chronic antigenic stimulation in autoimmune diseases, such as Hashimoto thyroiditis, contributes to an increased risk for developing MALT lymphoma.

The most frequent and specific aberration occurring in MALT lymphomas is t(11;18)(q21;q21.1). Although it has been described in other B-cell lymphomas, t(11;18) in MALT lymphoma is usually the only genetic lesion and does not show additional chromosomal anomalies. It is the only recurrent translocation that does not involve IG genes, even though it presents as a B-cell lymphoma. As a consequence of t(11;18), API2 gene on chromosome 11, band q21, which encodes an inhibitor of apoptosis (also known as IAP2, HIAP1, and MIHC), and a novel gene MALT1 on chromosome 18, band q21, characterized by several Ig-like C2-type domains, are often rearranged. The resultant chimeric transcript consists of 5′-API2 and 3′-MAT located on der(18). More than 90% of breakpoints in the API2 locus occur in intron 7, whereas the breakpoints within MALT1 are variable and occur in four different introns. The API2-MALT1 fusion is easily identified using a dual-color API2-MALT1 FISH probe or the breakapart strategy of dual-color MALT1 probe on lymph node biopsies (see Fig. 54-42, *F*). However, detection of deletions and duplications occurring at high frequencies in both the API2 and MALT1 genomic sequences requires more precise molecular cytogenetic methods.

t(1;14)(p22;q32) and its variant t(1;2)(p22;p12) occur in less than 5% of MALT lymphomas, typically display other chromosomal abnormalities, and are associated with an advanced stage of disease at diagnosis (see reference list for more information). This translocation relocates the entire BCL10 gene from 1p22 to chromosome 14, bringing it under the control of an IGH enhancer. Currently, a specific probe for detecting BCL10-IGH fusion is not available, but IGH dual-color breakapart FISH strategy may determine IGH rearrangements without identifying the partner chromosome. The t(3;14)(p13;q32) abnormality, which results in fusion of the FOXP1F gene on chromosome 3 to IGH, is a rare rearrangement that causes FOXP1F overexpression. Its significance in lymphoma remains unknown. t(14;18)(q32;q21), which occurs in 2% to 18% of all MALT lymphomas, results in fusion of IGH-MALT. The 18q21 breakpoint involving the MALT1 gene is 5 Mb centromeric from the BCL2 breakpoint on chromosome 18 associated with follicular lymphoma. In contrast to API2-MALT1 cases, patients with IGH-MALT1 fusion have disease outside the gastrointestinal tract, usually presenting with ocular, skin, liver, or salivary gland tumors. FISH studies are useful for detecting the IGH-MALT fusion in paraffin-embedded lymph node biopsies. Although a unifying concept linking MALT-associated translocations to the pathogenesis of MALT lymphoma is not available, compelling evidence links these translocations to constitutive activation of the NF-κB pathway.

Lymphoplasmacytoid lymphoma (LPL) is a small lymphocytic lymphoma with plasmacytoid differentiation ($CD5^-CD10^-$) characterized by t(9;14)(p13;q32) in approximately 50% of cases. As a result of this translocation, the paired homeobox 5 (PAX5) gene on 9p13 moves to the IGH locus on der(14), causing dysregulation of PAX5. Molecular characterization of t(9;14) revealed that the coding region of the PAX5 gene remains intact in some patients. In those individuals, t(9;14) should be considered a regulatory mutation in which the PAX5 gene is brought under the control of the IGH locus. In other cases, molecular studies of t(9;14) reveal that the breakpoint occurs upstream of the PAX5 promoter, leading to insertion of the IGH enhancer upstream of the PAX5 gene.

Waldenström macroglobulinemia (see Chapter 86) is a plasma cell dyscrasia characterized by a CD138, CD19 phenotype, with a lympho/plasmacytic clonal expansion in the marrow. The biologic nature is different from lymphoplasmacytoid lymphoma because patients do not display t(9;14)(p13;q32). Recurrent chromosomal abnormalities include deletion of the long arms of chromosome 6 in 55% of cases by cytogenetics and in 21% of cases by FISH. Trisomy 4 is present in approximately 20% of cases. In contrast to other B-cell disorders, abnormalities of IGH at 14q32 as measured by FISH and Southern blot are rarely identified in Waldenström macroglobulinemia.

Not much progress has been made in delineating recurrent chromosomal abnormalities in Hodgkin lymphoma (HL) (see Chapters 72 and 73). Less than 1% of the cells in HL are Reed-Sternberg cells, of B-cell origin, and the paucity of dividing tumor cells for karyotype analysis has represented a major obstacle for conventional cytogenetics. In one study, simultaneous fluorescence, immunophenotyping, and interphase FISH (FICTION) demonstrated numerical aberrations of CD30 cells in all HL patients. The most specific chromosomal abnormalities in HL are hyperdiploidy/tetraploidy with tremendous variations in chromosome number, indicating heterogeneity from patient to patient. Even with use of nine different centromeric probes, no specific numerical chromosomal abnormality has been identified. Deletions of 1p, 4q, 6q, and 7q are recurrent, and JAK2, located on 9p21, frequently is amplified in patients with HL. Another gene, c-REL, on chromosome 2, band region p14-p15, is amplified in 50% of patients. Of note, c-REL is under the influence of NF-κB transcription factor, and constitutive NF-κB activation is a critical prerequisite for HL/Reed-Sternberg cell survival and proliferation. Thus it appears that constitutive NF-κB activation is the unifying concept and the hallmark of HL.

T-Cell Lymphoproliferative Diseases

This is a diverse group of hematologic disorders. The group includes T-cell ALL and T-cell CLL/promyelocytic leukemia, as well as several indolent or small T-cell disorders, large granular lymphocyte leukemia, natural killer leukemia/lymphoma, and anaplastic large cell lymphoma (ALCL).

T-cell ALL represents 15% of childhood ALL cases and 25% of adult ALL cases. At diagnosis, approximately 50% of patients have a normal karyotype. Table 54-11 lists recurrent cytogenetic and molecular genomic changes associated with T-cell ALL. Immunophenotypic and gene expression analyses are consistent with genetic heterogeneity in T-cell ALL, reflecting, to some degree, distinct stages of T-cell maturation arrest.

One of the common themes in T-lymphoid malignancies is the juxtaposition of T-cell receptor (TCR) gene enhancer element adjacent to a variety of transcription factors located at or near breakpoints on the partner chromosome. The chromosomal bands most frequently involved are 14q11, where TCRA and TCRD are located; 7q35, the site of TCRB; and 7p15, the site of the TCRG. TCR translocations are found in approximately 35% of T-cell ALL cases (see Table 54-12). The rearrangements of TCRB and TCRG are relatively rare, whereas 14q11 rearrangements involving both TCRA and TCRD are frequent in T-lymphoid neoplasms[29] (Table 54-13).

In children, the overall frequency of T-cell ALL translocations is 40% to 50%, and several molecular/cytogenetic abnormalities have prognostic relevance (Table 54-14). TAL1 rearrangements include t(1;14)(p32;q11), t(1;7)(p32;q35), rare t(1;3)(p32;p21), and t(1;5)(p32;q31). Generally, TAL1 rearrangements are submicroscopic and

Table 54-13 Frequency of TCR Rearrangements Using Conventional Cytogenetics Versus FISH

Modified from Graux C, Cools J, Michaux L, et al: Cytogenetics and molecular genetics of T-cell acute lymphoblastic leukemia: From thymocytes to lymphoblast. *Leukemia* 20:1496, 2006.
ALL, Acute lymphoblastic leukemia; *TCR*, T-cell receptor.

best identified with FISH. They are observed in approximately 3% of patients with T-cell ALL and are more frequent in pediatric ALL than in adult ALL. In children, rearrangements involving the TAL1 gene occur at a frequency of 20% and tend to be associated with better outcome. TAL2, residing at 9q32, is detected in rare t(7;9)(q34;q32) as a result of juxtaposition of TAL2 to TCRB. LYL1, originally described as a fusion partner of TCRB in rare (7;19)(q34;p13), is associated with poor prognosis. Rearrangements of HOX11L2, which include cryptic t(5;14)(q35;q32), t(5;7)(q35;q21), and other variants, occur at a frequency of 24% in children and represent a predictor of poor outcome, regardless of treatment strategies. Similarly, the presence of t(10;11)(p13;q14), which results in the CALM-AF10 fusion gene and occurs at a frequency of 2% to 5% in children, may be associated with poor outcome. Abnormalities of

HOX11 are more common in adults (31%) than in children (7%) and are associated with t(10;14)(q34;q24) and t(7;10)(q34;q24). According to the French collaborative study, t(10;14) is the most frequent chromosomal translocation in patients with T-cell ALL. It is associated with excellent outcome in both children and adults. In t(10;14) the homeobox gene HOX11 (TCL3) is fused with TCRD. The coding regions of HOX11 are not disturbed by the translocation. In the variant translocation t(7;10)(q35;q24), HOX11 is juxtaposed to TCRB, which results in overexpression of normal HOX11 mRNA by bringing HOX11 under the influence of TCR promoter sequences.

MLL rearrangements are present in 8% of T-cell ALL cases. The most frequent MLL translocation partners in T-cell ALL include ENL, which results from t(11;19)(q23;p13.3) and is associated with better prognosis than are other fusion partners. Gene expression profiling data characterized T-cell ALL with MLL rearrangements as a distinct molecular subtype with specific molecular signature. Homeobox genes, regulators of embryonic development, are known targets of MLL and are overexpressed in patients with T-cell ALL and MLL rearrangements.

Deregulation of NOTCH, tyrosine kinase genes (ABL1, JAK2), and LIM domain genes (LMO1, LMO2) is also common in T-cell ALL. NOTCH1 has been discovered to be a fusion partner of TCRB in t(7;9)(q34;q34.3). These mutations are present in 56% of T-cell ALL cases. The NOTCH1 gene is important in lymphocyte lineage specification, and resequencing of functional domains of NOTCH1 revealed that activating NOTCH1 mutations are present in most primary pediatric and adolescent molecular subtypes of T-ALL. Three types of NOTCH1 mutations have been described: those in the heterodimer domain, those in the PEST domain, and rarely, as internal tandem duplications of the juxtamembrane portion (7 of 210 of pediatric T-ALL). Mutations in heterodimer domain and internal tandem duplication result in constitutive ligand-independent activation of NOTCH1.

The LIM family of genes is found at the breakpoint of rare but consistent chromosomal translocations in T-cell ALL. LMO1, located at 11p15, is involved in t(11;14)(p15;q11). LMO2, located at 11p13, is involved in t(11;14)(p13;q11) and t(7;11)(q35;p13). As an oncogenic transcription regulator, LMO2 overexpression in erythroid and T cells leads to differentiation arrest, which is a prerequisite for development of T-cell malignancies 30.

The C-MYB gene, which is localized on chromosome 6, band q23.3, in normal cells, is rearranged in rare T-cell ALL subtype observed in young patients (median 2.2 years). Two types of recurrent C-MYB genomic alterations are found in T-cell ALL: (a) a reciprocal t(6;7)(q23;q34) that results in juxtaposition of C-MYB near to TCRB regulatory sequences on chromosome 7 and (b) a short genomic tandem duplication, identified using genome-wide copy-number analysis. Both rearrangements are cytogenetically cryptic. The breakpoints in t(6;7) are subtelomeric and usually missed. The translocation was discovered using a locus-specific FISH probe for C-MYC. The tandem MYB duplication is cryptic using both conventional cytogenetics and locus-specific FISH. It is mapped using high-density oligonucleotide array CGH. Discovery of MYB highlights the strength of high-density array CGH in identifying cryptic copy-number abnormalities associated with leukemia.

Although only 1% of Ph-positive ALL consist of patients with T-cell ALL, the ABL1 gene, which is involved in BCR-ABL1 fusion-positive B-cell ALL and CML, is also involved in fusion with Nup21, creating the Nup214-ABL1 chimeric gene, which is identified in up to 6% of T-cell ALL cases. Additionally, this fusion gene is found amplified only in T-cell ALL. When identified with FISH using ABL1 probe, it appears as an amplified episome between the chromosomes in metaphase cells. RT-PCR also can be used for its detection. Nup214-ABL1 is a constitutively activated tyrosine kinase activating similar pathways as BCR-ABL1 and is sensitive to inhibition with tyrosine kinase inhibitors, especially nilotinib and disatinib. These patients usually have homozygous or heterozygous deletion of CDKN2A at 9p21 chromosomal site and trisomy 8, t(7;10)(q35;q24), or t(10;14)(q24;q11) abnormalities. The estimated 5-year overall survival rate of these patients in one study was 49%. In rare cases of T-cell ALL, JAK2 has been identified as a partner chromosome with ETV6 in t(9;12)(p24;q13) (Fig. 54-45), one of the three JAK2 fusion transcripts seen in hematologic malignancies (see Ph-Negative Myeloproliferative Neoplasms, earlier, and Table 54-13).

Numerical changes are rare except for tetraploidy, which occurs in less than 5% of cases and is of unknown prognostic significance. In contrast, cryptic cytogenetic abnormalities revealed by FISH are frequent in ALL. They include deletion of 9p21 (INK4/ARF) and 1p32 regions. Deletion of 6q is less common, and the region 6q16 appears to be the common deletion band region.

In contrast to childhood B-cell ALL, the majority of childhood T-cell ALL cases develop after birth. In utero origin of this leukemia is rare. Dramatic treatment advances have been achieved in children with T-cell ALL in the last four decades. Initial results with GEP to determine specific molecular prognostic markers for children with T-cell ALL who may benefit from more intense therapy identified that expression of three genes, CFLAR, NOTCH2, and BTG 3, at the time of diagnosis may accurately predict disease outcome. All three genes are involved in regulation of apoptosis and cellular proliferation. Expression of NOTCH2, but not of the other two gene abnormalities, is implicated in T-cell ALL. Genome-wide expression profiling at the time of diagnosis can likely identify novel molecular markers that may be used to predict the clinical outcome of patients.

T-cell CLL and prolymphocytic leukemia are characterized by T-cell leukemia 1 (TCL1) gene rearrangements. These include inv(14)(q11q32.1), t(14;14)(q11;q32.1), and t(7;14)(q35;q32.1). In patients showing these karyotypic changes, TCL1 is found to be dysregulated.

Adult T-cell leukemia/lymphoma is associated with human T-cell lymphotropic virus type 1. The most frequent genetic lesions include altered expression of CDKN2 (cyclin-dependent kinase inhibitor) gene on 9p21 (15% to 20%) and loss of heterozygosity at 6q15 to q21. The most frequent chromosomal abnormalities are gain of 3p, 7q, and 14q and loss of 6q and 13q. Translocations involving 14q32 or 14q11 are frequently observed. Patients with more chromosomal gains than losses show significantly shorter survival.

Natural killer lymphoma/leukemia, a group of highly aggressive hematolymphoid malignancies of natural killer cell lineage, exhibit chromosomal rearrangements in greater than 80% by conventional karyotyping. The most frequent abnormalities include del(6)(q21-23) and gain of the X chromosome. FISH, CGH, and spectral karyotyping confirmed the presence of del(6) in $CD3^{-}CD56$ tumor cells. Other less common but recurrent karyotypic changes include isochromosome 1q, 6p, and 17q, as well as del(11q), 13q, and 17p, and trisomy 8.

Angioimmunoblastic T-cell lymphoma and unspecified peripheral T-cell lymphoma are the most frequent nodal T-cell lymphomas.

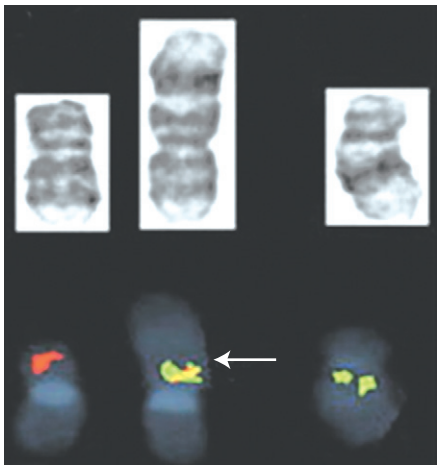

Figure 54-45 Partial karyotype of t(9;12)(p24;q23) *(top)* and after FISH study *(bottom)* with JAK2 *(red)* and TEL/ETV6 *(green),* showing JAK2-TEL fusion *(yellow)* at 9p24.

Losses of 5q/10q/12q, identified by CGH, characterize a subtype of peripheral T-cell lymphoma associated with a better prognosis. Gain of 11q13 may represent a primary change in angioimmunoblastic T-cell lymphoma. In general, chromosomal imbalances are more common in unspecified peripheral T-cell lymphoma than in angioimmunoblastic T-cell lymphoma. Both disorders may share similar genomic imbalances.

The molecular basis of ALCL is the result of t(2;5)(p23;q35), which fuses part of the NPM gene on 5q35 with part of the ALK receptor tyrosine kinase gene on 2p23 to produce a chimeric NPM-ALK gene. This encodes a chimeric NPM-ALK protein that has a constitutively activated kinase. ALK is thought to play a direct role in the malignant transformation of lymphoid cells, probably by aberrant phosphorylation of intracytoplasmic substrates because accumulation of the ALK protein is observed only in cytoplasm. The WHO classification of lymphoid tumors considers ALCL a distinct clinical entity, with t(2;5) detected by cytogenetics in 60% to 85% of patients. The NPM-ALK fusion is identified by FISH (Fig. 54-46) and by RT-PCR assay in 88% of pediatric patients and 60% of adult patients. The other cases of ALCL have variant translocations. These include rearrangements of the 2p23 region: t(1;2)(q25;p23), t(2;5)(q37;q31), t(2;19)(p23;p13), and inv(2)(p23q35), all associated with ALK gene expression. They also include rearrangements of the 5q35 region: t(1;5)(q32;q35), t(3;5)(q12;q35), and t(3;5)(q25;q34-35). Detection of ALK rearrangements by FISH corresponds to a cytoplasmic staining pattern associated with translocations other than t(2;5).

As a result of these variant rearrangements, three new fusion genes have been identified. ATTIC-ALK is a fusion gene resulting from inv(2)(p23q35). This translocation fuses ALK and 5-aminoimidazole-4-carboxamide ribonucleotide formyltransferase/IMP cyclohydrolase (ATIC). This molecular variant is detected by RT-PCR and is the most common ALK variant. TFG-ALK is a consequence of t(2;3)(p23;q21), which fuses TRK-fused gene (TFG) with ALK at the same breakpoint as found in t(2;5). In t(1;2)(q25;p23), the TPM3 gene on chromosome 1, which encodes nonmuscular tropomyosin, is fused to ALK, producing the TPM3-ALK fusion gene.

The prognosis of patients with t(2;5) or variant translocations is excellent but is clearly different from that of patients with ALK-negative ALCL. The true nature of ALK-negative ALCL remains obscure. GEP showed that ALK ALCL and ALK$^-$ ALCL have different GEZPS, indicating that different, as yet unknown, oncogenic mechanisms may be associated with each type. Of interest, C/EBPβ transcription factor, which is implicated in leukemogenesis of AML, is constitutively active and overexpressed in patients with ALK ALCL but not in ALK$^-$ patients or other lymphomas. C/EBPβ expression is transcriptionally induced through the kinase activity of NPM-ALK, which provides insight into the molecular pathogenesis of ALK ALCL.

A variety of genomic rearrangements are seen in the T lymphocytes of patients with mycosis fungoides and Sézary syndrome. However, specific cytogenetic abnormalities are not associated with these disorders. Most frequent abnormalities involve loss of chromosome 10, deletion of 1p, isochromosome 17q, additions of 17p and 19p, and translocations involving 1p, 10q, and 14q. Both CGH and M-FISH identify chromosome 10, region 10q22-26, as the most frequent abnormality in these disorders.

Posttransplant lymphoproliferative disorder (PTLD) is a morphologically diverse group of lymphoid disorders that occurs in immunosuppressed organ transplant recipients. Chromosomal abnormalities are detected in 51% to 72% of B-cell diseases and in almost all T-cell proliferations, as measured by CGH, FISH, and conventional karyotyping. Although a number of recurrent genomic imbalances are observed, the unfavorable prognostic effect on survival is observed in two main WHO morphologic groups—monomorphic PTLD (M-PTLD) and polymorphic PTLD (P-PTLD)—and can be correlated with the grafted organ. Generally, three groups of nonrandom abnormalities are of importance. The pathogenetic roles of abnormalities known to be involved in lymphomas, such as 8q24 and MYC, 17p13 and P53, and 18q21 associated with BCL2 and MALT1, and those associated with large genomic imbalances, such as 2p24-25, 9q22-34, 12q22-24, and 14q32, await elucidation. Trisomy for chromosomes 9 and 11 appears to be associated with EBV PTLD and prolonged survival. In contrast, PTLD patients showing MYC rearrangements are associated with Burkitt lymphoma and an aggressive clinical course. PTLD associated with T cells develops late after transplantation. These disorders are EBV$^-$ and are associated with poor outcome and short survival.

ALLOGENEIC HEMATOPOIETIC CELL TRANSPLANTATION

Molecular and cytogenetic analyses can be used to characterize the origin of engrafted cells and the development and evolution of recurrent malignancies after allogeneic HCT. Newly developed hematopoietic cells that emerge after allogeneic HCT may be of host origin, donor origin, or both. Genetic studies of posttransplant hematopoiesis are called *chimerism analysis*. This term was introduced into medicine by Anderson and others in 1951 to indicate an organism whose cells are derived from two or more distinct zygote lineages. Chimerism should be distinguished from mosaicism, which is characterized by two or more different cell populations originating from one zygote. Monitoring chimerism in recipients of allogeneic HCT is essential to identify early engraftment, monitor residual disease in leukemia patients, predict relapse, and optimize posttransplantation therapy in case of graft failure.

Historically, karyotype analysis was used to evaluate engraftment after sex-mismatched allogeneic HCT. Polymorphism of chromosomes 1, 9, and 16, as well as satellite polymorphism of chromosomes 13, 14, 15, 21, and 22, were used to differentiate donor from recipient cells in sex-matched allogeneic HCT. Karyotype analysis could identify not only chimerism but also recurrence of hematologic malignancies. However, this is a time-consuming process and has low sensitivity (5%). In the past two decades, many methods for detection of chimerism have been developed. All follow the basic principle of using the differences in polymorphic genetic markers to distinguish donor from patient hematopoiesis. These methods, such as restriction fragment length polymorphism, red cell phenotyping, and interphase FISH, do not offer the possibility to study all patients. The most

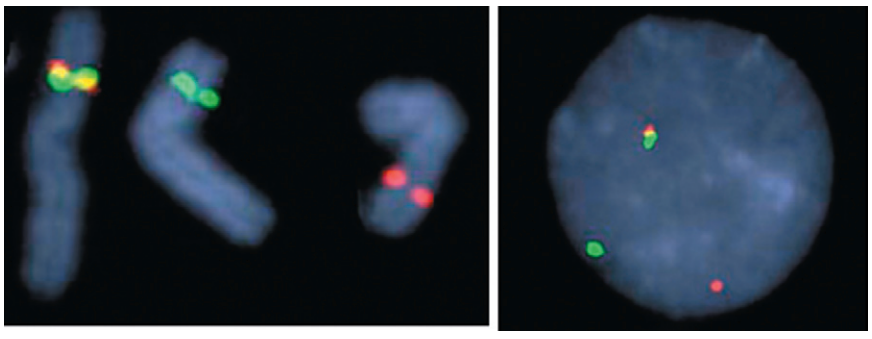

Figure 54-46 FISH STUDY WITH BREAKAPART ALK GENE AT 2p23 IN A PATIENT WITH ANAPLASTIC LARGE CELL LYMPHOMA. Partial karyotype shows a normal chromosome 2 *(left)* with yellow signal, as the 3′ end and the 5′ end of ALK gene are in close proximity on chromosome 2. The other chromosome 2 homologue *(middle)* has only a single green signal (5′ end) as a result of t(2;5)(p23;q35), the most frequent translocation in anaplastic large-cell lymphoma. The 3′ end *(red)* of the ALK gene is translocated to 5q35. Abnormal ALK gene is also shown in interphase cell *(right)*.

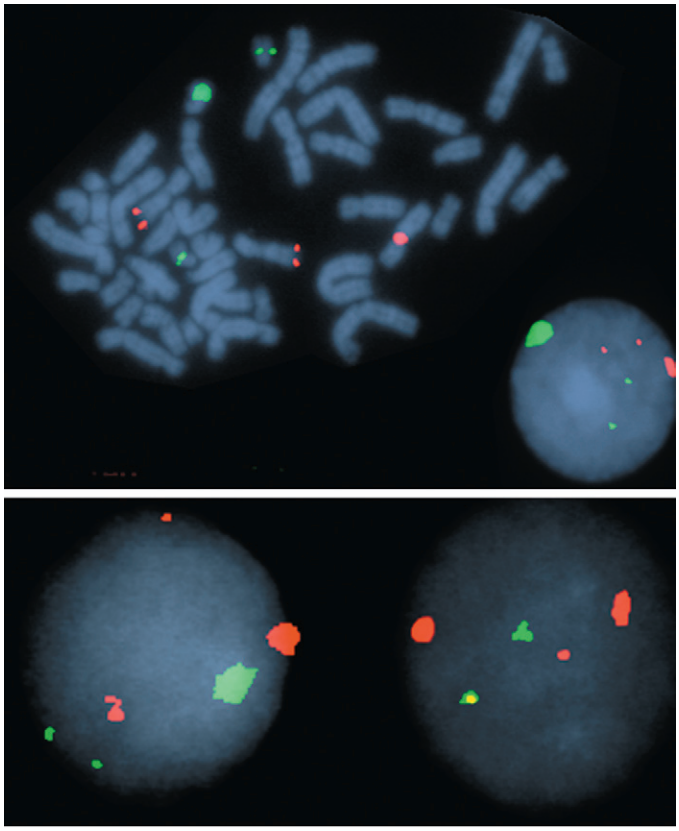

Figure 54-47 DETECTION OF ENGRAFTMENT AND RESIDUAL DISEASE WITH FISH IN SEX-MISMATCHED HEMATOPOIETIC CELL TRANSPLANTATION. Metaphase and nondividing cell *(blue)* after DAPI counterstaining, hybridized with X *(large red)* and Y *(large green)* for detection of engraftment and with ABL *(small red)* and BCR *(small green)* for detection of residual chronic myelogenous leukemia *(top panel).* Left nucleus *(bottom panel),* is showing a donor male (XY) cell origin and lack of BCR-ABL fusion. In contrast, a host female (XX), BCR-ABL fusion *(yellow)*–positive cell is shown on the *right*. Combination of XY FISH probes with diagnostic genomic markers is a powerful and fast FISH method for simultaneous detection of chimerism and minimal residual disease.

widely used technique is PCR for a variable number of tandem repeats/short tandem repeats (VNTR/STR-PCR). This technique has a moderate sensitivity of 3% to 5%, and the quantitation of donor and recipient cells may be cumbersome. The method that allows study of chimerism in all patients involves fluorescence labeling of the primers and resolution of PCR products with capillary electrophoresis. It provides high quantitative accuracy with 1% to 5% sensitivity. Real-time PCR or RQ-PCR for analysis of the SRY gene on the Y chromosome allows identification of male cells in the background of 100,000 female cells, providing a high sensitivity for mixed chimerism. However, this approach is limited to the 50% of patients who receive sex-mismatched transplants. Nevertheless, it remains the most sensitive and fastest method of chimerism analysis, providing reliable quantitative results within 2 hours.

Detection of SNPs by chimerism analysis (SNP-PCR) is highly sensitive. In one study using 11 different SNP loci, SNP-PCR analysis identified independent predictors of relapse after HCT. The two most commonly used methods for detection of chimerism after HCT are fluorescence-based PCR amplification of short tandem repeats (STR-PCR) and interphase FISH (Fig. 54-47). Both methods have high quantitation accuracy and reproducibility. The sensitivity of both methods approaches 1%; however, STR-PCR is sex independent and can be applied to all patients. FISH analysis, on the other hand, permits simultaneous evaluation of chimerism and residual disease in the same cell when high sensitivity is not a requirement.

Genetic Testing for Hematopoietic Cell Transplantation

Testing consists of either variable number of tandem repeats/short tandem repeats PCR for detection of engraftment in patients with sex-matched HCT or single-nucleotide polymorphism PCR, which has a high sensitivity. In sex-mismatched HCT, both interphase FISH with XY probes and real-time quantitative PCR for analysis of SRY gene on the Y chromosome can be used for detection of engraftment. Detection of both engraftment and minimal residual disease is best accomplished by FISH, simultaneously using probes for XY and the probe for diagnostic genetic defect, such as XY and BCR-ABL.

FISH analysis for diagnostic genomic abnormalities in conjunction with conventional cytogenetics remains useful and reliable in determining the presence of residual disease (see Fig. 54-47).

Leukemia relapse occurring in donor cells after allogeneic HCT is a rare complication reported in 0.12% to 5% of cases. It was first described in 1971, and more than 60 cases have been reported. Careful genetic analysis of relapse cells is essential. VNTR, restriction fragment length polymorphism, STR analysis, or FISH XY analysis alone may not definitively assign the origin of the leukemic clone because genomic deletions or amplifications of chromosomal segments may occur during the transplantation or disease process. The increased use of unrelated cord blood as a source of stem cells for allogeneic HCT raises the concern that hematopoietic progenitors containing preleukemic clonal molecular rearrangements may be inadvertently transplanted. Systematic screening of unselected cord blood samples revealed putative preleukemic rearrangements such as ETV6-RUNX1 and RUNX1-RUNXT1. However, a recent study including 1417 umbilical cord blood samples revealed no positive findings for the ETV6/(TEL) or RUNX1/RUNXT1 fusions. Kaplan-Meier analysis of pooled data on 13 cases of donor-derived leukemia after unrelated cord blood HCT appears to show an increased risk for donor-derived leukemia when compared with other sources of stem cells. The reason for an increased risk for leukemia or myelodysplasia in donor cells is not understood and may be a function of the conditioning regimen used or the less stringent HLA matching required for unrelated cord blood SCT. Specific mechanisms that result in development of donor cell leukemia are unknown. Proposed mechanisms include the following: (a) sustained host-origin antigenic stimulation, (b) impaired hematopoietic microenvironment and defective stromal support system, (c) immune surveillance escape secondary to posttransplant immunosuppressive therapy, (d) similar genetic susceptibility in cases of related donors, (e) viral driven pathogenesis (CMV, EBV), (f) delayed effects of conditioning regimen, and (g) transfection of host cell oncogene into donor cells. Most likely, the underlying cause is a combination of these mechanisms active in individual cases. A very compelling hypothesis for the mechanisms leading to the development of donor-derived leukemia HCT is the "2-hit hypothesis." A donor HSC that has an inherent susceptibility to malignant transformation (hit 1) is placed within a defective stromal structure elaborating a microenvironment that applies repeated stress signals (hit 2), inducing additional genetic or even epigenetic mutations promoting malignant transformation. A common cytogenetic abnormality has not been recognized, and almost half of cases are associated with a normal karyotype. Nevertheless, these patients must be carefully evaluated using an array of molecular methods for determination of leukemia in donor cells (see box on Genetic Testing for Hematopoietic Cell Transplantation).

FUTURE DIRECTIONS

The question of how initial genetic damage in hematopoietic stem cell disorders causes a cascade of other genetic events that leads to the development of malignancy is unresolved for many diseases. However,

major advances have been made, and molecular unraveling of the Philadelphia chromosome led to the rationally designed imatinib treatment that has transformed CML from a fatal disease into a chronic disorder compatible with normal life in many patients. Precise molecular characterization of leukemic cells not only provides more insight into the pathogenesis of disease but allows patients to be stratified as having high or low risk for recurrence and adverse outcome. The ultimate goal is to translate this basic knowledge into increasingly better treatment outcomes. Molecular diversity is currently the genetic hallmark of many leukemias, even within a single disease entity such as AML or T-cell ALL. We are at the threshold of understanding other genetic events and common genetic pathways. Such an understanding is crucial to designing molecular interventions for specific abnormalities of genetic pathways underlying hematologic malignancies. It is clear that genetic revolution has already changed the clinical hematology practice.

CHAPTER 55

PHARMACOLOGY AND MOLECULAR MECHANISMS OF ANTINEOPLASTIC AGENTS FOR HEMATOLOGIC MALIGNANCIES

Stanton L. Gerson, Paolo F. Caimi, Erica Campagnaro, Kapil N. Bhalla, Steven Grant, and Richard J. Creger

The treatment of patients with several hematologic malignancies has been revolutionized over the past decades as new therapeutic targets have been identified through studies of the molecular and cell biology of these malignancies. These studies have spawned the discovery, clinical evaluation, and Food and Drug Administration (FDA) approval of new mechanistic-based therapeutic agents. A surprising number of these agents have progressed from discovery, validation, animal modeling, and successful clinical testing. In addition, there has been a wider spectrum of agents, including small molecules, peptides, antibodies, radiolabeled molecules, drug immunoconjugates, immunotoxins, and complex delivery systems. This chapter provides information on several new therapeutic agents available for the treatment of patients with hematologic malignancies. The chapter reviews the "classic" agents as well as the newly developed, targeted agents. Both cytotoxic and growth-inhibitory agents are covered; however, the use of therapeutic antibodies and antibody conjugates is reviewed within the chapters dealing with specific diseases.

CELL KINETICS, THE CELL CYCLE, AND TUMOR GROWTH

Malignant hematopoietic cells proliferate more than their normal counterparts. It is important to recognize that this characteristic of hematologic malignancies is exploited in developing treatment strategies. The cell cycle consists of a series of stages through which normal and neoplastic cells proceed during the course of cellular replication (shown schematically in Fig. 55-1). The cell cycle is divided into G_1 (pre-DNA synthetic phase), S phase (in which DNA replication takes place), G_2 (post-DNA synthetic phase), and mitosis (M), during which chromosomal division and segregation occur. In addition, nonproliferating, resting cells reside in G_0, a phase that may theoretically last for an indefinite period. Such cells remain in G_0 until they are induced to cycle (at G_1) by specific triggers (e.g., hematopoietic growth factors). The *growth fraction* of a tumor represents the percentage of cycling cells relative to the total cell population. The *generation* time represents the time required for a cell to proceed through a single cell cycle (generally 24-36 hours for hematopoietic tissues). Surprisingly, in the case of acute myeloid leukemia (AML), the generation time of leukemic blasts is not shorter than that of normal hematopoietic progenitors and may in fact be longer. The proliferative advantage of malignant hematopoietic cells (and of many nonhematopoietic tumors) stems, at least in part, from the fact that a higher percentage of cells are in cycle at any one point in time (i.e., the growth fraction is higher). The *doubling time* represents the period required for a tumor to double in mass and is, in general, inversely related to the tumor's growth fraction. Tumor-doubling times range from longer than 120 days in the case of some solid tumors (e.g., lung and colon) to less than 2 weeks (in some leukemias and lymphomas). Tumor-doubling times are influenced by multiple other factors, including the rate of spontaneous cell death (or apoptosis) and the availability of appropriate nutrients. The importance of these considerations stems from the fact that tumors with high growth fractions and short doubling times tend to be more sensitive to chemotherapy than slowly growing neoplasms with low growth fractions and long doubling times. It is unlikely to be a coincidence that many advanced neoplasms that are potentially curable by chemotherapy (e.g., hematologic malignancies such as leukemia, lymphoma, and testicular cancer) fall into the former group; conversely, most incurable advanced malignancies (e.g., non–small cell lung cancer, colon cancer) fall into the latter.

The transition of normal as well as neoplastic cells through the cell cycle is governed by a complex network of proteins consisting of cyclins, cyclin-dependent kinases (CDKs), and CDK inhibitors. The progression through S phase is regulated primarily by CDK2 in association with cyclins A and E; the progression through G_2M is regulated by CDK1 ($p34^{cdc2}$) and cyclin A and cyclin B; and progression through G_1 involves CDKs 4 to 6 in conjunction with cyclin D. CDK inhibitors fall into two major categories: the low-molecular-weight inhibitors (pINK14, -15, -16, -17, and -18), which primarily inhibit cyclin D (and to some extent, CDK2) complexes, and the higher-molecular-weight inhibitors, p21, p27, and p57, which are more universal in their actions and inhibit most or all CDKs. Signals for the progression of cells through G_1S are essential for maintenance of the neoplastic phenotype. In the commonly accepted model of G_1S progression, inactivation of the retinoblastoma protein (PRB) is required. In quiescent cells, PRB is in an active dephosphorylated state and bound to the transcription factor E2F. Phosphorylation of PRB by CDK4 and CDK6 and CDK2 leads to release of E2F, which is then free to activate diverse genes essential for S-phase progression, such as *MYC* (also known as c-Myc), *TYMS* (thymidylate synthetase), and *DHFR* (dihydrofolate reductase). Conversely, induction of CDK inhibitors (e.g., by transforming growth factor β [TGFβ] or differentiation-inducing agents) results in inactivation of CDK4 and CDK6 and CDK2, dephosphorylation of PRB, inactivation of E2F, and inhibition of the progression through S phase. Aberrant expression of cyclins and CDK inhibitors is commonly encountered in human malignancies, and it has been postulated that the resultant cell cycle dysregulation contributes to the neoplastic phenotype.

In addition to growth control, cell cycle proteins are intimately involved in the regulation of programmed cell death (apoptosis) and checkpoint control mechanisms. Consequently, cell cycle regulatory proteins can exert a major influence on the response of neoplastic cells to cytotoxic agents. For example, when cells undergo DNA damage, they may arrest in G_2M or G_1, during which repair occurs, or if the damage is too severe, the cells undergo apoptosis. In particular, the tumor suppressor gene *TP53* and its downstream inducible target p21 have been implicated in the G_1 arrest process after genotoxic insult. Dysregulation of various cell cycle regulatory proteins can have a major impact on the sensitivity of neoplastic cells to chemotherapeutic agents. Loss of the *TP53* gene renders cells resistant to diverse chemotherapeutic agents, presumably by preventing cells from undergoing repair in G_1 and thereby inhibiting the cell death processes and allowing DNA damage to accumulate, culminating in cellular transformation. Conversely, transfection of P53-negative cells with wild-type P53 restores responsiveness to most drugs. Dysregulation of the CDK inhibitors p21 (a downstream target of P53) and p27 increases the sensitivity of neoplastic cells to various cytotoxic agents, possibly by uncoupling S-phase progression and mitosis. In this model, loss of the CDK inhibitors p21 or p27 prevents cells that have sustained DNA damage from arresting in G_1 and allows them to progress inappropriately through S and ultimately G_2M, eventually

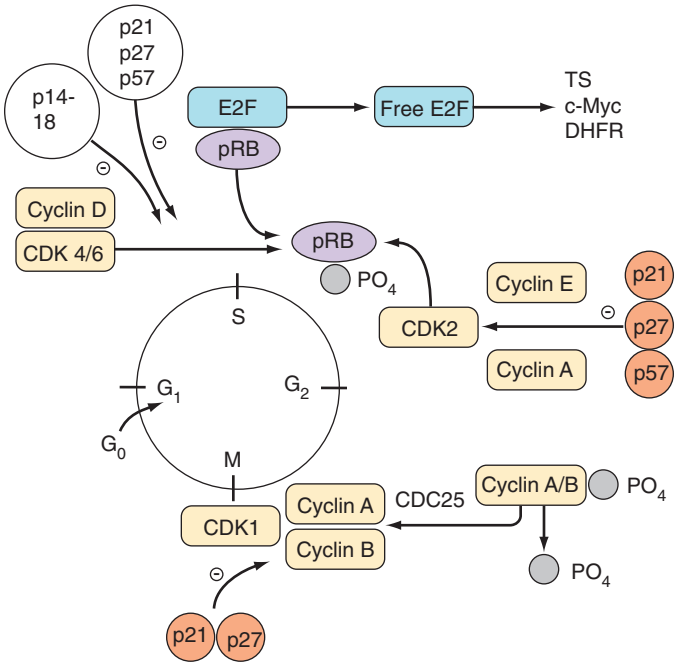

Figure 55-1 PROGRESSION THROUGH THE CELL CYCLE IS CONTROLLED THROUGH COMPLEX INTERACTIONS AMONG CYCLINS, CYCLIN-DEPENDENT KINASES (CDKs), AND CDK INHIBITORS. Progression across the G_1S interface and through S phase involves the E2F transcription factor, which activates numerous enzymes (e.g., thymidylate synthase, dihydrofolate reductase) required for DNA replication. The retinoblastoma protein (pRb) in its dephosphorylated state binds to and inactivates E2F in conjunction with DP proteins, thereby inhibiting S-phase progression. Conversely, phosphorylation of pRb antagonizes binding to E2F, allowing S-phase events to proceed. Phosphorylation of pRb results from activation of (1) cyclin-dependent kinase-2 (CDK2):cyclin A/E and (2) CDK4/6:cyclin D complexes. The former complexes are inhibited by the CDK1s p21, p27 (and p57), and the latter are inhibited by the low-molecular-weight CDK inhibitors (p14-18) but also by p21 and p27. The complex formed by CDK1 ($p34^{cdc2}$) and cyclins A and B regulates G_2M progression and is inhibited by the "universal" CDK inhibitor, p21. Moreover, its phosphorylation status, which plays a major role in determining activity, is regulated by the phosphatase cdc25. Proteins such as pRb, E2F, p21, and p27 can influence the response of cells to chemotherapeutic agents by controlling cell cycle progression and possibly via cell cycle–-unrelated actions.

leading to cell death. Mutations in the E2F protein have been shown to lengthen S phase and increase the sensitivity of malignant cells to S phase–specific agents. Furthermore, cells lacking functional PRB have been shown to be significantly less sensitive to the actions of antimetabolites, including methotrexate. Aside from regulating cell cycle status and the susceptibility of neoplastic cells to cell cycle–specific agents, cell cycle regulatory proteins can actively contribute to the cell death response.

The growth of tumors is best described by Gompertz's law rather than classic exponential kinetics. For neoplasms that grow exponentially, the tumor growth rate remains constant as the number of cells increases. However, in vivo, the growth of tumors is limited by various factors such as vascular supply, nutritional requirements, and possibly physical restraints. Consequently, the rate of tumor growth declines as the number of cells increases. To the extent that tumor-doubling times are inversely correlated with drug responsiveness, large, late-stage tumors would be anticipated to be less susceptible to cytotoxic drugs than early stage tumors, with higher growth fractions. Most chemotherapeutic drugs kill by *first-order kinetics*. This results in a given drug dose killing a constant fraction, rather than number, of tumor cells. The implication of this phenomenon is that it requires the same drug dose to reduce the number of tumor cells from 10^4 to 10^1 cells as it does to reduce the tumor burden from 10^{10} to 10^7 cells.

Recent emphasis on leukemic and lymphoma stem cells has raised a new potential cellular target for therapeutics and provides another level of analysis of the efficacy of available agents both in clinical and preclinical settings. The value of targeting leukemia, lymphoma, and myeloma stem cells either in clinical trial design or therapeutic development is unclear at present. However, for neoplasms now considered incurable with chemotherapy, a focus on the stem cell subpopulation might lead to curative therapies. Regardless of the availability of targeted therapies, the ability to identify and track cancer stem cells will likely lead to more sensitive and precise measurement of minimal residual disease. One factor in common for most malignant stem cells is the overexpression of the ABC transporters. Adenosine triphosphate (ATP)–binding cassette transporters are often highly expressed in early hematopoietic stem cells and other tissue stem cells that are CD44 positive. Inhibition of these transporters is a logical approach to therapeutically targeting leukemic stem cells. Progress in this area is discussed in the section on multidrug resistance protein (MRP) and the ABC transporters.

Cytotoxic agents may be divided into several categories with respect to their effects on the cell cycle or the cell cycle specificity of their actions or both.

1. *Non–cycle-active drugs* kill both cycling and noncycling cells in all phases of the cell cycle. Examples include steroids and antitumor antibiotics (except bleomycin).
2. *Cycle-active, non–phase-specific drugs* are more active against cycling cells and can kill cells in each phase of the cell cycle. However, such drugs may preferentially kill cells in a particular phase of the cell cycle. Examples include alkylating agents, cisplatin, and 5-fluorouracil.
3. *Cycle-active, phase-specific drugs* primarily kill cells in a specific phase of the cell cycle. Examples include most antimetabolites, which are active against cells engaged in DNA synthesis (S-phase cells), and microtubule-active drugs (e.g., vinca alkaloids, taxanes), which kill cells in G_2M.

An example of a cytokinetically rational approach to chemotherapy involves the combination of a non–cycle-active agent (e.g., daunorubicin) with a cycle- and a phase-specific agent (e.g., cytosine arabinoside [ara-C], fludarabine, decitabine, clofarabine and nelarabine). From a theoretical standpoint, administration of a non–cycle-active agent may reduce tumor mass, leading in turn to an increase in the growth fraction caused by recruitment of cells into cycle. Such cells would then be more susceptible to a cycle- and phase-specific agent, particularly one administered over a prolonged interval. In the case of hematopoietic malignancies, attempts have been made to recruit neoplastic cells into the more susceptible S phase of the cell cycle through the use of *hematopoietic growth factors*. The success of such a strategy has been limited because of several factors, including the inability of growth factors to increase the S-phase fraction significantly, the lack of selectivity of this strategy, and the theoretical possibility that growth factors may protect neoplastic cells from apoptosis.

Unfortunately, cytokinetic differences between normal and neoplastic tissues have been difficult to exploit. Both normal hematopoietic stem cells and hematologic malignant stem cells have a low proportion of cells in G1. However, prolonged dosage schedules can provoke these malignant cells into cell cycle and may explain their efficacy. Consequently, rapidly dividing normal tissues such as gastrointestinal epithelium and normal hematopoietic progenitors tend to be very sensitive to most chemotherapeutic agents. As a result, mucositis and myelosuppression represent frequent dose-limiting toxicities for many cytotoxic drugs.

TUMOR CELL HETEROGENEITY OF HEMATOLOGIC MALIGNANCIES

Whereas hematologic malignancies are of *clonal* origin (i.e., they are derived from a single transformed cell), individual neoplastic cells

from a patient's malignancy exhibit a great deal of phenotypic diversity and acquire secondary mutations that affect proliferation, drug sensitivity, and resistance. This diversity likely arises from the progeny of clonal populations and subsets of stem cells. In animal models, it has been shown that the clones themselves can give rise to progeny that can transmit the clonal malignancy after transplantation into secondary recipients, suggesting that stem cells are not required to transmit the malignant phenotype.

New evidence indicates that leukemia stem cells are more quiescent, have higher levels of protective proteins such as efflux pumps for drugs, and have higher levels of DNA repair proteins or antiapoptosis proteins than the more abundant cell making up the circulating population of cells. Tumor cell heterogeneity arises as a consequence of spontaneous mutational events, changes in gene promoter methylation, impact of abnormal expression of transcription factors, lymphoid reactivity, and cytokine responsiveness. In fact, these can be reinforced if they provide a survival, tissue homing, or including homing to bone marrow (BM) niches for preferential engraftment and metastasis or a proliferative advantage for the affected cells and their progeny. For example, a mutation or change in expression that renders a hematopoietic cell clone autonomous or growth factor–independent would be expected to render such cells less susceptible to adverse environmental conditions (e.g., growth factor withdrawal). Similarly, one would also predict that a genetic change facilitating cell cycle entry or disruption of cellular maturation would ultimately lead to overgrowth of affected clones. For obvious reasons, mutations that interfere with drug metabolism or the cell death pathway itself would provide a net survival advantage, particularly under the selection pressure of cytotoxic drug treatment.

Malignant myeloid and lymphoid cells have many reasons to have increased mutational rates. Genomic instability can arise from dysregulation of the cell cycle machinery because of a number of events, including pertubations of cyclins leading to MYC overexpression; AKT activation; disruption of replication sequences; loss of DNA repair enzymes such as mismatch repair; enzymes' loss of proper homologous recombination from a defect in the BRCA–Fanconi pathways; and loss of ATM/ATR, which can give rise to chromosomal recombination, loss and microsatellite instability, and loss of checkpoint regulation. These events can give rise to intraclonal emergent point mutations, translocations, and intragenic losses that might not only result in malignant transformation but also lead to disruption of genomic stability and selection in favor of proliferative and apoptosis-resistant subclones. Leukemic clonal evolution favors drug resistance.

Common mechanisms may be involved in events associated with malignant transformation and the development of mutations that result in tumor heterogeneity. For example, the cell cycle checkpoint and tumor suppressor gene, *TP53,* is induced during DNA damage, leading to G_1 arrest and, if the damage is too severe to repair, cell death by apoptosis occurs. The presumed goal of this process is to eliminate cells that develop deleterious mutations as a result of damage to the genome. Loss of *TP53* may not only increase cellular survival by inhibiting the cell death process but may also promote the transmission of mutations that would otherwise be deleted. In this manner, a defect of the cell death pathway can have multiple consequences, including (1) selection of cells exhibiting a growth advantage over their normal counterparts, (2) development of drug resistance, and (3) promotion of mutations that result in either (1) or (2) as well as neoplastic cell heterogeneity. Age-dependent changes in these processes may explain the more favorable behavior of leukemias and lymphomas in response to chemotherapy in young patients than older patients.

A model of the relationship between tumor growth rate, the occurrence of spontaneous mutations, and the development of drug resistance was first described by Goldie and Coldman and is referred to as the Goldie and Coldman hypothesis. In this model, the size of a tumor depends on a complex interaction between tumor growth rate and cell loss, the latter stemming from the status of the cell death process, exhaustion of available nutrients, and outstripping of the blood supply. As tumors increase in size, the cell death rate tends to increase. The heterogeneous nature of additional mutations makes it likely that multiple mechanisms of resistance will develop as well. From an operational standpoint, this model has clear implications for the rational design of therapeutic strategies and provides a basis for early and intensive combination drug therapy. The successful implementation of this strategy is exemplified by the administration of dose-intensive multidrug regimens (i.e., the BEACOPP [bleomycin, etoposide, Adriamycin, cyclophosphamide, vincristine—Oncovin—procarbazine, and prednisone] regimen in Hodgkin disease, CODOX-M-IVAC in Burkitt lymphoma [non-Hodgkin lymphoma or NHL]) and combinations of cytotoxic agents with monoclonal antibodies, such as CHOP (cyclophosphamide, hydroxydaunorubicin, vincristine [Oncovin], and prednisone)–rituximab, which are potentially curative when given early in the course of the disease. Other examples include combined use of multitargeted agents such as lenalidomide and bortezomib for myeloma, fludarabine and rituximab for chronic lymphocytic leukemia (CLL), or maneuvers to overcome resistance of pretreated disease outside of cell-based therapies. However, as predicted by the model, administration of these or other intensive regimens in patients with relapsed or late-stage disease generally fails because of a generalized resistance of tumor cells to all classes of chemotherapeutic agents.

DEVELOPMENT OF CHEMOTHERAPEUTIC AGENTS

The quest for anticancer agents for hematologic malignancies began with the nitrogen mustard class of compounds developed from the chemical warfare agent sulfur mustard gas used in World War I. Since that time, the National Cancer Institute (NCI) and the pharmaceutical industry have developed complex approaches to drug development, screening, and evaluation. Initial screening consisted of toxicity assessment against murine tumor cell lines. Currently, screening is directed toward numerous cell targets, including receptor and downstream signaling kinases; inducers of cell death pathways, including those at the cell surface, mitochondrial DNA, and nuclear DNA; DNA processing and repair proteins, including topoisomerases and telomerase; and inhibitors of histone deacetylase (HDAC) cell cycle proteins, proteasomes, and the mitosis and spindle machinery. Although killing cells remains the backbone of chemotherapeutic approaches to human malignancies, the field of antineoplastic agent development is at a tipping point moving toward novel targeted and highly effective compounds that block the function of specific kinases with surprising efficacy even at late stages of disease. Examples include Bruton tyrosine kinase and phosphatidylinositol 3-kinase (PI3K) inhibitors in lymphoid malignancies as well as Janus kinase (JAK) inhibitors for treatment of myelofibrosis. A number of differentiating agents, kinase inhibitors, and immunomodulatory and cytostatic agents have now entered the antineoplastic armamentarium. In addition, agents that target tumor angiogenesis have been evaluated. Although "conventional" cytotoxic agents cause myelosuppression and mucositis because of their effect on rapidly dividing normal cells, newer agents cause more diverse systemic side effects. Secondary leukemias induced by hematopoietic progenitor cell damage incurred by alkylating agents, topoisomerase inhibitors, and combination chemotherapy and radiation are not associated with the newer classes of compounds. The emphasis on targeted therapeutics in recent drug development has focused in several areas, including recognized fusion or mutant proteins specific to the malignant cell, such as Bcr-Abl in chronic myeloid leukemia (CML) (see Chapter 66), PML-RARα in promyelocytic leukemia (see Chapter 65), and the JAK2V617F mutation present in myeloproliferative neoplasms (see Chapters 67 to 69); cellular signaling pathways such as B-cell receptor signaling, PI3 kinase, mammalian target of rapamycin (mTOR), bcl-2, and nuclear factor kappa-B (NFκB); and monoclonal antibodies and immunoconjugates, antibody–toxin conjugates, antibody–drug conjugates, and radioimmunoconjugates (see Chapter 81).

Screening for Antitumor Activity Among Chemotherapeutic Agents

While in the past, discovery of new agents to treat hematologic malignancies relied on the NCI Division of Cancer Treatment initiative to maintain a large cell bank of malignancies for drug testing, newer approaches are using high-throughput drug screening with either cell-based or specific mechanism–based assays. For instance, to screen for a kinase inhibitor, cells overexpressing an activated kinase may be used. The NCI has evaluated more than 60,000 compounds for cytotoxic and growth inhibitory activity using a standard human tumor cell line screen, and this database remains the most comprehensive even as both pharmaceutical companies and academic laboratories develop their independent screening programs. After an initial in vitro screen, human tumor cell activity is evaluated using a series of athymic mouse xenograft studies targeting tumors from tissues that show promise in in vitro assays. Drugs with promising efficacy and novel mechanisms of action then go on to formulation and toxicology testing and ultimately are developed for phase I clinical testing through industry or the NCI Cancer Therapy Evaluation Program. Cell lines are being used, along with cell line banks of human hematologic malignancies for high-throughput screening efforts that are especially useful for screening for noncytotoxic agents that affect gene expression, differentiation, migration, and other cell-based assays. In addition, drug discoveries that start as a survey of specific pathway inhibition, such as signaling kinases (Bcr-Abl, JAK2, platelet-derived growth factor [PDGF], kit, and FLT3) and Src kinases, represent new approaches validated by the discovery of agents such as imatinib, dasatinib, nilotinib, and ruxolitinib.

Human tumor xenografts have been used as a requisite screen in preclinical testing of new chemotherapeutic agents. For leukemia and lymphoma cell lines, prolongation of life span is used as an end point measured at the percent increased life span (ILS), $((T - C/C) \times 100)$, where T is the life span after drug treatment and C untreated. The best predictive mouse systems for this purpose are primary malignancies grown in immunodeficient mice and mice with specific chromosomal translocations and oncogenes that mimic human disease. In mice with severe combined immune deficiency (SCID), the RPMI 8226 human myeloma cell line and the multidrug-resistant subline, 8226-C1N inoculated intraperitoneally led to a life span that was numbered in days, and the tumor cells in vivo were completely resistant to treatment with doxorubicin. Investigators established a human acute promyelocytic leukemia (APL) ascites model in the SCID mice and found responses to all-trans retinoic acid (ATRA). Other investigators have used the SCID leukemia model to test antisense oligonucleotide strategies directed against such tumor-specific genes as *BCR-ABL* in CML. Use of primary and serially passaged human leukemias and myelomas in the SCID model have facilitated drug screening. In both instances, infusion of antisense constructs increased the ILS significantly and led to clinical studies with these agents. Others have used the SCID model for B-cell lymphomas to study chemotherapy or lymphotoxins. Although these models have not entered the NCI drug screen, they represent significant systems to test new agents.

Phase I Clinical Trial Design

New anticancer agents are assessed through a series of clinical trials termed *phase I, phase II,* and *phase III* (Table 55-1). The purpose of phase I clinical trials is to establish the safe and optimal biochemically active dose of the compound in question with acceptable toxicity that can be used in disease-targeted phase II testing. During phase I development, pharmacokinetics and pharmacodynamic measures are studied in detail so that appreciable information can be forthcoming from the very first set of patients targeted for treatment and to allow confirmation of these observations in larger phase II disease-focused trials. Dose schedule and route of administration are key considerations in early phase I development. Numerous considerations have guided dose escalation strategies that accompany phase I trial development. The starting dose is typically 10% of the lethal dose (LD10) in animals adjusted for species dose equivalency. In classic phase I development, a modified Fibonacci dose schedule is used. Groups of three patients are treated at each of the following doses until the maximum tolerated dose is observed: 1N (the starting dose), 2N, 5N, 7N, 9N, 12N, and 16N. Typically, the maximum tolerated dose is defined as the maximum dose not causing irreversible toxicity of any type and causing less than grade 4 toxicity in any organ. Newer agents often have off-target toxicities, and these complicate drug evaluation because the dose-dependent toxicities are replaced by rashes, cardiac effects from prolonged QT intervals, activation or inhibition of other pathways, and unusual side effect profiles such as pleural and pericardial polyserositis. Typically, if one dose-limiting toxicity is observed, the patient cohort is expanded to six patients, and if two patients develop dose-limiting toxicity, typically defined as grade 4 toxicity except as previously noted, then further entry at this dose is not pursued, and the next lower dose level is used to establish the maximum tolerated dose with a total of six patients accrued at that dose level.[1]

Table 55-1 Clinical Trial Design

Phase I
Evaluate safety by dose escalation and multiple dose schedules.
Establish maximum tolerated dose and dose-limiting toxicity.
Consider use of hematopoietic support if myelosuppression is dose limiting.
Phase II
Establish response (complete, partial, objective) in specific diseases.
Phase III
Compare new treatment with established regimen for the disease in randomized trials.

Alternative strategies of drug escalation have included the use of toxicity grades to enhance dose escalation in early drug development, allowing that if no toxicity is observed, fewer patients might be accrued to each dose. Using the modified Fibonacci scheme, one patient is entered at each dose level until grade 2 toxicity is observed, at which point cohorts of three patients are entered at each level. Early in drug development, level skipping may take place if no toxicity is observed. The overall impact of this is to reduce the number of patients treated at suboptimal doses of therapy and to increase the number of patients evaluated at biologically active doses.

More importantly, biomarker driven studies can be used to optimize inhibition of the target rather than treating to toxicity. This can then be extended in phase 2 to determine whether the drug effects on its biochemical target correspond to efficacy and tolerance.

Phase II Drug Development

Phase II drug development uses the established phase I dose to define therapeutic efficacy, typically in a two-stage design. If an expectant response rate in excess of 20% is deemed clinically significant, 15 patients are accrued, and if two or more responses are seen, accrual is continued to a total of 26 patients to establish the definite response rate. At this point, combination therapies are instituted in an effort to optimize therapeutic efficacy. For instance, topotecan was found in phase I testing to have efficacy against refractory leukemias leading to combinations of topotecan with ara-C and other agents. Likewise, fludarabine was initially evaluated as a single agent for activity against low-grade lymphomas and acute and chronic leukemias and is now used in combination with ara-C for the treatment of acute lymphocytic leukemia and with chlorambucil for the treatment of CLLs. In the past, strategies for combination chemotherapeutic agents have

included the use of non–cross-resistant agents with non-overlapping toxicities. However, more recently, mechanism-based therapeutics has become the focus of drug development. For instance, with the combination of fludarabine and cisplatin, fludarabine may inhibit nucleotide excision repair and enhance persistence of cisplatin-induced DNA adducts, resulting in increased antitumor efficacy in CLL. Likewise, combining a receptor kinase inhibitor with a cell cycle inhibitor might potentiate efficacy in leukemias.

Most phase III trials randomize patients between an established standard therapy and a new therapy that has appeared promising in the phase II setting. These studies are usually multi-institutional and many involve large national and international cooperative groups. The end point of these studies is disease response, survival, and patient tolerance. Linking multiple centers removes the vagaries of reports from single centers, which remain the focus of phase II trials. Phase III trials are important for positive and negative results.[2]

PHARMACOLOGY OF CHEMOTHERAPEUTIC AGENTS

As noted earlier, although cytotoxic anticancer agents may be divided into several categories based on the cell cycle specificity of their action, in keeping with traditional classification, they are more appropriately divided into alkylating agents, antimicrotubule agents, antimetabolites, topoisomerase I or II inhibitors, platinum analogs, and miscellaneous agents. The pharmacology and cellular mechanisms of action of these agents are schematically presented in Fig. 55-2. Targeted therapeutics such as imatinib and bortezomib are discussed in later sections.

Alkylating Agents

Drug treatment for cancer began with the use of the mustard class of alkylating agents, initially mechlorethamine (nitrogen mustard),

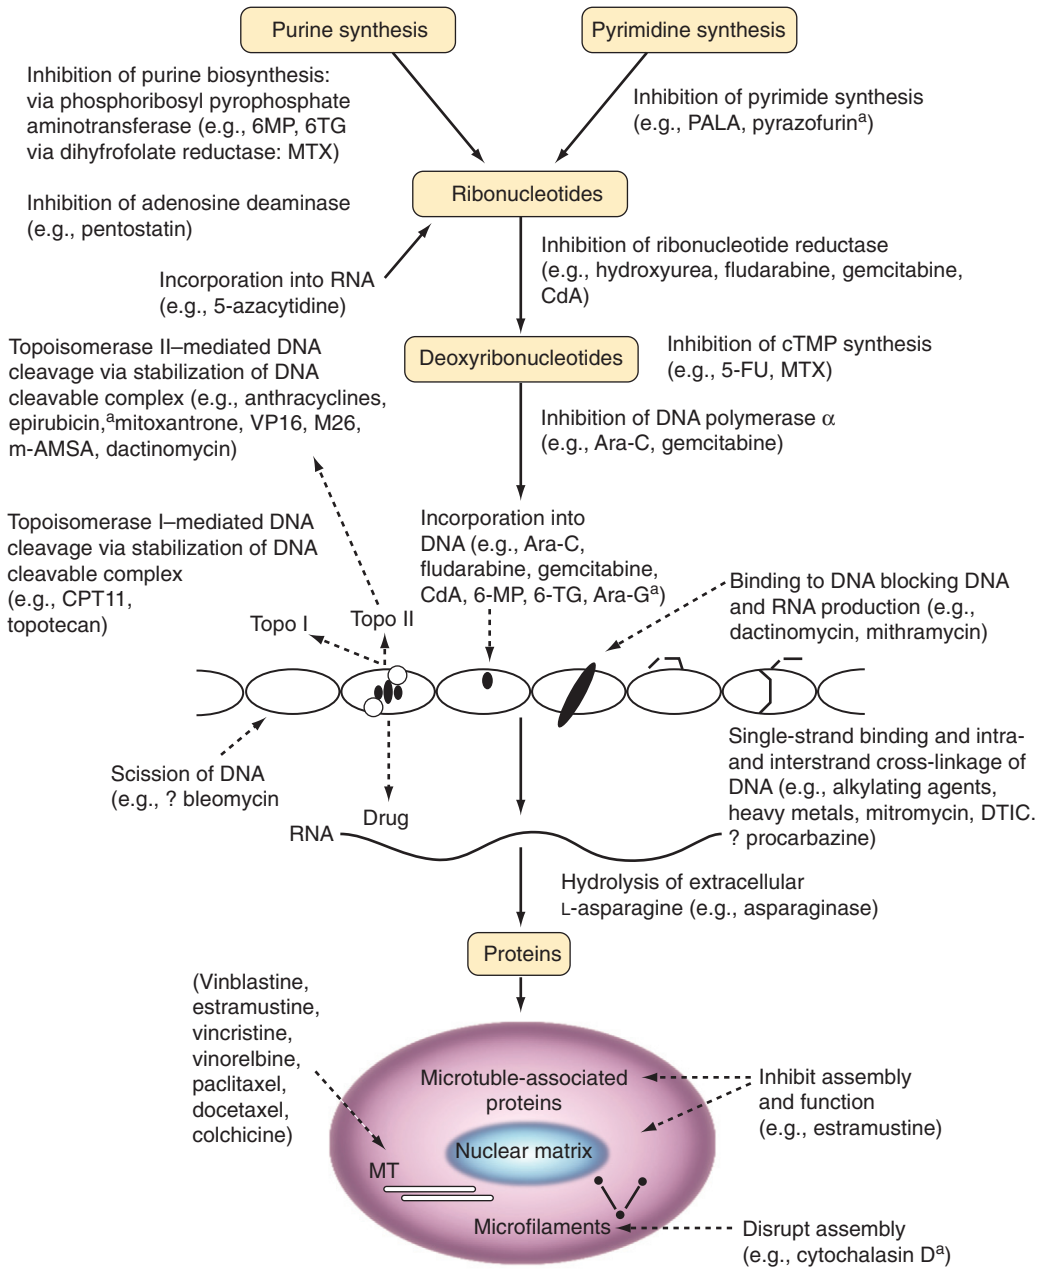

Figure 55-2 OVERVIEW OF SITES AND MECHANISMS OF ACTION OF THE MOST USEFUL CHEMOTHERAPEUTIC AGENTS.

which entered into clinical use in the mid-1940s. Alkylating agents are used in many regimens but are rapidly being supplanted by newer classes of agents.

Nitrogen Mustard

The nitrogen mustard class includes mechlorethamine, cyclophosphamide, 4-hydroperoxy cyclophosphamide, ifosfamide, chlorambucil, and melphalan. These drugs all share a common bischloroethyl group attached to nitrogen and a substituted "R" group that provides drug specificity (Fig. 55-3). All nitrogen mustards react with DNA in an SN_2 reaction, a bimolecular nucleophilic displacement reaction, also called a second-order reaction. Although numerous sites are targeted for alkylation, nucleophiles in DNA, including nitrogen (N), oxygen (O), and phosphate (P), attract the chloroethyl moiety attached to the R-N backbone, and the chlorine is displaced by the nucleophilic atom to form an aziridinium moiety. The remaining chloroethyl group is then attracted to a second nucleophilic atom, forming a second aziridinium intermediate, leading to a second alkylation, forming a cross-link. Both intrastrand and interstrand cross-links are formed. Although the nitrogen mustards also attack DNA at other nitrogens, including N^1 and N^3 of the adenosine and N^3 of thymidine, it appears that the N^7 guanine position is the most critical for cytotoxic cross-link formation. Clinical use of mechlorethamine is limited because the MOPP regimen (mechlorethamine, vincristine [Oncovin], procarbazine, prednisone) has been replaced by ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, dacarbazine) in Hodgkin disease (see Chapter 74). Local use of mechlorethamine occurs in a dermatologic suspension for the treatment of cutaneous T-cell lymphomas (CTCLs; see Chapter 84).

Cyclophosphamide is a nitrogen mustard with a ringed structure off the end-chloroethyl backbone that decreases spontaneous decomposition (see Fig. 55-3). Enzymatic activation is required through multifunction P450 enzymes in the liver. Phenobarbital and corticosteroids may alter activation. The bioavailability of cyclophosphamide orally and intravenously is quite similar, although most use of the drug is by bolus intravenous (IV) injection. Cyclophosphamide is detoxified through oxidation to 4-keto-cyclophosphamide and carboxyphosphamide by aldehyde dehydrogenase. Cyclophosphamide is used in doses as little as 50 to 100 mg/day orally and in bolus doses of 400 to 700 mg/m^2 for solid tumors and 750 mg/m^2 in combination with doxorubicin and vincristine and prednisone as part of the CHOP regimen for NHLs. It is also used at doses of up to 60 mg/kg/day for 4 days in autologous and allogeneic BM transplantation (BMT) protocols. Cyclophosphamide is used in numerous treatment protocols for NHLs and high-dose therapy regimens designed to eradicate tumor and BM in patients with lymphomas and leukemias and those undergoing BMT. It is commonly used with granulocyte colony-stimulating factor (G-CSF) for mobilizing hematopoietic stem cells to be collected before autologous transplantation.

Cyclophosphamide is metabolically activated by cytochrome P450 mixed function oxidases in the liver to 4-hydroxycyclophosphamide. 4-Hydroxycyclophosphamide is further converted to aldophosphamide and then to phosphoramide mustard, the alkylated species, and acrolein. Acrolein is a highly reactive aldehyde and the cause of hemorrhagic cystitis. Mercaptoethane sulfonate (Mesna) is used to prevent recurrence and to provide prophylaxis against hemorrhagic cystitis caused by cyclophosphamide and ifosfamide and is now standard for doses of cyclophosphamide and ifosfamide above 1000 mg/m^2. Mesna is given in divided doses every 4 hours or as a continuous infusion for 18 to 24 hours in a dose equivalent to either cyclophosphamide or ifosfamide. Other than hemorrhagic cystitis, BM suppression is dose limiting and can be rescued by reinfusion of autologous or allogeneic hematopoietic progenitor cells. Other toxicities include alopecia and cardiac toxicity, which is unusual and most often seen after high-dose therapy.

4-Hydroperoxycyclophosphamide is a chemically stable form of the reactive intermediate of cyclophosphamide, 4-hydroxycyclophosphamide, is more toxic to committed hematopoietic progenitors such as colony-forming unit–granulocyte/macrophage (CFU-GM), burst-forming unit–erythroid (BFU-E), and colony-forming unit–erythroid (CFU-E) but spares early progenitors, presumably on the basis of their expression of the detoxifying enzyme aldehyde dehydrogenase, which is quite high in early progenitor populations.

Melphalan, or phenylalanine mustard, has an amino acid side chain that alters its cellular uptake and stabilizes its structure, allowing oral (PO) administration (see Fig. 55-3). It is available in both PO and IV forms and has a similar intracellular pathway to DNA cross-linking as cyclophosphamide and the other nitrogen mustards.

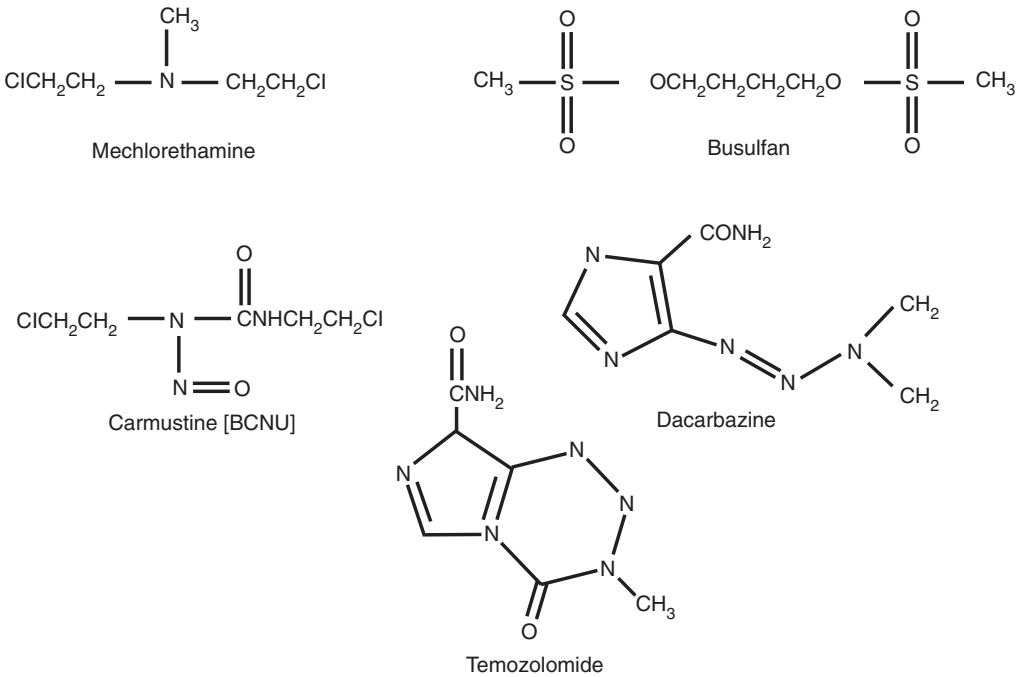

Figure 55-3 STRUCTURE OF COMMON ALKYLATING AGENTS.

Melphalan uptake by cells is by means of a neutral amino acid transporter. Its rate of cross-link formation is much slower than that of mechlorethamine, presumably because of delayed metabolism. PO melphalan is used predominantly for the standard treatment of multiple myeloma and intravenously in high-dose regimens in preparation for stem cell transplantation (see Chapter 85) for multiple myeloma patients.

Chlorambucil has been used for more than 40 years for the treatment of CLL. Chlorambucil is the phenylbutyric acid derivative of nitrogen mustard and is very stable, entering the cell by diffusion rather than by a specific uptake mechanism. It is typically administered orally on a daily basis or intermittently. It appears to have greater bioavailability than melphalan and a more consistent half-life of approximately 2 hours.

Busulfan is an alkylsulfonate, unique among alkylating agents because of two sulfur groups and the lack of a chloroethyl moiety (see Fig. 55-3). Busulfan, similar to the nitrogen mustards, reacts predominantly at the N^7 position of guanine and produces an N^7–N^7 biguanyl DNA cross-link, although the precise nature of this cross-link appears different than that of the nitrogen mustards. This may explain the different clinical effects of busulfan compared with the nitrogen mustards. The pharmacokinetics of busulfan is important for its use in high-dose therapy for ablation of the BM in patients undergoing autologous transplantation for acute leukemia or allogeneic stem cell transplantation (see Chapters 104 and 105). Busulfan clearance does not appear to be accurately predicted by creatinine clearance. Because the incidence of venoocclusive disease is lower in patients receiving high-dose busulfan with predosing pharmacokinetics performed, this is now recommended in high-dose regimens, the target being an area under the curve (AUC) of 800 to 1200 ng hr/mL. Busulfan is a potent stem cell toxin, killing both early and late hematopoietic progenitor cells and damaging the BM stroma. Other toxicities of busulfan include nausea and vomiting and pulmonary interstitial and intraalveolar edema leading to fibrosis. The pulmonary fibrosis is distinct from the interstitial pneumonitis, which accompanies allogeneic stem cell transplantation and is not related to cytomegalovirus or other viral infections.

Nitrosoureas

Four chloroethyl nitrosoureas and one methyl nitrosourea are in clinical use. These agents are different from the nitrogen mustards in that they alkylate through an SN^1 reaction, forming a highly reactive intermediate in the presence of N, O, and P nucleophiles in DNA. The commonly used clinical agent is (2-chloroethyl)-*N*-nitrosourea (BCNU). *N*-[(4-amino-2-methyl-5-pyrimidinyl) methyl]-*N*-(2-chloroethyl)-*N*-nitrosourea (ACNU) is commonly used in Japan. A third agent, *N*-(2-chloroethyl)-*N*-cyclohexyl-*N*-nitrosourea (CCNU), is used predominantly as an PO nitrosourea in children with brain tumors. All of these compounds have high hydrophobicity, actively penetrating the blood–brain barrier.

The DNA alkylation sites include N^7 and O^6 of guanine. Chloroethylation at the O^6 position of guanine appears critical to cytotoxicity. DNA cross-linking by chloroethyl nitrosoureas include at 1-(3-cytosinyl), 2-(1-guanyl) ethane, and 1-2-bis(7-guanyl) ethane. The former is responsible for much of the cytotoxicity observed with the chloroethyl nitrosoureas. It is formed after alkylation at the O^6 position of guanine. This adduct undergoes intramolecular rearrangement to a circular intermediate, N^1. O^6 ethanoguanine is formed, which can then rearrange by attack at the opposite hydrogen-bonded base N^3 of cystine forming the interstrand cross-link. This is a unique DNA cross-link and is poorly recognized by DNA repair processes, leading to marked cytotoxic potency of this cross-link.

The pharmacokinetics of the chloroethyl nitrosoureas have been evaluated in both conventional and high-dose schedules. A very short half-life has been detected, which is quite variable, but an association between the AUC of BCNU and pulmonary toxicity has been observed. BCNU is predominantly used for high-dose treatment of recurrent lymphomas. In both settings, it is an effective form of therapy with sustained complete remission (CR) rates of approximately 40% to 60%. Doses of between 600 and 1000 mg/m^2 have been safely administered. The chloroethyl nitrosoureas cause profound and cumulative BM suppression at conventional doses of 120 to 150 mg/m^2, limiting treatment to three to five cycles at 6-week intervals.

Complications of high-dose BCNU therapy include pulmonary toxicity and renal toxicity at doses higher than 600 mg/m^2. Pulmonary toxicity, as evidenced by a decrease in the DL_{CO} (diffusing capacity of the lung for carbon monoxide), occurs in up to 40% of patients and is symptomatic in 10% to 15% of patients. It can be managed with steroids during the inflammatory but not during the fibrotic phase and is lethal in some cases. Fibrosis is associated with an early interstitial infiltrate followed by evidence of hyaline membrane formation and replacement of the chronic inflammatory cells by fibrosis over a 4- to 6-week period. Renal dysfunction associated with nitrosourea therapy occurs less frequently than severe cumulative myelosuppression and pulmonary fibrosis and is typically seen at doses above 1000 mg/m^2. Interstitial nephritis with glomerulosclerosis, interstitial fibrosis, and dropout of tubules has been reported with BCNU or CCNU.

Methylating Agents

Four methylating chemotherapeutic agents are available for clinical use. These include procarbazine, dacarbazine (DTIC), streptozotocin, and temozolomide. Procarbazine and DTIC are triazines. Streptozotocin is a monofunctional methyl nitrosourea derivative with an attached sugar moiety, and temozolomide is an imidazotetrazine synthesized in England in the 1960s, reaching clinical trials in the late 1980s. All react with DNA by undergoing SN^1 reactions forming a methyldiazonium ion, resulting in methylation of N^7 guanine, O^6 guanine, O^4 and O^2 thymine, and N^3 adenine. None form DNA cross-links. However, all induce high levels of DNA methylation. N^7 methylguanine is unstable, leading to ring opening and both spontaneous and enzymatically mediated depurination. Repair proceeds through the base excision repair system. Recognition by the *N*-methylpurine glycosylase results in removal of the adducted base with formation of an abasic site that is recognized by the apurinic (AP) endonuclease, which then cleaves the backbone at the AP site. Subsequently, the free 5′ sugar is released by DNA lyase with repair initiated by β-polymerase and DNA ligase. Base excision repair effectively removes N^7 methylguanine and N^3 methyladenine and restores DNA to normal. These lesions appear to contribute little to cytotoxicity and appear to be up to 500-fold less potent as cytotoxic adducts than O^6 methylguanine.

O^6 methylguanine mispairs with thymine during DNA synthesis, resulting in a lesion recognized by the mismatch repair system. This system consists of two sets of enzyme homologs of mismatch repair in prokaryotes, mutS and mutL. Mispair recognition proteins are MSH6, MSH3, and MSH2, homologs of the mutS system in bacteria. MSH2 and MSH3 form a stable heterodimer with MSH6. Recognition of the mispair recruits additional proteins to the complex, including MLH1 and PMS1/PMS2, which are homologs of mutL in bacteria. These proteins initiate exonuclease cleavage of a long patch in the newly synthesized strand of DNA. This is then repaired by polymerases delta and epsilon. Unfortunately, if the O^6 methylguanine adduct is not removed before repair synthesis, a thymine is again inserted opposite the O^6 methylguanine and the repair process begins again, resulting in an aberrant episode of repair and multiple single-strand breaks. Cell protection from methylating agents arises either by removal of O^6 methylguanine (vide infra) or inactivation of the mismatch repair system. Cells expressing high levels of the DNA repair protein for O^6 methylguanine, O^6 alkylguanine DNA alkyltransferase are approximately 10-fold more resistant to methylating agents than alkyltransferase-negative cells. Mismatch repair-mediated single-strand patches promote chromosomal aberrations, homologous and nonhomologous recombination, and induction of apoptosis in a p53-dependent and -independent manner. Absence of one or

more protein components responsible for mismatch repair, leads to the phenotype of replication error repair (RER), which is commonly observed in hereditary colon cancer as well as endometrial cancer, gastric cancer, and approximately 15% of lymphomas. Cells lacking mismatch repair are up to 100-fold more resistant to methylating agents than cells with mismatch repair, regardless of alkyltransferase activity. Acquisition of mismatch repair defects is associated with acquired resistance to methylating agents and cisplatin, which is also recognized by this protein complex.

Procarbazine was synthesized as a monoamine oxidase inhibitor and has been used since the 1950s for the treatment of Hodgkin lymphoma and NHL, as well as a component of combination therapies for gliomas. Recent use has been superseded by newer agents. Patients receiving procarbazine form O^6 methylguanine DNA adducts with depletion of the alkyltransferase enzyme, a suicide protein that removes the methyl group in irreversible stoichiometric reaction. Chromosomal breaks, single-strand breaks, and chromosomal aberrations and sister chromosome exchanges observed after procarbazine treatment support its association with treatment-related myelodysplasia and leukemia.

DTIC is metabolically activated by cytochrome P450 microsomal oxidoreductases, ultimately leading to formation of the methyldiazonium ion and DNA methylation. DTIC is used in combination with doxorubicin, vinblastine, and bleomycin (ABVD) for treating Hodgkin disease (see Chapter 74) and is also used for metastatic malignant melanoma in combination with BCNU, cisplatin, and tamoxifen. Activation of DTIC requires hydroxylation of one terminal methyl group caused by demethylation forming 5(3-methyltriazeno)-imidazole-4-carboxamide (MTIC), with spontaneous decomposition to the methyldiazonium ion, which alkylates the DNA, as noted earlier. Similar to procarbazine, DTIC has been shown to form N^7 methylguanine and O^6 methylguanine DNA adducts in human peripheral blood lymphocytes and to deplete alkyltransferase through repair of O^6 methylguanine DNA adducts. A correlation has been documented between tumor response and formation of O^6 methylguanine DNA adducts, indicating their importance in clinical antitumor effects. Maximum tolerated doses of DTIC are approximately 1000 mg/m^2, with myelosuppression and gastrointestinal toxicity (including severe watery diarrhea) as the most common side effects.

Temozolomide represents an imidazotetrazinone. It differs from DTIC in that it is chemically degraded to the monomethyl triazine, MTIC, at neutral pH and does not require P450 enzymatic demethylation. Compared with DTIC, temozolomide has much more consistent pharmacokinetic parameters, including peak serum concentrations, volume of distribution and clearance, and conversion to MTIC. Clinical studies found considerable activity in acute leukemias. Dose-limiting toxicity was thrombocytopenia and, less frequently, neutropenia, with maximum tolerated doses of 1000 mg/m^2 given over 5 days on a daily or twice daily regimen. Nausea and vomiting were the other common side effects, easily controlled with antiemetics. Formation of O^6 methylguanine has been documented in clinical trials with temozolomide with much more rapid depletion of the alkyltransferase, suggesting that temozolomide may be more effective than the other methylating agents because of its ability to form higher levels of toxic O^6 methylguanine DNA adducts. Early phase clinical trials using temozolomide in patients older than 60 years with AMLs indicated that the drug is well tolerated and has a modest response rate. A second study has shown that combination therapy including temozolomide, which may induce neoantigens, is also effective.

Bendamustine

Bendamustine is comprised of a 2-chloroethylamine nitrogen mustard alkylating group, a benzimidazole ring, and a butyric acid side chain. Its mechanism of action is unknown but appears to be different than other alkylating agents, causing DNA damage that is repaired predominantly by the base–excision repair system and has activity against lymphoid cell lines resistant to alkylating agents.[3] Myelosuppression with leukopenia and thrombocytopenia is the most frequent side effect, with mild nonhematologic side effects, including nausea, fatigue, constipation and diarrhea. In vitro studies demonstrated synergy between bendamustine and rituximab. This observation led to several phase II trials of the combination for treatment of relapsed CLL and low-grade lymphoma patients, with high response rates observed. Phase III studies comparing standard treatment with bendamustine and rituximab in frontline treatment of CLL[4] and indolent lymphomas (see Chapter 76) have been completed, with demonstrated efficacy in this setting. Bendamustine is also active against multiple myeloma, and combinations with steroids and bortezomib or the immunomodulatory agents thalidomide and lenalidomide have been reported to result in high response rates in patients with relapsed or refractory disease.

Alkylating Agent–Induced Leukemias

Alkylating agents induce dose-limiting myelosuppression and cause sublethal DNA damage to hematopoietic progenitors, causing mutational events that lead to malignant transformation to preleukemic and leukemic states. A concern exists about the use of hematopoietic growth factors after exposure to alkylating agents (see Chapter 59). There is evidence of increased cytotoxicity to hematopoietic progenitors during simultaneous exposure to these agents and growth factors. Treatment-related AML (T-AML) accounts for approximately 15% of all adult AML. Approximately 50% of T-AML patients have a preleukemic phase compared with only 10% of patients with de novo AML. CRs are achieved in 15% to 30% of patients with T-AML and a mean remission duration of 2 months. Chromosomal abnormalities are common in T-AML, with more than 90% of cases expressing a chromosomal rearrangement, loss, or addition.

Historically, patients with Hodgkin disease treated with mechlorethamine and procarbazine in the MOPP regimen or with CCNU were at the highest risk if exposed to radiation as well as an alkylating agent combination. Patients with polycythemia vera treated with chlorambucil were at much higher risk than patients treated with phlebotomy alone, which can contribute to a shift in treatment strategy. Patients with myeloma and ovarian cancer have developed T-AML, especially after prolonged exposure to alkylating agents. The introduction of temozolomide for the treatment of glioblastoma multiforme is of concern given its use as a 5 day per month or daily regimen for an extended period of time. There have been a number of reports of secondary leukemia in this patient population indicating that the mutagenic effect of temozolomide seen preclinically will need to be monitored in treated patients. Patients treated with alkylating agents for benign diseases such as nephritis, lupus, psoriasis, rheumatoid arthritis, and Wegener granulomatosis also have an increased risk of T-AML. The mean latency between exposure and T-AML from alkylating agents is 4 to 5 years, in contrast to T-AML from etoposide, which has a latency period as short as 1 year. The cumulative risk of developing T-AML is between 10% and 17% at 4 to 6 years for myeloma patients treated with melphalan and between 2% and 10% at 7 to 10 years in patients with Hodgkin disease. Alkylating agent–associated T-AML has also been recognized in patients with breast and colon cancer. A series of nonrandom chromosomal aberrations associated with T-AML has been identified. Loss or deletion of all or part of the long arm [q] of chromosomes 5 or 7 is common, as are trisomy chromosome 8 and deletions of the short arm of chromosomes 12, 17, and 21.

Antimicrotubule Agents

The antimicrotubule drugs include the vinca alkaloids (e.g., vincristine, vinblastine, vinorelbine and vindesine), taxanes (e.g., paclitaxel and docetaxel), and novel epothilones (ixabepilone).

The vinca alkaloids are naturally occurring (vincristine and vinblastine) or semisynthetic (vinorelbine) nitrogenous bases derived

from the pink periwinkle plant, *Catharanthus roseus*. Paclitaxel was originally isolated from the bark of the Pacific yew, *Taxus brevifolia*. Paclitaxel can also be isolated from other members of the *Taxus* genus and from a fungal endophyte that grows on the Pacific yew. Docetaxel is derived semisynthetically from 10-deacetyl-baccatin III, which is obtained from the needles of the European yew, *Taxus baccata*.

The vinca alcaloids bind to the protein tubulin at a site distinct from that of the taxanes and, at low concentrations, inhibit microtubule dynamics. At higher concentrations, these vinca alkaloids disrupt microtubules and mitotic spindle, resulting in cell cycle mitotic arrest and apoptosis of cells (see Fig. 55-3). In contrast, after binding to a-tubulin, taxanes kinetically stabilize microtubule dynamics at their plus ends and shift the equilibrium toward tubulin polymerization into micrutubule bundles. This also causes mitotic arrest and apoptosis of cells. The mitotic arrest caused by antimicrotubule drugs is associated with phosphorylation of the BCL2 protein and increased intracellular levels of the BCL2-associated X protein (BAX), which promote apoptosis.

Antimicrotubule agents, particularly the vinca alkaloids, are used in the management of lymphomas and leukemias and continue to be used in the mainstay of clinical chemotherapeutic regimens. Because of their mechanism of action, they are best used in multiagent combinations, in which potentiation of efficacy with other classes of agents, such as antimetabolites and DNA-damaging agents, provide better therapeutic responses and well-tolerated treatments.

Antimetabolites

The antimetabolites consist of low-molecular-weight compounds that interfere with micromolecular synthesis. As a group, they may be contrasted with agents such as the anthracycline antibiotics, which interfere with macromolecular synthesis. The nucleoside analogs exhibit structural similarities to naturally occurring nucleosides and are incorporated into either DNA or RNA with lethal consequences. Alternatively, they block key enzymes in de novo purine or pyrimidine biosynthesis. The antimetabolites in use in hematologic disorders can be divided into the following broad categories:

1. Inhibitors of de novo purine or pyrimidine synthesis (e.g., hydroxyurea)
2. Folic acid analogs (e.g., methotrexate)
3. Pyrimidine analogs (e.g., cytosine arabinoside [ara-C], 5-azacytidine, gemcitabine)
4. Purine analogs (e.g., 6-thioguanine, 6-mercaptopurine, fludarabine, chlorodeoxyadenosine, deoxycoformycin, clofarabine, nelarabine)

These categories are not mutually exclusive; for example, some nucleoside analogs (e.g., ara-C and 6-thioguanine) also inhibit enzymes involved in DNA or deoxyribonucleotide biosynthesis. The antimetabolites are predominantly cycle-active agents and in most cases are phase specific, being primarily active against cells in S phase. Because the growth fraction of hematologic malignancies tends to be higher than that of nonhematologic malignancies, antimetabolites are particularly useful in the former disorders. In contrast to alkylating agents, antimetabolites have limited carcinogenic and leukemogenic potential. The fluorinated pyrimidines (e.g., 5-fluorouracil) are generally not used in treating hematologic disorders and are not discussed further in this chapter.

Clofarabine (2-chloro-2′-arabino-flouro-2′-deoxyadenosine) is a purine analog with activity in patients with relapsed acute leukemia. Its activation requires cellular uptake and conversion to the triphosphate nucleotide. It then decreases ribonucleotide reductase; alters nucleotide precursors; inhibits and reduces the function of antiapoptotic proteins such as Bcl-X(L), Mcl-1, and Bax with dephosphorylation of akt; and inhibits DNA synthesis. It appears more active against B-cell than T-cell lymphomas but also has activity in AML and myelodysplastic syndromes (MDS). Reversible liver toxicity and myelosuppression can be dose limiting (see Chapter 58).

Nelarabine (9-β-D-arabinofuranosylguanine) is another FDA-approved purine analog for the treatment of refractory T-cell leukemias and lymphomas. It preferentially accumulates in T cells and is incorporated into DNA, causing chain termination and inhibiting DNA synthesis. The FDA approved this drug after analyzing the results of two phase II clinical trials, one in pediatric T-cell acute lymphoblastic leukemia (ALL) and the other in adults with T-cell lymphoblastic lymphoma. In both cases, patients had relapsed after at least two induction regimens. Because CRs were seen in 13% of the 39% of pediatric patients and in 18% of the 28 adult patients, the FDA granted approval. Neurologic toxicity is dose limiting. Good response rates, including CRs, have been seen in patients with refractory T-cell leukemias.

Inhibitors of DNA Topoisomerase I and II

The inhibitors of DNA topoisomerases I and II include such drugs as doxorubicin, daunorubicin, mitoxantrone, etoposide, and topotecan. Before describing the specific inhibitors, a brief review of the drug targets (topoisomerase enzymes) will be presented (Table 55-2).

DNA Topoisomerase I

Topoisomerase I is a ubiquitous enzyme whose function in vivo is to relieve the torsional strain in DNA, specifically to remove positive supercoils generated in front of the replication fork and to relieve negative supercoils occurring downstream of RNA polymerase during transcription. Topoisomerase I is catalytically active as a 100-kd monomer and is concentrated in nucleoli, although smaller amounts are found in a diffuse nuclear distribution. The gene for this enzyme is located on human chromosome 20q12-13.2. Topoisomerase I does not require ATP for catalytic activity. It binds double-strand DNA over 15 to 25 bp (with a preference for supercoiled or bent DNA) followed by cleavage of one DNA strand and forming a transient covalent phosphotyrosyl bond at the 3′-end of DNA. DNA torsional strain is then relieved by a "controlled rotation" mechanism (see Fig. 55-1) subsequent to which the cleaved DNA is religated. The three-dimensional crystal structure of human topoisomerase I, both in covalent and noncovalent complexes with DNA, has defined the structural elements of the enzyme that contacts DNA. The association between topoisomerase I and the 3′-end of cleaved DNA has been termed the *cleavable complex,* which is stabilized by topoisomerase I inhibitors.

DNA Topoisomerase II

Two isoforms of human topoisomerase II (α and β) exist. They act as homodimers to cleave double-stranded DNA and require ATP for full activity. Their role in vivo is to relieve torsional strain in DNA, and their cellular distribution is determined by nuclear localization signals contained in the C-terminal domain. These isoforms are distinct in that they have different-size monomers (see Table 55-2), their genes are located on separate chromosomes, their nuclear distribution is different, and only the α-isoform shows cell cycle variations in amount and activity (with maximal activity being in G_2/M). The mechanism of action of topoisomerase II involves several steps (Fig. 55-4): DNA recognition and binding (curved and supercoiled DNA, as well as DNA crossovers, are preferred), the sequential cleavage of the two strands of DNA with covalent attachment of a monomer to each 5′-end of the cleaved DNA, passage of another DNA duplex through the break site (e.g., to relieve DNA torsional strain or decatenate daughter chromosomes at the end of replication), religation of the cleaved DNA, and ATP hydrolysis-dependent enzyme turnover. The binding of ATP by topoisomerase II is required for the strand passage reaction. Again, the association between topoisomerase II monomers and the 5′-end of the cleaved DNA has been termed the *cleavable complex,* the stabilization of which generally correlates with the cytotoxic activity of specific topoisomerase II inhibitors.

Table 55-2 Characteristics of Mammalian DNA Topoisomerases

	Topoisomerase I	Topoisomerase IIα and Topoisomerase IIβ	
Size of monomer (kd)	100	170	180
mRNA (kb)	4.2	6.2	6.5
Chromosome	20q12-13.2	17q21-22	3p24
DNA cleavage	Single-strand breaks	Double-strand breaks	Double strand
Covalent intermediate	3′PO_4-Tyr^{723}	5′PO_4-Tyr^{804}	5′PO_4-Tyr^{821}
ATP requirement	No	Yes	Yes
Nuclear location	Nucleoli, diffuse	Nuclear matrix and scaffold, nucleoli	Nucleoli Nuclear matrix
Cell cycle dependence	None	Yes, maximum in G_2/M	None
Nuclear localization signal	NH_2-end	COOH-end	COOH-end
Phosphorylation	By CK II and PKC (increases activity)	By CK II, PKC, $p34^{cdc2}$, MAPK	Increases mass to 190 kd
Role	In replication, transcription, and recombination	In replication, transcription, chromosome condensation/segregation, and recombination	rRNA transcription
Inhibitors	Camptothecins	(see Table 55-3)	

ATP, Adenosine triphosphate; *MAPK,* mitogen-activated protein kinase; *PKC,* protein kinase C.

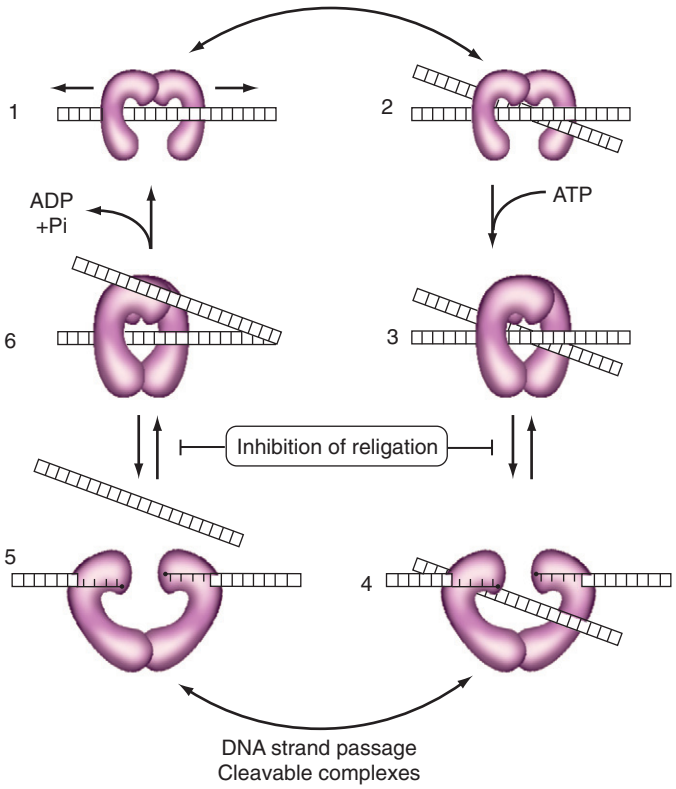

Figure 55-4 DNA TOPOISOMERASE II CATALYTIC CYCLE. (1) Noncovalent binding of DNA by the topoisomerase II homodimer. (2) DNA recognition and preferential binding to crossovers by topoisomerase II. (3) Binding of adenosine triphosphate (ATP) promotes the formation of a topologic complex. (4) DNA cleavage with covalent linkage of each topoisomerase II monomer to the 5′-DNA terminus of the break. (5) Poststrand passage cleavable complex. (6) Religation of the cleaved DNA is followed by ATP hydrolysis and enzyme turnover. DNA topoisomerase II inhibitors generally increase cleavable complexes by inhibiting the religation activity.

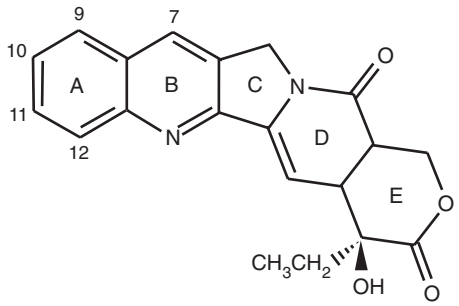
Because topoisomerase I and II inhibitors convert their respective enzymes into DNA-damaging agents, it is usually true that the more enzyme target a cell contains (provided it is in the nucleus), the more cytotoxic is the specific inhibitor. An exception to this generalization is CLL cells, which have abundant topoisomerase I but are not very sensitive to topoisomerase I inhibitors because topoisomerase I inhibitors are S phase–specific and CLL cells have very few cells in S phase. Finally, in addition to topoisomerase I and II, a mammalian DNA topoisomerase III has been described and found to be essential for early embryogenesis in the mouse. In addition to the presumed lethality of a homozygous deletion of the topoisomerase II gene, topoisomerases I and III appear to be essential for cell growth and division in mammals. The specific role of topoisomerase III in humans is unknown at present.

DNA Topoisomerase I Inhibitors

Camptothecin is a plant alkaloid first identified in 1966 from the tree *Camptotheca acuminata.* Early clinical studies with camptothecin were stopped primarily because of hemorrhagic cystitis, resulting from conversion of the sodium salt form to the active lactone form owing to its acidic pH in the bladder. Renewed interest in camptothecin occurred in 1985 when topoisomerase I was identified as the target of this drug and as new more water-soluble analogs became available. At present, two topoisomerase I inhibitors have been approved by the FDA as second-line agents for the treatment of ovarian carcinoma and colorectal cancer; these are topotecan and irinotecan (CPT-11) (Fig. 55-5). Topotecan has been shown to be active in the treatment of MDS and inactive in the treatment of CLL. Responses to topotecan have also been seen in refractory multiple myeloma, refractory large cell lymphoma, and refractory acute leukemia.



The lactone forms of topotecan and SN-38 (the active form of CPT-11 generated in vivo by the action of a carboxylesterase) are as much as 1000-fold more active inhibitors of DNA topoisomerase I than are their carboxylate forms. The lactone form predominates at an acidic pH. Topoisomerase I inhibitors stabilize the DNA–enzyme cleavable complex and thus inhibit DNA religation, but the production of DNA double-strand breaks results from a collision of the DNA replication fork with the ternary drug–enzyme–DNA complex

that is the lethal event (see Fig. 55-4). Topoisomerase I inhibitors are considered S phase–specific agents because they require ongoing DNA synthesis to exert their cytotoxic effect.

DNA Topoisomerase II Inhibitors

Inhibitors of DNA topoisomerase II are commonly used for the treatment of hematologic malignancies. Three general types of topoisomerase II inhibitors (Table 55-3) exist. The first are the topoisomerase II *poisons,* typified by etoposide, which results in the stabilization of cleavable complexes. The second group are the *catalytic inhibitors,* represented by aclarubicin, merbarone, and the bis-2,6-dioxopiperazine derivatives (ICRF-193, ICRF-159, ICRF-187); these are drugs that, except for aclarubicin, do not bind DNA and do not stabilize cleavable complexes but rather interfere with some aspect of topoisomerase II catalytic activity (e.g., ICRF-187 inhibits topoisomerase II adenosine triphosphatase [ATPase] activity). The final class includes drugs that can inhibit both DNA topoisomerases I and II and are represented by intoplicine and saintopin.

DNA topoisomerase II poisons (see Fig. 55-5 for structures) are most likely cytotoxic because they trap DNA topoisomerase II complexes on nascent DNA in the nuclear matrix. The topoisomerase II poison-stabilized enzyme–DNA complex likely acts as a replication fork barrier and leads to the generation of irreversible DNA damage and cell death in proliferating cells. Whereas experiments in yeast show that although DNA synthesis is a major determinant for cell killing by topoisomerase I inhibitors, topoisomerase II poisons are also cytotoxic during other phases of the cell cycle.

Drug Resistance to Topoisomerase Inhibitors

Essentially all of the topoisomerase II poisons (see Tables 55-2 and 55-3) are substrates for the drug efflux pump P-glycoprotein (PGP), and many are substrates for MRP and lung resistance–related protein. In addition, several point mutations and gene deletions have been defined in the gene for topoisomerase II, resulting in the production of an enzyme with altered catalytic or cleavage activity. The third mechanism of resistance is a decrease in expression of the enzyme such that there is less target for the inhibitor to "convert" to a DNA-damaging agent. This can result from a proliferation-dependent or cell cycle–dependent decrease in topoisomerase II, from a specific attenuation of topoisomerase II or from an intrinsic absence of topoisomerase II (identified in some acute and chronic leukemias). The fourth resistance mechanism involves alterations in the subcellular distribution of the enzyme. Truncation of the COOH-end of topoisomerase II has resulted in the cytoplasmic distribution of enzyme caused by a loss of nuclear localization signals, so that the enzyme cannot interact with DNA in the presence of an inhibitor and the cell is resistant. However, mutations in the gene for topoisomerase II do not appear to be common because only a single patient with AML has been found to have a point mutation. By contrast, CLL cells are resistant to topoisomerase II inhibitors because they express very low levels of the protein.

Platinum Analogs

During a study of the effects of electric current on growing bacteria, the antibacterial and, later, the antitumor activities of the platinum compounds were fortuitously discovered. The antitumor agent cisplatin, its cis-carboxylester analog, carboplatin, and the diaminocyclohexane-containing oxaliplatin, are heavy metal platinum complexes. They are activated when one of their ligands (cisplatin; chloride and carboplatin; carboxylester) is displaced by water, leading to the formation of positively charged aquated platinum complexes, allowing platinum to stably bind DNA, RNA, proteins, or other critical biomacromolecules (see Fig. 55-2). With DNA, platinum complexes form covalent links to the N^7 position of guanine and adenine. The N^7 adducts at d(GpG) or d(ApG) result in intrastrand or interstrand DNA cross-links that bend the DNA helix and inhibit DNA synthesis. The cytotoxicity of platinum analogs correlates with the total platinum binding to DNA, as well as with the intrastrand or interstrand cross-links. This results in DNA damage, which triggers apoptosis of sensitive cells.

Cisplatin, carboplatin, and oxaliplatin are used in the treatment of refractory lymphomas as part of high-dose and intensification therapy.

Miscellaneous Agents

Among the agents included in this category, only plicamycin, bleomycin, procarbazine, L-asparaginase, gallium nitrate, and glucocorticoids are of current interest to hematologists; these are discussed in Appendix 55-6.

Targeted Agents

Imatinib Mesylate and Other BCR/ABL Kinase Inhibitors

Imatinib mesylate (formerly CFP57148; Gleevec; STI571) is a phenylaminopyrimidine developed as an inhibitor of the aberrant tyrosine kinase BCR-ABL, expressed in the leukemic cells of most patients with CML (see Chapter 66). The role of the BCR-ABL kinase in the pathogenesis of CML and its use in CML treatment are discussed in further detail in Chapter 69.

Imatinib mesylate represents the prototypical molecularly targeted agent belonging to the class of signal transduction inhibitors and exerts its action through direct inhibition of the BCR-ABL kinase, expressed in CML but not in normal cells. Imatinib mesylate is not absolutely specific for the BCR-ABL kinase because it also inhibits other kinases, including KIT (formerly designated c-KIT), PDGF, stem cell factor (SCF), and TEL-ARG. Radiographic crystallography studies revealed that imatinib mesylate competitively binds to the ATP-binding site of the Abl kinase and stabilizes it in an inactive conformation. The 50% inhibitory concentration (IC_{50}) of imatinib mesylate for BCR-ABL is in the submicromolar range and is substantially lower than the supramicromolar levels achievable in the plasma of patients receiving the drug by the PO route.

Exposure of $BCR\text{-}ABL^+$ leukemic cells to imatinib mesylate not only blocks their proliferation but also induces apoptosis. This finding suggests that CML cells have become "addicted" to constitutive activation of BCR-ABL for their survival. This is believed to be secondary to activation of a large number of downstream survival pathways, including those related to STAT5A (signal transducer and activator of transcription 5A, previously designated STAT5), MEK/extracellular signal-regulated kinase (ERK), NFκB, AKT, and Bcl-xL, among others. In addition to promoting survival in $BCR\text{-}ABL^+$ cells, activation of these pathways also confers resistance to conventional cytotoxic drugs.

Despite the success of imatinib mesylate in the treatment of chronic phase CML and, to a lesser extent, accelerated or blast phase CML, the preexistence or development of resistance represents a major therapeutic challenge that can occur at any stage of the disease. Primary or secondary resistance can develop through a variety of mechanisms.[5] BCR-ABL–dependent mechanisms correspond to the emergence of mutations in ABL kinase domain, which can be located in the imatinib-binding site, the P loop, the catalytic domain, or the activation loop. Many of these mutations are present at the time of diagnosis, and resistant clones emerge after exposure to imatinib. Resistance mechanisms independent of BCR-ABL include development of multidrug resistance mechanisms (e.g., P-gp related); decreased levels of human organic cation transporter (hOCT-1); acquisition of additional genetics abnormalities (clonal evolution), including acquisition of an additional Philadelphia chromosome, trisomy 8, and isochromosome 17q; increased expression of the BCR-ABL protein; and SRC kinase overexpression.

One logical approach to enhancing imatinib mesylate activity or overcoming resistance, or both, is to combine it with more conventional cytotoxic agents, including ara-C, interferon, and others. The combination of imatinib mesylate with pegylated interferon resulted in higher rates of major molecular response (MMR) than standard dose imatinib, albeit with increased toxicity, including rash, depression, and cytopenias. The combination of imatinib and cytarabine resulted in similar response rates and was associated with higher rates of toxicity. Longer follow-up is needed to determine whether the improved response observed with imatinib combined with interferon results in higher survival rates. Use of imatinib doses higher than 400 mg/day was explored in several large randomized clinical trials, with higher doses achieving confirmed complete cytogenetic and major molecular responses more rapidly but without a clear survival benefit.

Imatinib also has activity in diseases dependent on other kinases, such as PDGF receptor A (PDGFRA), PDGFRB, or Kit, and is active against myeloproliferative neoplasms associated with eosinophilia and FIP1L1/PDGFRA or PDGFRB fusion genes, as well as against systemic mastocytosis without KIT^{D816V} mutation (see Chapter 66).

Dasatinib

Dasatinib is a second-generation Abl kinase inhibitor approved for the treatment of patients with CML. Dasatinib is a PO multikinase inhibitor, affecting Abl, Kit, PDGFR, and Src kinases. It binds the ATP-binding site of Abl in opposite direction than imatinib, can inhibit active and inactive forms of the kinase, and requires fewer points of contact. Compared with imatinib, dasatinib is several hundred times a more potent inhibitor of Abl. Initial studies demonstrated dasatinib induced responses in patients who had developed resistance to imatinib who are treated in the chronic, accelerated and blast phase of CML. A recent large phase III randomized trial compared dasatinib and imatinib as initial therapy for chronic phase CML and observed that dasatinib therapy led to deeper and more rapid responses, albeit with no differences in survival outcomes.[6] As a multikinase inhibitor, it has a broader and alternative toxicity profile, with pulmonary edema, pleural effusions, and thrombocytopenia being the more frequent adverse effects. Recently, higher rates of pulmonary hypertension have been observed in patients receiving dasatinib. There is a high response rate in patients with wild-type sequences of BCR-ALB and in patients with mutations in the Abl protein, conferring resistance to imatinib, with the exception of the T315I mutation. Dasatinib is approved in two doses: 70 mg twice daily and 100 mg once daily for chronic phase and 70 mg twice daily or 140 mg once daily for accelerated phase. Once-daily dosing achieved comparable efficacy with less toxicity (see Chapter 66).

Nilotinib

Nilotinib is the other second-generation Abl kinase inhibitor approved for treatment of patients with CML (see Chapter 66). Nilotinib has increased affinity for the Abl kinase compared with imatinib, binding with an improved topologic fit to the kinase site in its inactive form.[7] Nilotinib is active in chronic and accelerated phase CML patients who have developed resistance to imatinib. As with dasatinib, nilotinib was compared with imatinib in a phase III randomized trial as

initial therapy for chronic phase CML patients, with nilotinib achieving higher rates of complete cytogenetic and major molecular responses and with fewer cases of disease progression or clonal evolution in the nilotinib-treated cohorts. Survival outcomes were similar in all arms. Common adverse events with nilotinib included rash, gastrointestinal disturbances (nausea, vomiting, diarrhea), neutropenia, and thrombocytopenia. Pleural effusion and peripheral edema are less common than with dasatinib. In addition, QT prolongation and a risk of pancreatitis are serious side effects of nilotinib.

Bruton Tyrosine Kinase Inhibitors

Bruton tyrosine kinase (Btk) is a cytoplasmic tyrosine kinase with a well-defined role in B-cell receptor signaling that is fundamental in B-lymphocyte development, differentiation, and signaling. Btk is a member of the Tec family of kinases (see Chapter 76). Activation of Btk triggers a cascade of signaling events that culminates in the generation of calcium mobilization and fluxes, cytoskeletal rearrangements, and transcriptional regulation of NFκB and nuclear factor of activated T cells (NFAT).[8] Ibrutinib (PCI-32765) is a first-in-class, selective, irreversible, small molecule inhibitor of Btk. Ibrutinib binds covalently to a cysteine (Cys 481) in the Btk active site, with potent and irreversible enzymatic activity. Early clinical trials have demonstrated a favorable toxicity profile with remarkable clinical activity in patients with relapsed CLL.

An early transient phase of lymphocytosis followed by resolution was associated with response in CLL and mantle cell lymphoma patients. Serious adverse events associated with PCI-32765 occurred in approximately 10% of patients, with rash and febrile neutropenia as reported events. Rare cases of serious bleeding were reported. Dosing has not yet been established, and ibrutinib has not to date received FDA approval. Tested doses were 420 mg and 840 mg/day, with both doses having similar efficacy.

PI3K/AKT Inhibitors

The PI3K/AKT (PKB) pathway is involved in the regulation of diverse cellular functions, including cell growth, protein synthesis, cell cycle regulation, glucose metabolism, and motility. PI3K catalyzes the conversion of phosphatidylinositol diphosphate to phosphatidylinositol triphosphate, which activates, through PDK1, the phosphorylation and activation of the serine/threonine kinase AKT. The dual-specific phosphatase and tensin homologue (PTEN) opposes the actions of PI3K and is mutated in many cancers. Activation of AKT signals to multiple downstream targets, and generally results in pro-survival actions. Targets of AKT involve proteins involved in cell survival (e.g., Bad, procaspase 9, CREB, forkhead transcription factors [FHKR], IB), cell cycle regulation ($p21^{CIP1}$, $p27^{KIP1}$, cyclin D_1), glycogen synthesis (GSK3), and protein synthesis (FRAP1, $p70^{S6K}$). Because of the frequency of PTEN mutations in transformed cells and the dependence of numerous cancers on an intact PI3K/AKT pathway for survival, the PI3K/AKT cascade has become an attractive target for therapeutic intervention.

In addition, evidence indicates that dysregulation of the PI3K/AKT pathway is a key proliferative pathway in hematologic malignancies. For example, the fusion protein nucleophosmin/anaplastic large cell lymphoma (NP-ALK) constitutively activates the PI3K/AKT cascade and has been shown to play a functional role in NP-ALK–related transformation. Constitutive activation of AKT plays a pathogenetic role in mantle cell lymphoma.[9] In vitro studies with the AKT inhibitors wortmannin and LY294002 have resulted in apoptosis of mantle cell lymphoma cell lines.

PI3K Inhibitors

CAL-101 (GS 1101) is a highly selective inhibitor of the p110d isoform of PI3K (PI3Kδ), an isoform of PI3K that is expressed selectively in hematopoietic cells. CAL-101 has been shown to have in vitro activity against lymphoid cell lines and primary CLL cells (see Chapter 76). CAL-101 inhibits not only B-cell receptor signaling pathway–induced survival signals but also appears to disrupt the effects of microenvironmental signals on neoplastic cells,[10] affecting chemotaxis of tumor cells, which could explain the transient lymphocytosis observed after treatment of CLL patients with CAL-101. Clinical trials have shown that CAL-101 is active in treating patients with relapsed CLL and other relapsed lymphoid malignancies. The most common dose-limiting toxicity was elevation of tests measuring liver function. Dose escalation and dose response assessments support use of the 150 mg twice daily dose schedule. Ongoing trials include combinations of CAL-101 and rituximab or bendamustine.

AKT Inhibitors

The frequent presence of AKT abnormalities in human neoplasms makes this enzyme an attractive target for potential novel treatment strategies. Several drugs have been developed using dephosphorylation of the active enzyme, ATP competition, or allosteric inhibition of the enzyme as strategies for targeting AKT. These agents have, however, shown modest activity and some have been associated with significant toxicity. Perifosine, a synthetic PO alkylphospholipid, inhibits AKT by targeting the lipid-binding domain of AKT, which is essential for membrane translocation and subsequent activation of the enzyme. Early trials showed that perifosine had modest clinical activity as a single agent in patients with Waldenström macroglobulinemia and in patients with myeloma alone or in combination with bortezomib. A phase III study of perifosine plus bortezomib and dexamethasone for treatment of plasma cell myeloma is underway.

Janus Kinase 2 Inhibitors

Janus kinase 2 is a nonreceptor tyrosine kinase that plays a central role in the transduction of differentiation and proliferation signals in hematopoietic progenitor cells. Ligand-binding to surface receptors for hematopoietic growth factors leads to phosphorylation of JAK2 with subsequent activation of transcription factors in the JAK/STAT pathway, including STAT3 and STAT5 (see Chapters 67 to 69). Identification of the JAKV617F mutation in patients with myeloproliferative neoplasms, including polycythemia vera, essential thrombocytosis, and primary myelofibrosis (PMF), represented a fundamental step in understanding the pathophysiology of these disorders. The genetic abnormality corresponds to a point mutation in nucleotide 1849 of the molecule, where guanine replaces thiamine, resulting in substitution of a valine for phenylalanine in the JH2 pseudokinase autoinhibitory domain of the molecule. The result is either hypersensitivity to cytokine signals or constitutive activation of the kinase. Development of JAK2 inhibitors followed as a rational, targeted therapeutic strategy for these neoplasms (see Chapters 67 to 69).

Ruxolitinib (INCB018424) is a small molecule inhibitor of JAK1 and JAK2, and the first-in-class JAK inhibitor to receive FDA approval for treatment of intermediate and high-risk myelofibrosis[11,12] (see Chapters 67 to 69). It exerts its inhibitory activity through competitive inhibition of the kinase's ATP-binding catalytic site. In preclinical studies, JAK1/2 inhibition with ruxolitinib decreased STAT3/5 signaling both in wild-type cells and those carrying JAKV617F. In the initial phase I/II study, the maximum tolerated dose was 25 mg when given twice daily and 100 mg on once-daily dosing. The most common side effect was myelosuppression, primarily thrombocytopenia. After only 3 months of therapy, 44% of patients with splenomegaly experienced a reduction of more than 50%. Responses were observed in patients with carriers of the JAKV617F mutation as well as those with wild-type JAK2. Importantly, the majority of patients experienced a decrease in constitutional symptoms and improved exercise tolerance and performance status as well as weight gain. Of concern are subsequent observation

of rapid redevelopment of splenomegaly as well as the reported development of life-threatening syndromes when the agent was discontinued abruptly.

The COMFORT I and II randomized controlled clinical trials compared the efficacy of ruxolitinib for treatment of patients with intermediate- and high-risk myelofibrosis with either placebo or best available therapy, respectively. Both trials reached their primary end point with spleen volume reduction rates markedly superior with ruxolitinib (see Chapters 67 to 69). A survival benefit was observed when compared with placebo, but no progression-free survival (PFS), overall survival (OS), or leukemia-free survival was observed when compared with the best available therapy. Of note, treatment with ruxolitinib was not effective in reversing histologic, cytogenetic, or molecular abnormalities in peripheral blood or BM, suggesting that this agent may not be curative. Longer follow-up is needed to determine whether a survival benefit is present when ruxolitinib is used instead of other conventional agents. An ongoing phase III trial is comparing ruxolitinib with the best available treatment in patients with hydroxyurea-resistant polycythemia vera requiring phlebotomy.

A phase II trial from MD Anderson Cancer Center examined the role of ruxolitinib at a dose of 25 mg orally twice daily for the treatment of patients with relapsed or refractory AML (de novo or secondary to myeloproliferative neoplasms), MDS, ALL, or CML either in blast phase or resistant to tyrosine kinase inhibitors (TKIs). Ruxolitinib was very well tolerated, with only 4 out of 38 patients experiencing grade 3 or greater toxicities. Three patients achieved CR (CR = 08032; CRi = 1); these patients all had AML secondary to myeloproliferative neoplasms, and two were positive for the JAKV617F mutation. Further studies of combinations of ruxolitinib with hypomethylating agents are planned.

Other JAK2 Inhibitors

SB1518, also known as ONYX, is a JAK2 inhibitor with activity against the wild-type kinase as well as the JAKV617F mutated kinase; it also inhibits FLT3. It achieves high rates of reduction in spleen volume. The tested dose is 400 mg/day. The main side effects are gastrointestinal, predominantly diarrhea, nausea, and vomiting, with no hematologic toxicity observed.

CYT387 is a PO multikinase inhibitor, affecting JAK1/2, TYK2, TBK1, PRKD1, ROCK2, PRKCN, MAPK8 (mitogen-activated protein kinase 8), and CDK2/cyclin A. Early trials in myelofibrosis patients resulted in decreased splenomegaly and improvement in symptoms in the majority of patients treated. Of note, more than one-third of patients with improved splenomegaly had previously been treated with ruxolitinib. The most common side effects included myelosuppression (grade 3/4 thrombocytopenia in 22%; anemia in 3%). Nonhematologic side effects included headache, QTc prolongation, and abnormal liver test results. The maximum tolerated dose has been established at 300 mg/day given continuously in 28-day cycles.

TG 01348 is a multikinase inhibitor with activity against JAK2, FLT3, and RET. The maximum tolerated dose has been established at 680 mg/day. In a phase I study performed in intermediate- and high-risk PMF patients, a large proportion achieved spleen volume reduction, with symptom improvement as well as normalization of thrombocytosis and leukocytosis. Hematologic toxicities, including anemia and thrombocytopenia, were common. The most frequent nonhematologic toxicities were gastrointestinal disturbances.

Hypomethylating Agents

Promoter methylation within CpG islands regulates gene expression in all cells. Disruption of normal gene expression profiles accompanies malignant transformation, giving rise to complex patterns of gene expression. As a consequence, promoters of many genes have an altered pattern of methylation, resulting in either gene activation or gene repression. The link between these concepts and the interest in agents that alter promoter methylation began with the realization that azacytidine, an agent used sparingly for treating myeloid leukemias, had efficacy when given at low doses either intravenously or subcutaneously for extended periods of time and that in these cases, altered gene expression accompanied responses. Both azacytidine and 5-aza-2′-deoxycytidine (decitabine) act by irreversible inhibition of the DNA methyltransferases responsible for methylation of the cytidine in CpG islands and are thus S phase–specific agents. Wijermans et al first described that a related compound, 5-aza-2′-deoxycytidine, was effective when given as a continuous infusion to elderly patients with high-risk MDS, with a 54% response rate. The mechanism of action included both a direct change in promoter methylation and independent changes, with up to 70% genome-wide demethylation, suggesting either that genes with altered expression either up- or downregulated a second set of genes through altered pathways such as induction of WAFp21, p15, and p16 or in a more direct fashion through altered transcription factor expression. More recent studies have identified activity of these agents in both AML and CML. Most often, partial responses or short-lived complete responses are seen in AML with complete responses more common in MDS. Recent studies also describe a number of extended therapy regimens. Kantarjian et al reported a comparison of 20 mg/m^2 decitabine intravenously for 5 days with 20 mg/m^2 subcutaneously daily for 5 days and 10 mg/m^2 intravenously for 10 days. The 5-day IV dose schedule was judged superior on the basis of clinical outcome with 39% CR, a higher proportion of reactivation of p15, and achievement of a hypomethylation state as well as clinical tolerance.

Ubiquitin–Proteasome Inhibitors

The 26S proteasome is the central proteolytic machinery of the highly conserved ubiquitin proteasome system. In eukaryotic cells, whereas the lysosomal pathway degrades extracellular proteins imported into the cell through endocytosis or pinocytosis, the proteasome controls the degradation of intracellular proteins. Numerous studies have demonstrated that the ubiquitin–proteasome system controls basic cellular functions such as cell cycle progression, signal transduction, and programmed cell death, hence the interest in therapeutic interventions that manipulate proteasomal activity and potentially restore cellular homeostasis into transformed cells (see Chapter 85).

Ubiquitin is a highly conserved 76-amino-acid polypeptide that is expressed in all eukaryotic cells. Under the sequential action of E1 (ubiquitin-activating enzyme), E2 (ubiquitin-conjugating enzyme), and E3 (ubiquitin ligase), ubiquitin is activated and covalently conjugated to potential proteasome substrates via an isopeptide bond between the C-terminal glycine residue of ubiquitin and the ε-amino group of internal lysine residues in target proteins. The same set of enzymes also catalyzes the formation of the isopeptide bond between G76 and the lysine residue (K48) of previously conjugated ubiquitin, leading to formation of a polyubiquitin chain. Polyubiquitinated substrates are usually targeted for proteasomal degradation.

The 26S proteasome is a large (2000-kd) threonine protease present in the nucleus and cytoplasm of all eukaryotic cells. This ATP-dependent, multicatalytic protease eliminates damaged or misfolded proteins and regulates cyclins and CDK inhibitor cell cycle regulatory proteins as well as other proteins that govern the transcription factor activation, apoptosis, and cell trafficking. Its structure consists of two parts: the 20S core and the 19S cap regulatory particle (Fig. 55-6). The 19S cap is involved in the recognition, binding, and unfolding of ubiquitinated proteins and in the regulation of the opening of the 20S core. The 20S core is a cylinder composed of four stacked heptameric rings, each containing seven different α or β subunits (α7β7β7α7) (Figs. 55-6 and 55-7). Three different active sites are located inside the cylindrical core within the β-subunit rings. At least three distinct proteolytic activities are associated with the proteasome: chymotryptic, tryptic, and peptidylglutamyl. After release from the substrate, the polyubiquitin chain is hydrolyzed into single ubiquitin moieties, and tagged proteins are degraded to small peptides. Both the assembly of the 26S proteasome and the degradation of protein substrates are ATP dependent.

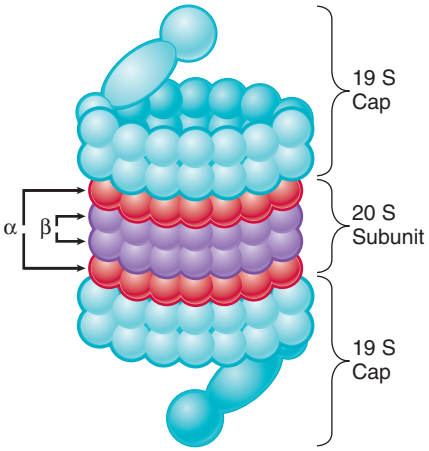

Figure 55-6 26S PROTEASOME.

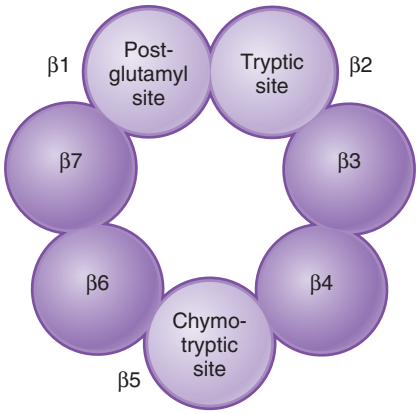

Figure 55-7 CROSS SECTION OF BETA RING OF THE 20S CORE OF THE 26S PROTEASOME.

Transformed cells are much more sensitive to blockade of the proteasome than are normal cells; the exact mechanism of this selective susceptibility is not fully understood. Early studies revealed that proteasomes are abnormally highly expressed in rapidly growing metazoan embryonic and human neoplastic cells but not in their well-differentiated and normal proliferating cells. The selectivity of proteasome inhibitors is not solely dependent on proliferative status because both transformed and normal fibroblasts have similar growth rates, although proteasome inhibitors are selectively toxic to SV-40–transformed cells. Cyclins A, B, D, and E; CDK inhibitors (p21, p27); inhibitory proteins (I-kB); oncogenes *(FOS, MYC);* and tumor suppressors (e.g., cyclin B1, p21WAF1/CIP1, p27, p53) are known substrates for the ubiquitin–proteasome pathway. The specificity of the ubiquitin proteasome is such that the degradation of individual substrates can be upregulated without affecting the proteolysis of others. Different classes of proteasome inhibitors have been identified and include peptide aldehydes (MG132, PSI, LLnV, ALLN, CEP1612, Z-LLF), streptomyces metabolite (lactacystin), dipeptidyl boronic acid bortezomib, vinyl sulfone tripeptides (NLVS), and natural products such as epoxomycin.

Proteosome Targeted Agents (Bortezomib)

Bortezomib (pyrazylcarbonyl-Phe-Leu-boronate), the first in this class of agents to enter clinical trials, is a dipeptidyl boronic acid that is a specific and selective inhibitor of the 26S proteasome. The Boron atom interacts reversibly with the catalytic threonine residue of the proteasome, primarily inhibiting its chymotrypsin-like activity. The inhibition of the ubiquitin–proteasome pathway with bortezomib was demonstrated to arrest the growth of malignant cells (breast, colon, prostate tumor cell lines, Burkitt lymphoma, adult T-cell leukemia, Lewis lung carcinoma, CLL, and myeloma cell lines) and sensitize them to chemotherapeutic agents (5-fluorouracil, cisplatin, taxol, doxorubicin, CPT-11, and gemcitabine). Bortezomib mediates these effects through multiple mechanisms by regulating the expression of proteins involved in cell cycle progression ($P21^{cip1}$, $P27^{Kip1}$), oncogenesis (P53, I-kB), apoptosis (BCL2, BIRC2, BIRC3, BIRC4, BAX), and more recently DNA repair (DNA-PKcs, ATM). Loss of I-kB destabilizes NFκB, reducing expression of a critical plasma cell cytokine stimulatory molecule, interleukin-6 (IL-6) (see Chapter 85). The process of cell death appears to be p53-independent and to result in mitotic catastrophe, although the classical caspase 8–dependent apoptosis pathway has also been implicated. A recent study found a strong correlation between immunoglobulin production and apoptotic sensitivity to bortezomib, suggesting that the active requirement for protein folding in the endoplasmic reticulum (ER) provides a direct target and explains sensitivity to proteasome inhibition. It also suggests a selective mechanism that could explain the emergence of less differentiated myeloma cells with decreased immunoglobulin production during treatment. These processes also increase oxidative stress and contribute to apoptotic signaling, explaining the sensitivity of myeloma cells to proteasome inhibition.

Preclinical Studies With Bortezomib. Screening of the NCI tumor cell lines revealed that bortezomib is active against a broad range of tumor types. The average growth inhibition of 50% (GI_{50}) value for bortezomib across the entire NCI cell panel (60 human-derived cell lines) was 7 nM. Among solid tumor cell lines, those of the prostate, breast, colon, and pancreas were exquisitely sensitive to proteasomal inhibition. PC-3 prostate carcinoma cells, treated with bortezomib, underwent growth arrest in G2-M phase with a parallel increase in P21 levels and decreased activity but not the levels of CDK-4. Bortezomib treatment also led to caspase activation, PARP cleavage, and apoptotic cell death with an IC_{50} of 20 nM. Bortezomib exhibited synergistic effects when combined with SN-38 and radiation against colon tumor cells and in mouse xenografts. Similarly, pancreatic tumor xenografts were sensitive to the cytotoxic effect of bortezomib, particularly when combined with gemcitabine or CPT-11. Cytotoxic activity was reported as well against Lewis lung carcinoma cells and nasopharyngeal squamous cell carcinoma cells. In most of these studies, an increase in the cellular levels of P21WAF1, P27KIP1, P53, and I-kB was observed.

In hematologic malignancies, proteasome inhibitors exhibited cytotoxic activity in a wide range of cell lines, including multiple myeloma, U937 human monocytic leukemia, HL-60 promyelocytic leukemia, Jurkat T-cell leukemia, K562 CML, Ramos Burkitt lymphoma, and primary B-cell CLL. In multiple myeloma cells, bortezomib induced p53 and MDM2 protein expression, induced phosphorylation (Ser15) of p53 protein, and activated JUN NH2-terminal kinase (JNK), which in turn activated caspase 8 and caspase 3. Bortezomib was also shown to activate the intrinsic (mitochondria–cytochrome C–caspase 9) and extrinsic (JNK–death receptor-activated caspase 8) apoptotic pathways of the myeloma cells. Bortezomib blocked tumor necrosis factor (TNF)–induced NFκB activation through inhibition of IkB degradation. TNF-induced intracellular adhesion molecule (ICAM)-1 expression on RPMI8226 and MM.1S cells was also inhibited. The unfolded protein response not only is increased in plasma cells producing large quantities of immunoglobulin but also induces a stress apoptosis response. Bortezomib also induces osteoblast activity through the Runx2/Cbfa2 pathway. Furthermore, bortezomib inhibits RANKL-induced osteoclastogenesis through inhibition of P38 kinase. Increased osteoblast activity has the potential to restore the clinical osteoporosis associated with multiple myeloma when used with or without bisphosphonates. Moreover, it prevented the adherence of myeloma cells to BM stromal cells and the NFκB-dependent production of IL-6. Importantly, bortezomib demonstrated synergistic activity with dexamethasone, thalidomide, melphalan, and doxorubicin and did not appear to be a substrate for multidrug-resistance transporters. However, the NFκB blockade could not account for all of the antimyeloma activity of bortezomib, and other mechanisms clearly contribute to

its antineoplastic effects. Finally, an IC_{50} concentration of bortezomib in myeloma cells had no effect on peripheral blood mononuclear cells from healthy volunteers and did not affect cultured BM stromal cells. This did not preclude the observation of myelosuppression during treatment of patients with bortezomib as a single agent.

Pharmacology of Bortezomib. Bortezomib is primarily metabolized through cytochrome P450 (CYP) and not via phase II pathways (e.g., glucuronidation and sulfation). In vitro studies indicated that the primary metabolic pathway is deboronation mediated by CYP3A4. Bortezomib was also metabolized by CYP2D6, but the rate of metabolism was slower than that observed with CYP3A4. Deboronated metabolites have been shown to be inactive in the 20S proteasome assay. Bortezomib rapidly exits the plasma compartment with more than 90% cleared within 15 minutes of IV administration. In whole-body autoradiography of [^{14}C] boretezomib-treated rats, the central nervous system, testes, and eyes appeared to be protected from bortezomib. Bortezomib specifically and selectively inhibits proteasome function by binding tightly (K_i >0.6 nM) and reversibly to the enzyme's chymotrypsin-like site. In ex vivo 20S proteasome activity bioassays, the proteasome was inhibited within 1 hour of bortezomib administration, and baseline proteasome activity was restored within 48 to 72 hours. Intermittent but high inhibition (>70%) of proteasome activity was better tolerated than sustained inhibition. Thus a twice-weekly clinical dosing regimen is better tolerated. Nonetheless, this dose schedule is often associated with significant myelosuppression and onset of peripheral neuropathy. Reducing the dose schedule to a weekly regimen ameliorates these toxicities and appears to increase patient tolerance without jeopardizing clinical efficacy.

Clinical Studies With Bortezomib. In several phase I clinical studies, antitumor activity was reported in patients with squamous cell carcinoma of the nasopharynx, bronchoalveolar carcinoma, renal cell carcinoma, prostate cancer, NHL, and multiple myeloma. Richardson and coworkers reported on the activity of bortezomib in the treatment of relapsed and refractory myeloma patients. In a large, multicenter, nonrandomized phase II study, 202 patients were treated with a bolus IV infusion of bortezomib (1.3 mg/m^2). Of the 202 patients, 27% achieved a complete or partial response as defined by the Blade criteria; an additional 7% achieved a minimal response. The median time to response was 1.3 months, and the median time to progression among patients who achieved a partial or complete response was 13 months. The median survival time among all patients was 16 months. In a multivariate analysis, only age and the percentage of plasma cells in the BM at the time of enrollment predicated response to bortezomib. A recent study further defines the safety of using bortezomib in older patients with myeloma. The most common grade 3 to 4 adverse events were thrombocytopenia (31%), fatigue (12%), neuropathy (12%), and neutropenia (14%). The thrombocytopenia, although significant with a mean decrease of more than 60%, was rapidly reversible and associated with a shortened platelet survival rather than a direct toxic effect on megakaryocytes. The randomized phase III clinical trial compared bortezomib with dexamethasone and indicated that there was a significant advantage for bortezomib-treated patients. A response rate of 38% was seen with a greater than median 6-month time to progression. A second trial added dexamethasone after 2 cycles of bortezomib with an overall response rate of 88%. Additional clinical trials have shown the efficacy of bortezomib in multiple myeloma in combination with other cytotoxic agents, including dexamethasone, melphalan, liposomal doxorubicin, lenalidomide, and thalidomide (see Chapter 85). A recent study showed a significantly prolonged time to disease progression in patients with myeloma who had undergone at least one prior treatment regimen of bortezomib plus liposomal doxorubicin (Doxil) compared with bortezomib alone. The combination of melphalan and bortezomib is well tolerated, with an overall response rate of 68% in pretreated patients, and based on positive results from a phase III study by San Miguel et al, the combination of bortezomib with melphalan and prednisone has received FDA approval for use in the frontline treatment of myeloma.[13] Combining bortezomib, thalidomide, and dexamethasone is also well tolerated, with an overall response rate of 53% in pretreated patients. These combinations are also being explored in other hematologic malignancies (CLL, mantle cell lymphoma, and indolent NHL). In relapsed mantle cell lymphoma, an overall response rate of 33% was noted with a mean time to progression of 9 months; its use is FDA approved for patients with mantle cell lymphoma who have received at least one prior line of therapy.

Newer Proteasome Inhibitors

The success of bortezomib in multiple myeloma and mantle cell lymphoma has stimulated interest in the next generation of proteasome inhibitors. Second-generation proteasome inhibitors include PR-171 (carfilzomib), NPI-0052 (salinosporamide A, marizomib), MLN 9708, and others. Of these newer proteasome inhibitors, carfilzomib (see Chapter 85) is furthest along in clinical development and based on positive results of two phase II trials, was approved by the FDA for use in patients with relapsed and refractory myeloma who have received at least two prior therapies, including bortezomib and an immunomodulatory agent. Carfilzomib is distinct from bortezomib in that it is an irreversible and more selective inhibitor of the chymotryptic-like protease of the 26S proteasome. Because it has fewer off-target effects, carfilzomib causes little or no neuropathy, an often dose-limiting toxicity of bortezomib.[14] Third-generation proteasome inhibitors are now in development and target the regulatory, or 19S subunit, of the proteasome. Efforts to define the activity of these next generation proteasome inhibitors in multiple myeloma and NHL are currently planned or underway.

Immunomodulatory Agents

Thalidomide and Lenalidomide

The related compounds thalidomide and lenalidomide provide effective PO immunomodulatory (see Chapters 69 and 85) therapy for patients with multiple myeloma. They have complex mechanisms of action. Further details on their therapeutic impact are found in Chapters 69 and 85.

Thalidomide has been in clinical use for more than 50 years and has well-documented and sometimes serious side effects, including severe birth defects, somnolence, an axonal length-dependent peripheral neuropathy, orthostatic hypotension, neutropenia, bradycardia and occasional heart block, and increased HIV load in HIV-positive patients. The risk of developing thrombotic events is elevated in patients taking either agent, giving rise to the recommended use of an anticoagulant regimen such as aspirin, low-molecular-weight heparin or Coumadin. Experimental studies have identified that thalidomide reduces expression of the cellular inhibitor of apoptosis protein and potentiates proapoptotic processes such as TRAIL (TNF-related apoptosis-inducing ligand)/po2L. Thalidomide also reduces NFκB and I-kB expression, thereby reducing IL-6 expression. In addition, thalidomide decreases vascular endothelial growth factor (VEGF) and reduces angiogenesis and vessel density in the BM of patients with multiple myeloma. The lack of a simple mechanism of action has been confusing because it is unclear which, if any, biomarker is an appropriate correlate for clinical success or toxicity. Nonetheless, efficacy is certainly seen clinically and validated in SCID models of human myeloma. Data also point to its potential clinical efficacy in patients with solid tumors and MDS.[15]

Lenalidomide was identified as an analog of thalidomide with more potent immunomodulatory functions but fewer side effects, and it has emerged as a more potent agent. Both have similar anti-angiogenic properties, block IL-6 production, and reduce NFκB and I-kB levels. Lenalidomide also induces caspase 8–mediated apoptosis and mitochondrial-mediated cell death. In addition, lenalidomide induces T-cell activation and NK activity, providing some measure of anticancer immune response. It leads to a similar and dose-dependent peripheral neuropathy as thalidomide and more significant BM

suppression, which can be dose limiting. It is also associated with a significant increased risk of thrombosis, leading to recommendations for the use of anticoagulation in this population.[16] Hypersensitivity rash occurs in up to 10% of patients. However, a variety of dose schedules provide a flexible therapeutic approach and a high response rate in relapsed myeloma patients with an overall response rate of 25% and median OS of 28 months. Excellent results were seen, with 31 of 34 patients achieving an objective response combining lenalidomide 25 mg/m^2 for 21 days and dexamethasone 40 mg daily for 4 days on days 1, 9, 17, of the 28-day cycle. Both thalidomide and lenalidomide are under evaluation for the treatment of primary amyloidosis, MDS, CLL, and solid tumors. In amyloidosis, the combination of lenalidomide and dexamethasone is a well-tolerated regimen with an overall response rate of 67%, including complete hematologic remissions. Lenalidomide has been approved by the FDA for the treatment of 5q minus MDS based on studies indicating more than a 40% response rate owing to the rate of transfusion independence that occurred in this group of patients (see Chapter 59). In a randomized trial of patients with relapsed or refractory multiple myeloma comparing dexamethasone and lenalidomide with dexamethasone alone, a much higher and sustained response rate of 58% was observed. Effective dose ranges appear to be 5 to 25 mg daily for 21 days of a 4-week cycle, with a range of patient tolerance and adverse reactions that in large part are dose dependent.

Agents in Development

The newer drugs in the class of immunomodulatory agents have been designed to increase efficacy and improve the toxicity profile.

The newest drug immunomodulatory agent to enter development is pomalidomide (see Chapters 69 and 85). Pomalidomide has a mechanism of action similar to those of thalidomide and lenalidomide but demonstrates efficacy in treating relapsed and refractory myeloma patients, including patients who have previously failed treatment with thalidomide, lenalidomide, and bortezomib. Phase I studies have shown the drug to be well tolerated in doses ranging from 1 to 5 mg/day orally. Interrupted dosing may help with mitigating drug-induced cytopenias. Results of a phase II study combining pomalidomide with dexamethasone in patients with relapsed myeloma showed an encouraging overall response rate of 63% (partial response or better), including 60% of patients who were refractory to bortezomib and 40% of patients who were refractory to lenalidomide.[17]

TARGETING APOPTOSIS SIGNALING IN HEMATOLOGIC MALIGNANCIES

The processes of cell division and cell death are tightly coupled so that a net increase in cell numbers does not occur. Alterations in the expression or function of the genes controlling cell division and cell death can upset this delicate balance and are hallmarks of cancer. Although conventional anticancer drugs cause cell cycle perturbation or DNA damage, they do not directly interact with the intracellular machinery involved in apoptosis. Tumor selectivity of conventional agents is largely caused by the increased sensitivity to apoptosis of tumor cells after DNA damage or cell cycle perturbation. Novel therapeutic agents or strategies that target critical regulators or effectors of apoptosis are under development and clinical testing, and these agents or strategies have the potential to exert selective cytotoxicity against cancer cells.

Caspases are the "executioners" for apoptosis. They are proteases that exist as inactive zymogens and are activated by proteolytic cleavage of their proforms in response to a variety of death stimuli (explained in the next section). This processing occurs at conserved aspartic acid residues, thus generating the enzymatically active caspases. Caspase activation is organized as a cascade, with an upstream initiator and downstream effector caspase. Upstream initiator caspases contain large prodomains that interact with specific proteins involved in triggering the cascade. The downstream caspases, which function as the ultimate effectors of apoptosis, possess small prodomains and are activated predominantly by proteolytic cleavage by upstream caspases. The irreversible cleavage of specific protein death substrates by the downstream effector caspases directly or indirectly accounts for the biochemical and morphologic changes that are recognized as apoptosis.

At least three pathways of caspase activation leading to apoptosis have been identified (Fig. 55-8): (1) the receptor-initiated apoptosis pathway, where the TNF family of cytokine receptors activate initiator caspases such as caspase 8; (2) the mitochondria-initiated apoptosis pathway, where cytochrome C and other pro-death effectors are released from mitochondria into cytosol that results in activation of caspase 9; and (3) a pathway of caspase activation, which involves a serine protease, granzyme B, that directly cleaves and activates several caspases, including procaspase 3.

Proapoptotic Targets of Anticancer Agents

Most cancer cells have active antiapoptotic pathways that prevent cell death in response to growth, checkpoint, DNA damage, and metabolic stimuli. A number of current anticancer agents in development target these pathways and are designed to be effective alone or in combination with other agents that disrupt the cell cycle, DNA synthesis, invoke DNA damage, and so on.

Death Receptor–Initiated Apoptotic Signaling

Several TNF family receptors are known to transduce signals that result in apoptosis. These include TNFRSF1A (also known as CD120a and previously designated TNFR1), TNFRSF6 (also known as CD95, APO-1, or FAS), TNFRSF25 (also designated TRAMP and known as DR3 or APO3), TNFRSF10A (also known as DR4 or TRAIL-R1), and TNFRSF10B (also known as DR5 or TRAIL-R2). These receptors, also called *death receptors,* are characterized by the presence of a death domain within their cytoplasmic region, and have been shown to trigger apoptosis upon binding to their cognate ligands or specific agonist antibody. The activating ligands for these death receptors are structurally related molecules that also belong to the TNF gene superfamily such as TNFSF6 (also known as Fas ligand), TNF, and TRAIL.

Ligation of death receptors produces receptor trimerization and formation of a death-inducing signaling complex (DISC). This is composed of TNFRSF6, FADD (Fas [TNFRSF6]-associated via death domain), and procaspase 8, an apical signaling complex that mediates receptor-induced apoptosis. FADD binds directly to FasR, TNFRSF10A, or TNFRSF10B and indirectly to TNFRSF1A via TRADD (TNFRSF1A-associated via death domain protein). FADD is essential for cell death signaling from all three receptors. FADD interacts through its C-terminal death domain to cross-link TNFRSF6, TNFRSF10A, or TNFRSF10B receptors and recruits procaspase 8 and procaspase 10, or TRADD, through its N-terminal death effector domain (DED) to the DISC (see Fig. 55-8). Oligomerization of caspase 8 within the DISC results in a high local concentration of the zymogen. The induced proximity under these crowded conditions generates low levels of intrinsic proteolytic activity of caspase 8, enough to allow the various proenzymatic molecules to mutually cleave each other. Processing of caspase 8 removes the DED-containing prodomain, thus releasing the activated protease into the cytosol, where it can cleave and activate other downstream procaspases. In certain types of cells (type I), enough caspase 8 is activated by the activation of the death receptor to cause apoptosis. In other cell types, such as hepatocytes (type II), a high level of caspase 8 activation is not achieved and the apoptotic signal is amplified by the mitochondrial pathway. The active caspase 8 cleaves the cytosolic p 22 Bid into a BH3-only domain containing, proapoptotic, truncated p15 tBid fragment, which translocates to the mitochondria and triggers the release of cyt c into the cytosol. Cleavage by caspase 8 has been shown to cause exposure of a glycine residue on p 15 Bid

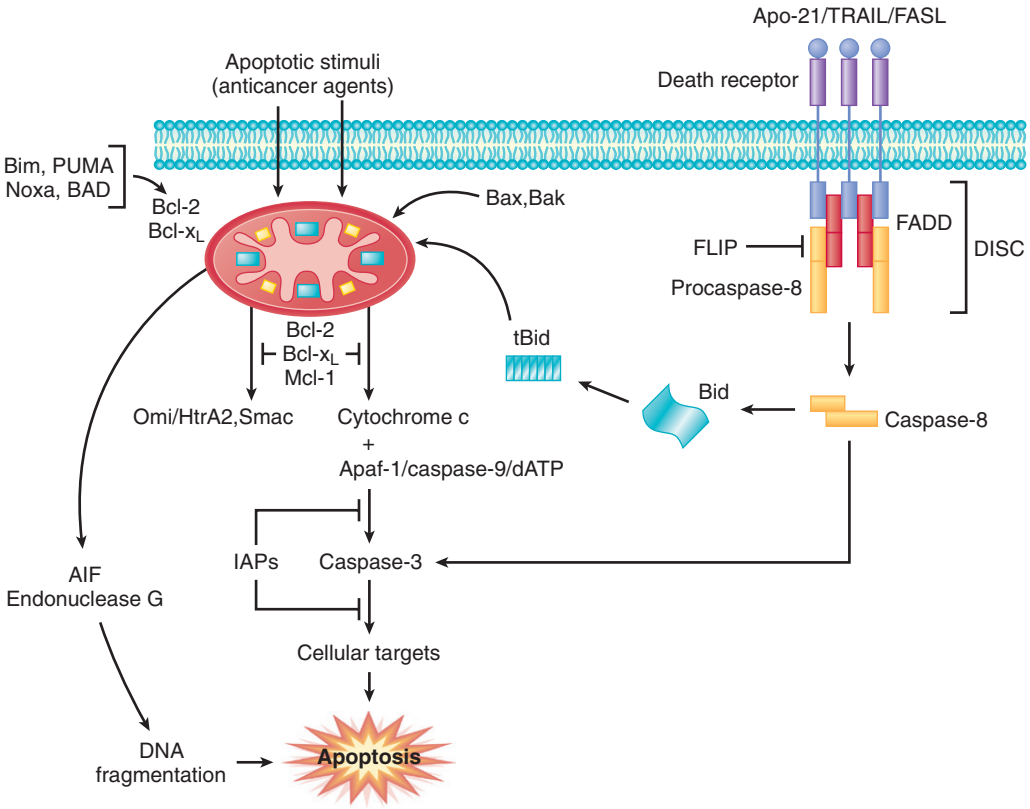

Figure 55-8 SCHEMATIC REPRESENTATION OF APOPTOTIC PATHWAYS.

that is myristoylated, thereby targeting p 15 Bid to the mitochondria. Thus N-myristoylation acts as an activating switch that enhances tBid-induced release of cyt c and apoptosis. The ability to cleave Bid may not be limited to caspase 8. Other caspases, such as caspase 3, as well other proteases, such as granzyme B and lysosomal proteases, have been shown to activate Bid. This indicates that Bid probably serves to amplify the caspase cascade rather than to initiate it (see Fig. 55-8).

Fas ligation has also been shown to initiate an alternative pathway leading to apoptosis, involving activation of c-Jun N-terminal kinase/stress-activated protein kinase (JNK/SAPK). After ligation, Fas recruits an adaptor protein called Daxx that interacts with the apoptosis signal-regulating kinase 1 (ASK1), activating the transcription factors AP-1 and ATF-2. After activation, ASK-1 launches a phosphorylation cascade that culminates in the activation of c-Jun N-terminal kinase (JNK). Activated JNK phosphorylates substrates such as c-Jun, p53, and a pro-death Bcl-2 member Bim. This, in turn, has been shown to trigger the mitochondrial or death receptor–initiated apoptotic signaling.

Mitochondria-Initiated Apoptotic Signaling

Mitochondria sequester a potent cocktail of proapoptotic proteins. These proteins promote apoptosis by activating caspases (e.g., by Cyt c), by inducing DNA fragmentation (e.g., by endonuclease G or apoptosis-inducing factor [AIF]), or by neutralizing cytosolic inhibitors of apoptosis or IAPs (e.g., by SMAC or Omi/HtrA2). On induction of apoptosis, unlike other proapoptotic proteins, mitochondrial AIF translocates to the nucleus to induce DNA fragmentation and apoptosis. Cyt c is a well-known component of the mitochondrial electron transfer chain. Cyt c is released from the mitochondria during apoptosis. After release into the cytosol, cyt c binds to Apaf-1 (apoptosis-activating factor), a cytosolic adapter protein that contains a caspase recruitment domain (CARD), a nucleotide-binding domain, and multiple WD-40 repeats. Binding of Cyt c to Apaf-1 increases its affinity for dATP or ATP by approximately 10-fold. It also triggers the oligomerization of Apaf-1 into a multimeric Apaf-1–Cyt c complex, also called the apoptosome. This exposes the CARD domain of Apaf-1, which recruits several molecules of procaspase 9, inducing their autoactivation. Only the caspase 9 bound to the apoptosome is able to efficiently cleave and activate downstream executioner caspase, caspase 3.

SMAC/DIABLO is a 25-kd mitochondrial protein that is released by mitochondria into the cytosol during apoptosis. SMAC contains a mitochondria-targeting sequence at its N-terminus. This sequence is removed on import into the mitochondria, generating the mature SMAC protein. In the mitochondria-initiated and common effector pathways of apoptosis, the processing and proteolytic activity of caspase 9 followed by caspases 3 and 7 are inhibited by the inhibitor of apoptosis (IAP) family of proteins. IAP family members include X-linked IAP (XIAP), cIAP1, cIAP2, and survivin. All IAPs contain at least one BIR domain, although some contain three. Another region, the RING domain, has ubiquitin ligase activity and promotes the self-degradation of IAPs through proteasomes in response to some apoptotic stimuli. Furthermore, during Fas death receptor–mediated apoptosis, XIAP is cleaved by activated caspase 3 into the amino-terminal BIR1 and 2 and BIR3-RING finger fragments. BIR3 domain binds and sequesters the monomeric and inactive caspase 9, thereby inhibiting its activation. Overexpression of XIAP inhibits anticancer drug (including Ara-C)–induced caspase activity and apoptosis. In contrast, downregulation of XIAP sensitizes cancer cells to apoptosis induced by chemotherapeutic drugs. The antiapoptotic activity of NFκB has also been shown to be mediated by the induction of IAPs. The first four amino acids of the mature Smac, Ala-Val-Pro-Ile (AVPI), bind to the BIR (baculovirus repeat) domain of IAP (inhibitor of apoptosis protein) proteins. The four amino acids (AVPI) of Smac that bind to the BIR3 domain of XIAP are similar to the XIAP-binding sequence of active caspase 9. In addition, Smac has been shown to form a stable complex with the BIR2 domain of XIAP. Smac binds to the linker-BIR2 domain and presumably disrupts its inhibition of the active caspase 3 and caspase 7 by steric

hindrance. On induction of apoptosis, another mitochondrial protein, Omi/HtrA2 (a serine protease), is released from mitochondria and can induce caspase-independent cell death. Additionally, like Smac, the mature Omi protein contains a conserved IAP-binding motif (AVPS) at its N-terminus. Omi complexes with XIAP at high stoichiometry and promotes apoptosis by neutralizing the caspase-inhibitory effect of XIAP. Recently, Omi has also been shown to process XIAP and promote its proteasomal degradation.

The Bcl-2 family of proteins is divided into three subfamilies. Members of the subfamily that include Bcl-2, Bcl-x_L, and Mcl-1 inhibit apoptosis (see Fig. 55-8). The Bax subfamily members that promote apoptosis, including Bax and Bak, share with Bcl-2 three of the four Bcl-2 homology domains, BH1 to BH3. A C-terminus hydrophobic tail is responsible for the localization of these proteins to the outer membranes of the mitochondria and ER. The third BH3-only subfamily of proteins that includes Bid, Bim, and Bad also promotes apoptosis by binding and inactivating prosurvival Bcl-2 family members. The prosurvival Bcl-2 family members, to a variable degree, are bound to the membranes of the mitochondria, ER, and the nuclear envelope. In the event of an apoptotic stimulus, BH3-only proteins require Bax and Bak to trigger mitochondrial apoptotic signaling. For example, the exposed BH3 domain of tBid oligomerizes with Bak and Bax, causing their mitochondrial membrane insertion and Cyt c release. In response to apoptotic stimuli, Bax and Bak undergo conformational change and form membrane-associated homooligomers, disrupting the outer membrane of the mitochondria and ER and releasing the pro-death molecules into the cytosol. Besides tBid, Humanin peptide has been shown to activate Bax. Bcl-2 can block these events involving Bax activation by titrating tBid or Bim and/or heterodimerization with Bax and preventing mitochondrial permeabilization.

Induction of $P53^{wt}$ in cells triggers apoptosis by transcriptional activation of pro-death effectors, including Bax, Noxa, Puma, Apaf-1, and DR5, and by transcriptional repression of Bcl-2 and IAPs. P53-dependent apoptosis has also been shown to occur in the absence of any gene transcription or translation. In response to apoptotic stimulus such as irradiation, p53 translocates to the mitochondria, where it directly induces permeabilization of the outer membrane by forming complexes with the protective Bcl-2, resulting in the release of cyt c into the cytosol. The E2F transcription factor, normally restrained by the Rb tumor suppressor to inhibit cell proliferation, has been shown to induce apoptosis though p53-dependent and p53-independent mechanisms. These mechanisms include transcriptional activation of ARF (the alternate reading frame product of the INK4a/ARF tumor suppressor locus) or p73 (a member of the p53 family), repression of Mcl-1, and inducing the levels of caspase proenzymes.

Selective Antitumor Agents or Strategies

BCL2 Family of Proteins as Targets for Anticancer Drug Design

The antiapoptotic protein BCL2 was originally identified during the process of the discovery of the t(14;18) in human follicular lymphoma. Since this elucidation, overexpression of BCL2 has been shown in both hematologic and solid malignancies and to mediate resistance to traditional chemotherapeutic agents, radiation, and other antitumor treatments (Table 55-4).

Table 55-4 Effectors of Apoptosis Pathways as Targets for Cancer Therapy

Receptor-Mediated Pathway	Mitochondrial Pathway Targets or Agents
At the death receptors	Antisense oligos to BCL2 (Genasense)
TNFSF10	BH3 mimetic (peptides)
Anti-DR5 and anti-DR4	BCL2/BCL2L1 small molecule
Antibodies	Antagonists
CDDO	Tea polyphenols

Bcl-2 Antisense

Liposomal antisense Bcl-2 oligonucleotide (Bcl-ASODN) has been created and shown to cause apoptosis of many types of cancer and leukemia cells. Bcl-2-ASODN also sensitized tumor cells in vitro and in vivo to chemotherapeutic drugs. The most promising agent to target Bcl-2 is Genasense (oblimersan sodium; G3139), an 18-mer phosphorothioate oligodeoxynucleotide antisense compound. Clinical studies suggest safety and efficacy in solid and hematologic malignancies. In a phase III trial, 241 patients were randomly assigned to receive oblimersan 3 mg/kg/day as a 7-day continuous infusion in addition to fludarabine–cyclophosphamide versus fludarabine–cyclophosphamide. This study met its primary objective by demonstrating a significantly superior CR or nodular partial remission (CR/nPR) (17% vs. 7%; $P = .025$); however, no significant differences in overall response rates as well as time to progression were found. However, at 5-year follow–up, a significant improvement in survival was noted, with a hazard ratio of 0.6 for those treated with Oblimersen. Results of another phase III study were reported in which the addition of Oblimersan to high-dose dexamethasone did not improve OS or time to progression in myeloma patients.

BH3 Peptide/Mimetics or Bcl-2/Bcl-xL Small Molecule Antagonists

Another strategy to create Bcl-2 inhibitors has focused on developing small molecules that mimic the action of the endogenous Bcl-2-binding death agonists. Compounds that mimic the BH3-only class of death agonists such as Bad inhibit the survival proteins Bcl-2 and Bcl-x_L but do not appear to have independent proapoptotic activity. Two classes of novel small molecule cell-permeable inhibitors of the Bcl-x_L-BH3 domain (BH3I) have been identified. Studies have demonstrated that BH3Is induce apoptosis by preventing BH3 domain–mediated interaction between proapoptotic and antiapoptotic members of Bcl-2 family. Two natural products have been suggested to antagonize the antiapoptotic function of Bcl-2 or Bcl-x_L. Tetrocarcin A was reported to inhibit mitochondrial functions of Bcl-2 and suppress its antiapoptotic activity. In another report, Antimycin-A was shown to mimic activity of BH3 peptides and selectively induce apoptosis in cell lines overexpressing Bcl-x_L. Certain green tea catechins and black tea theaflavins were identified as potent inhibitors (K_i in the nanomolar range) of the antiapoptotic Bcl-2 family of proteins. On the basis of the high-resolution three-dimensional structure of the target receptor, small organic molecules that bind to this interface have been designed. ABT-737, is a BH3 mimetic that binds to Bcl-2, Bcl-xL, and Bcl-w with high affinity (K_i <1 nM) but not to Mcl-1. Preclinical data demonstrate cytotoxic activity in B lymphoid tumor cell lines, human follicular lymphoma, myeloma, and CLL cells as well as synergism with other chemotherapeutic agents. Also, ABT-737 effectively kills AML blast, progenitor, and stem cells without disturbing normal hematopoietic cell development. However, the clinical utility of ABT-737 is limited, as it undergoes rapid metabolism and is not orally bioavailable. Targeted modifications of ABT-737 led to synthesis of Navitoclax (ABT-263), an orally bioavailable BH3 mimetic. In the initial phase I trial[18] more than half of patients had a decrease in their lymphocytosis, with 35% achieving partial remission. The main toxicity was dose-dependent thrombocytopenia, which occurred early in the treatment cycle (days 2-5 of a 21-day cycle). Neutropenia occurred at higher dose levels. Other adverse events included gastrointestinal side effects and fatigue. The remarkable activity of this agent in early trials validates Bcl-2 as a target for the treatment of CLL. Trials of Navitoclax in combination with rituximab are ongoing.

Cyclin-Dependent Kinase Inhibitors as Therapeutic Targets

Orderly progression through the cell cycle is regulated by the coordinated expression of a variety of genes and proteins, and the decision of a cell to progress through the cell cycle is determined by the activity of cyclins, levels of which fluctuate throughout the cell cycle, CDKs (e.g., CDKs 1-9), and several endogenous small molecule CDK inhibitors (e.g., $p21^{CIP1}$, $p27^{KIP1}$, and $p57^{KIP2}$) (see Fig. 55-1). In general, whereas CDK1, in association with cyclins A and B, is involved in G_2M progression, CDK2, CDK4, and CDK6, in association with cyclins A, D, and E, are involved in G_1S progression. Activation of CDKs results in phosphorylation of the retinoblastoma protein (PRB), which leads to its dissociation from the E2F transcription factor. Once freed, E2F triggers the transcription of diverse genes involved in cell cycle progression (thymidylate synthase and dihydrofolate reductase, among numerous others). Endogenous small molecule inhibitors such as $P21^{CIP1}$ and $P27^{KIP1}$ bind stoichiometrically to CDKs and inhibit their activity. Activity of CDKs can also be regulated through inhibitory phosphorylation of these proteins (e.g., on threonine 14 or tyrosine 15 residues) or, conversely, activating phosphorylation on threonine 160 or 161 (mediated by CDK5 or cyclin-dependent activating kinase [CAK]). Interference with the activation of CDKs results in dephosphorylation of PRB, leading in turn to binding and inactivation of E2F and inhibition of cell cycle progression.

Cell cycle dysregulation is a cardinal characteristic of cancer in general and hematologic malignancies in particular. A classic example of this phenomenon is the regular association of increased expression of cyclin D_1 in mantle cell lymphoma. Regulation of the cell cycle has been found to be closely related to apoptosis. Disruption of the cell cycle transit has been shown to be a potent cell death stimulus in a wide variety of neoplastic cell types, including those of hematopoietic origin. A corollary of this observation is that agents that interfere with the cell cycle, in addition to blocking cell cycle progression, can be potent inducers of programmed cell death. For these reasons, inhibitors of the cell cycle have become logical targets for therapeutic intervention in hematologic and other malignancies. Cell cycle inhibitors can be subdivided into several categories. For example, they can act directly, as in the case of CDK inhibitors, or indirectly, as in the case of HDAC inhibitors, compounds that block cell cycle progression by inducing endogenous cell cycle inhibitors such as $P21^{CIP1}$. The latter agents are discussed later in this chapter. CDK inhibitors can also be classified as specific (i.e., directed against a particular CDK, such as CDK2) or those that nonspecifically inhibit most CDKs (e.g., flavopiridol). The development of cell cycle inhibitors has primarily focused on CDK inhibitors, several of which have entered clinical trials, including those involving hematologic malignancies. A brief summary of the status of CDK inhibitors, with an emphasis on hematologic malignancies, follows.

Flavopiridol

Flavopiridol (L86-8275) is a semisynthetic flavonoid derived from the Indian plant *rohitukine* (see Chapter 76). It was the first CDK inhibitor to enter clinical trials in humans. Flavopiridol binds to the ATP-binding site of CDKs, resulting in reversible, competitive enzyme inhibition at concentrations of less than 100 nM. As noted earlier, flavopiridol is a relatively nonspecific CDK inhibitor and inhibits all CDKs, although it is less effective against CDK7. Flavopiridol induces G_1S or G_2M arrest, presumably a consequence of inhibition of CDK1 and CDK2. Flavopiridol may also act to block cell cycle progression by downregulating cyclin D_1 levels, inhibiting the CDK-activating complex (CDK7), or both.

In addition to blocking cell cycle progression, flavopiridol has been shown to be a potent inducer of apoptosis in malignant hematopoietic cells (e.g., acute and chronic leukemia) at low concentrations (e.g., u100 nM). Moreover, flavopiridol has shown activity against multiple myeloma cell in vitro.

The proapoptotic actions of flavopiridol have been attributed to its capacity to inhibit the positive transcription elongation factor-β (PTEF-β), cyclin T/CDK9 complex by inhibiting phosphorylation of the carboxy-terminal domain of RNA polymerase II. This leads to downregulation of several antiapoptotic proteins, including BIRC4; P_{21}^{CIP1}; and, in the case of multiple myeloma cells, Mcl-1. Flavopiridol has also recently been shown to block the antiapoptotic actions of the IAP family member survivin.

In clinical studies, flavopiridol was initially administered as a 72-hour continuous infusion every 2 weeks, with a maximally tolerated dose of 40 mg/m^2. Steady-state plasma levels in excess of those necessary to inhibit CDKs and induce apoptosis in leukemia cells (e.g., 350 nM) were achieved. Dose-limiting toxicities were fatigue, diarrhea, nausea, and myelosuppression. However, the occurrence of thromboembolic phenomena and the general lack of single-agent activity have limited enthusiasm for administering flavopiridol by this schedule. Flavopiridol has also been administered as a daily IV bolus for 1, 3, or 5 days every 3 weeks with manageable toxicity, and other schedules are being examined, including a hybrid schedule with half the dose administered as an IV bolus and the other half as a more prolonged infusion. When administered as a daily bolus infusion for 3 days every 3 weeks, flavopiridol exhibited modest activity in patients with mantle cell lymphoma. A novel pharmacologically directed schedule of flavopiridol has been developed in which half of the dose (e.g., 30 mg/m^2) is administered as a 30-minute bolus loading infusion and 30 mg/m^2 as a 4-hour infusion. In a phase I study, objective response rates of 45% were obtained with this schedule in patients with progressive CLL, including some with high-risk disease.[19] Because of the rapidity of response, particularly in patients with high white blood cell counts, aggressive measures designed to avoid tumor lysis syndrome (e.g., hydration, alkalinization of the urine, administration of rasburicase) are advisable. Efforts are now underway to use this novel flavopiridol schedule in combination with other agents and in other hematologic malignancies.

Because of limited single-agent activity, combination regimens involving flavopiridol are being explored in hematologic malignancies. On the basis of preclinical evidence of synergism with the antimetabolite ara-C, a regimen combining flavopiridol on a daily IV bolus schedule followed by high-dose ara-C has been initiated in patients with acute leukemia and has shown some activity. In a successive phase II study, flavopiridol was administered as a 1-hour bolus infusion of 50 mg/m^2 daily for 3 days before administration of high-dose ara-C (day 6) and mitoxantrone (day 9). Complete response rates of 67% were obtained in patients with high-risk AML and more than half were durable. More recently, evidence of synergism between flavopiridol and other signal transduction modulators has become the focus of considerable attention. For example, the observation that flavopiridol interacts synergistically with imatinib mesylate against CML cells, including some that are imatinib mesylate resistant, has prompted the initiation of a phase I trial of flavopiridol and imatinib mesylate in patients with progressive BCR-ABL$^+$ hematologic malignancies. Four of 21 patients responded. Evidence that flavopiridol interacts synergistically with HDAC and proteasome inhibitors in human leukemia cells has appeared, and clinical trials combining flavopiridol with the HDAC inhibitor vorinostat or the proteasome inhibitor bortezomib in patients with refractory AML/MDS and multiple myeloma/indolent NHL are currently underway.

SNS032

SNS032 is a small molecule CDK inhibitor discovered through high-throughput screening that is primarily active against CDK2. In preclinical studies, SNS032 has shown potent antiproliferative activity against ovarian and breast cancer cells in vitro. As is the case with other CDK inhibitors, SNS032 induces cell-cycle arrest; PRB dephosphorylation; and, under some circumstances, apoptosis in CLL and myeloma cell lines. At least in some tumor cell lines, however, CDK2 may be dispensable for cell cycle progression. In CLL

cells, SNS-032 was cytotoxic in vitro in untreated and refractory cell lines. RNA synthesis was suppressed after treatment, with evidence of CDK 2 and 7 inhibition.[20]

Several phase I trials of SNS032 have been initiated. SNS032 has been administered as either a 24-hour or 1-hour infusion every 3 weeks. Dose levels of 4 to 59 mg/m^2 have proven to be tolerable; the maximum tolerated dose for either of these schedules has not been reached. Toxicities have been mild and include rash, nausea and vomiting, diarrhea, and fatigue. In a clinical trial in patients with CLL (19 patients) and myeloma (18 patients), Cdk7 and -9 inhibition was observed, but responses as a single agent were modest.

Farnesyltransferase Inhibitors: Zarnestra

RAS proteins represent low-molecular-weight proteins that bind guanosine triphosphate (GTP) and are located at the cell membrane. They are critically involved in the regulation of signal transduction pathways implicated in the control of cell proliferation, differentiation, and survival. One of the key effectors of RAS proteins is the serine-threonine kinase RAF1, which is recruited to the cell membrane by activated RAS, and in turn activates the survival- and proliferation-associated kinases MEK1/2 (mitogen-activated kinase 1/2) and ERK (extracellular signal-regulating kinase). RAS is also involved in regulation of the AKT pathway, which exerts multiple antiapoptotic functions.

There are four separate RAS proteins: H-RAS, N-RAS, K-RAS4A, and K-RAS4B. Of these, H-RAS mutations are most commonly encountered in hematologic malignancies (i.e., myeloid leukemia). Because of the frequency of RAS mutations in human neoplasia and the importance of RAS downstream targets (e.g., RAF1/MEK/ERK and AKT) in the survival of neoplastic cells, the RAS pathway is a logical target for therapeutic intervention.

To function, Ras must be localized to the cell membrane. This in turn requires posttranslational modifications of the RAS protein, most notably farnesylation. This primarily involves addition of a 15-carbon isoprenoid farnesol to the C terminus of RAS following recognition of a CAAX motif. This process is catalyzed by the enzyme farnesyl transferase. Inhibitors of farnesyl transferase (FTIs) thus block RAS farnesylation, preventing the protein from associating with the plasma membrane and subsequently participating in downstream signaling events.

Initial preclinical studies suggested that FTIs inhibited the proliferation and survival of several tumors driven by RAS mutations. However, it soon became clear that tumors with H-RAS mutations were more sensitive to FTIs than those with N-Ras or K-RAS mutations. Furthermore, the antiproliferative effects of FTIs did not always correlate well with their effects on RAS farnesylation or the presence of Ras mutations. Two possible explanations may account for these findings. First, alternative prenylation events (e.g., geranylgeranylation of the RAS protein) may also promote its membrane localization, particularly in cells bearing N-RAS or K-RAS mutations, and could theoretically confer resistance to FTI lethality. Second, several other non-RAS candidate proteins have been identified in which interference with farnesylation might contribute to FTI-associated lethality. These include small GTPases (e.g., RHO family members) and a variety of nuclear proteins (e.g., CENP-E and CENP-F).

Zarnestra is an orally active FTI that has undergone extensive evaluation in patients with solid tumors and hematologic malignancies. In patients with hematologic malignancies, the generally accepted dose and schedule is 600 mg/m^2 orally twice daily for 21 days repeated at monthly intervals or for 28 days repeated at 6-week intervals. Dose-limiting toxicities include myelosuppression, nausea, vomiting, diarrhea, rash, neurotoxicity, and fatigue. In a series of phase I and II studies, promising activity was observed in patients with AML, ALL, CML, and MDS. For example, in one study, six of 22 patients with CML achieved complete or partial responses, and two of eight patients with myelofibrosis achieved objective responses. In a study in refractory leukemia, a response rate with 1200 mg/m^2 of about 15% was reported. In patients with AML, the combination with idarubicin cytarabine and escalating doses of Zarnestra, the combination was well tolerated with expected pancytopenia and a CR rate of more than 60% with a median duration of response of more than 17 months. A study in elderly patients with AML the combination of Zarnestra and etoposide generated an overall response rate of 25% in 84 patients. However, leukemias that expressed high RASGRP1 and low aprataxin (APTX), with a ratio of over 5.2 had a CR rate of 78%.[21] Responses in patients with multiple myeloma have also been observed but have been modest. Interestingly, blasts obtained from a number of leukemic patients who responded did not exhibit RAS mutations, suggesting that the lethal effects of Zarnestra may proceed, at least in part, through RAS-independent pathways.

Inhibitors of the RAF1/Mek/ERK Pathway

The MAPK pathways consist of three parallel serine-threonine kinase modules that are intimately involved in the control of cell survival, proliferation, and differentiation. Two of these, JNK and p38 MAPK, are activated in response to environmental stresses, including DNA damage and osmotic stress, but p42/44 MAPK (also known as ERK; extracellular signal-regulating kinase) is primarily induced by growth factors and other mitogenic stimuli. Although exceptions exist, JNK and p38 MAPK primarily exert proapoptotic functions, but ERK activation is generally associated with cell survival. The only well-defined activator of ERK is the serine-threonine kinase MEK1/2 (mitogen-activated protein kinase kinase 1/2), but numerous ERK targets have been identified, including ELK-1, CREB, BCL2, BAD, FRAP1 (also known as mTOR), and caspase 9, among numerous others. The activating effects of MEK1/2 on ERK are opposed by phosphatases that dephosphorylate and inactivate the enzyme (e.g., MAP kinase phosphatase 1/2 [MKP1/2]).

The major activator of MEK1/2 is the serine-threonine kinase RAF, of which three forms exist: RAF1, B-RAF, and A-RAF. RAF can be activated by Ras (discussed earlier) as well as through various RAS-independent pathways, including PKC, KSR, as well as the SRC and JAK family of kinases among others. The activation of RAF involves several processes, including recruitment to the plasma membrane, phosphorylation on serine and threonine residues, and dimerization. Interference with any of these processes can lead to inhibition of Raf activation as well as downstream targets.

Dysregulation of the RAF/MEK/ERK pathway has been observed in most hematopoietic malignancies, including acute leukemia, CLL, multiple myeloma, and lymphomas. Consequently, there has been considerable interest in the development of pharmacologic inhibitors of the RAF/MEK/ERK pathway in these disorders. In addition to their potential intrinsic activity against malignant hematopoietic cells, evidence indicates that such agents might also enhance the activity of conventional cytotoxic drugs.

Sorafenib

Initial approaches to RAF inhibition focused on efforts to destabilize the protein. For example, geldanamycin and the related compound 17-AAG act as inhibitors of HSPCA, a chaperone protein necessary for Raf processing and stabilization. Interference with HSPCA results in destabilization and proteasomal degradation of RAF as well as numerous other proteins, including AKT. More recently, however, a Raf kinase inhibitor, sorafenib, which is approved for use in kidney cancer, has been developed and has entered phase I and II clinical trials in humans for leukemias. In preclinical studies, induction of leukemic cell death by sorafenib has been shown to stem from inhibition of translation and downregulation of the short-lived antiapoptotic protein Mcl-1 and induction of ER stress with bim-mediated apoptosis. In the clinical setting, modest response rates of 10% were observed in two studies, suggesting the need to consider combination therapy.

Inhibitors of the Mammalian Target of Rapamycin

The first mTOR inhibitor discovered was the naturally occurring macrolide rapamycin (sirolimus), widely used as an immunosuppressant (see Chapter 109). The importance of mTOR in cancer suggested this agent would have antineoplastic activity. Improvements in solubility and pharmacokinetic properties led to development of rapamycin analogs (rapalogs), of which everolimus and temsirolimus are available as antineoplastic agents.[22] The mechanism of rapamycin and its analogs is similar: after complexing with the small protein FKBP12, they bind irreversibly to the FKBP12-rapamycin binding site on the mTOR protein. Acute rapamycin treatment only affects mTORC1 because the FKBP12-rapamycin is occluded in mTORC2. Prolonged rapalog exposure may result in decreased mTOR availability and therefore indirectly decreased mTORC2 activity through limited mTORC2 complex formation. It is well recognized that growth factor signaling initiated through the receptor tyrosine kinases (RTKs) or caused by the activity of cytosolic tyrosine kinases (TKs), such as BCR-ABL, results in the activation of the PI3K/AKT signaling. AKT has been shown to phosphorylate and inactivate TSC2 (tuberous sclerosis 2; also known as tuberin), thereby disrupting its interaction with TSC1 (or hamartin) (Fig. 55-9). Inhibition of TSC1-TSC2 complex de-represses RHEB, which is a small G protein that activates mTOR. When RHEB is in an active GTP-bound state, its localization to the membrane stimulates mTOR-mediated phosphorylation of the downstream eukaryotic initiation factor 4E (eIF4E)–binding protein 1 (4E-BP) and ribosomal protein S6 kinase 1 (S6K1) (see Fig. 55-9). However, the association of mTOR with the 150-kd Raptor (regulatory associated protein of mTOR) is necessary for the phosphorylation of 4E-BP and S6K1. mTOR-mediated phosphorylation and activation of S6K1 results in the phosphorylation of the ribosomal S6 protein and eIF4B (see Fig. 55-9). AKT has also been shown to directly activate S6K1. S6K1 activity is involved in regulating the translation of a group of mRNAs that have highly structured 5′UTR, including mRNAs that have a 5′TOP (terminal oligopyrimidines, a stretch of 4-14 pyrimidines).[23]

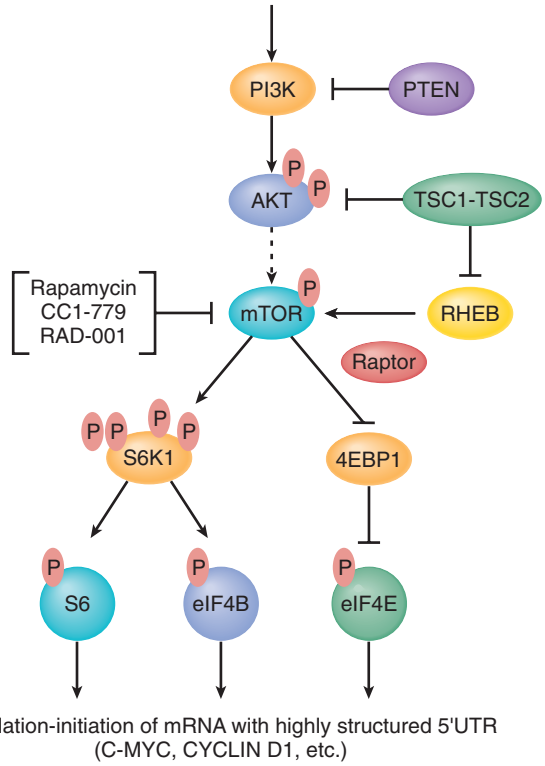

Figure 55-9 RAPAMYCIN OR ITS ANALOGS INHIBIT MAMMALIAN TARGET OF RAPAMYCIN (MTOR) AND THE DOWNSTREAM PHOSPHORYLATION OF S6K1 AND 4EBP1, THEREBY ATTENUATING THE TRANSLATION INITIATION OF MRNAS WITH HIGHLY STRUCTURED 5′UTR. Activation of the receptor (FLT-3) or cytosolic tyrosine kinase (e.g., Bcr-Abl) can lead to increased activity of phosphatidylinositol 3-kinase (PI3K)/AKT. Although it can directly phosphorylate mTOR, AKT activity inhibits the TSC1-TSC2 complex, thereby derepressing RHEB and activating mTOR. The phosphorylation and activation of S6K1, and phosphorylation and inactivation of 4E-BP through Raptor, results in the phosphorylation of S6, eIF4B, and eIF4E, which are involved in the cap-dependent translation of mRNAs with highly structured 5′URT.

The rapalogs temsirolimus and everolimus have been tested in lymphoid malignancies, and as single agents, they have demonstrated activity, although modest, against a variety of lymphomas (see Chapter 81). In the initial phase II study in patients with mantle cell lymphoma, temsirolimus was administered at a dose of 250 mg based on a phase II study done in renal cell carcinoma patients. A modest response rate was noted (overall response rate (ORR) 38%), but the majority of patients required a dose reduction because of myelosuppression, particularly thrombocytopenia. A second trial in relapsed refractory mantle cell lymphoma patients was conducted to determine if a lower dose of temsirolimus could be used. In a follow-up phase II study, temsirolimus was given at a dose of 25 mg IV weekly and was found to be as effective as the 250-mg IV dose, with a modest improvement in the side effect profile and dose reductions. This dose and schedule were also noted to be efficacious in non–mantle cell NHL with again thrombocytopenia being the main dose-limiting toxicity. A recent phase III study in relapsed refractory mantle cell lymphoma patients evaluated two different dosing regimens of temsirolimus, 175 mg weekly for 3 weeks followed by 75 mg weekly versus 175 mg weekly for 3 weeks followed by 25 mg weekly versus the investigator's choice.[24] At the conclusion of this study, it was determined that the temsirolimus regimen with 175/75 mg dosing had a significant improvement in PFS and objective response rate compared with the investigator's choice. Everolimus, given orally at a daily dose of 10 mg, has single-agent activity against Hodgkin lymphoma (PMI, Waldenström macroglobulinemia, DLBCL, CLL, and other relapsed lymphomas).

The most common side effect of rapalogs is myelosuppression; other common side effects include fatigue, oral ulcers, and dermatologic abnormalities. Metabolic abnormalities are common, including hyperglycemia, hypercholesterolemia, and hypertriglyceridemia. An uncommon pulmonary toxicity manifested as interstitial lung disease has also been observed with rapalogs.

Histone Deacetylase Inhibitors

Histone acetyl transferases (HATs) control gene expression through the modification of chromatin structure through acetylation of chromatin-bound histones. Regulation of acetylation is through histone deacetylation. Without the ability to fine tune histone binding to chromatin regions, gene expression is perturbed. Inhibition of this process by a group of agents termed *histone deacetylation inhibitors* alters gene expression in both normal and malignant cells. Often the result is differentiation of malignant cells or induction of apoptosis. Given the long history of the use of differentiating agents in leukemias, for APL (retinoids), low-dose ara-C and azacytidine, it is not surprising that newer HDAC inhibitors have undergone extensive evaluation in leukemias.

Posttranslational Histone and Nonhistone Protein Modifications and Gene Transcription

Nucleosomes are regularly repeating, structural units of chromatin, which are essential in packaging eukaryotic DNA. Each unit is composed of 146 base pairs of DNA tightly wrapped around a core histone octamer. Each histone octamer consists of 2 units each of histones H2A, H2B, H3, and H4, and each nucleosome in turn is connected to its neighbor by a short segment of linker DNA, approximately 10 to 80 base pairs in length. Histone H1 binds and stabilizes

linker DNA. Each core histone has an amino (N) terminal tail, which is lysine rich and positively charged. Specific amino acid residues at the N-terminal undergo a variety of enzymatic posttranslational modifications. Modifications can also occur within the globular domain of histones that make extensive contacts with DNA. *Histone code* is the name given to the combination of biochemical modifications affecting different histone residues that specify chromatin function. However, it has been suggested that various postsynthesis histone modifications be considered an epigenomic alphabet. Each modification is a letter, and the combination of modifications at a specified genomic region is a word that may have different functional meanings depending on the context.

Histone acetyl transferases and HDACs are two classes of enzymes that mediate the acetylation and deacetylation, respectively, at evolutionarily conserved N-terminal lysine residues. Acetylated histones are negatively charged and do not bind as tightly to negatively charged DNA, thereby facilitating gene transcription. In contrast, deacetylated histones bind closely to DNA, preventing transcription. Acetylation status of chromatin and hence gene transcription is dictated by balanced activity of HATs and HDACs. Acetylation of core histone bases has also been implicated in chromatin assembly, DNA repair, and replication timing of specific genomic regions. Crosstalk also exists between acetylation and ubiquitination. Thus HDACs can decrease the half-lives of substrates by exposing the lysine residue for ubiquitination. Other crucial functions affected by the delicate balance between HATs and HDACs include activation of the apoptotic program via interaction between Ku70 and BAX; protein localization (nuclear vs. cytoplasm); and DNA binding of transcription factors such as p53, E2F1, GATA1, RelA, YY1, and hormone receptors. There is a growing list of nonhistone proteins that are modulated by HATs or HDACs. These include hypoxia-inducible factor-1α (HIF-1α), β-catenin, α-tubulin, Ku70, importin-α 7, cortactin, and most recently heat shock protein (hsp) 90. HATs and HDACs can be classified into subfamilies according to the presence of highly conserved structural motifs. Please refer to Table 55-5 for details.

Aberrant Histone Acetyl Transferase and Histone Deacetylase Activity in Hematologic Malignancies

Aberrant activity of HATs and HDACs resulting in aberrant gene transcription is a hallmark of many cancers, including many hematologic malignancies. Several chromosomal translocations in leukemia that produce chimeric fusion oncoproteins have been shown to recruit HDACs to promoters and repress genes involved in cell cycle growth inhibition and differentiation. For example, PML-RARα in APL and AML1-ETO generated by t(8;21) translocation in AML recruit HDACs to their target genes, resulting in chromatin modification and repression of genes, leading to blocked differentiation and inhibition of apoptosis. HDACs have also been found in complexes with proteins that regulate cell cycle checkpoints such as Rb and its family members. Resistance to chemotherapy can occur because of increased levels of thioredoxin, a thiol reductase, and decreased levels of thioredoxin-binding protein (TBP-2) in many cancers; HDAC inhibitors (HDIs) can reverse this phenomenon. These effects create a strong rationale for developing inhibitors of HDAC activity that would correct transcriptional deregulation of genes involved in cell-cycle regulation and apoptosis as cancer therapeutic agents.

Mechanisms of Anticancer Activity of Histone Deacetylase Inhibitors

Treatment with HDIs modulates expression of 2% to 10% of a selective, but variable, subset of genes in various cell types with as many genes upregulated as are downregulated. Normal cells are more resistant than cancer cells to the effects of HDIs. HDI-induced cell cycle arrest, and apoptosis is usually correlated with upregulation of p21, p27, and p16 and attenuation of cyclin A and D levels, leading to decreased activity of CDK4 and CDK2. Induction of GADD45α and -β and upregulation of TGF-β, which inhibits c-Myc, may also contribute to the cell cycle arrest in G1 or G2. Promoter regions of p21 and the telomerase catalytic unit TERT have been shown to contain SP1 sites that bind HDAC-recruiting transcription complexes. HDIs also activate the mitochondrial apoptotic pathway by transcriptional activation of apoptotic proteins such as TBP2, Bad, Bim, Bid, BAK, Bax, and caspases 3 and 9 and repression of antiapoptotic proteins such as thioredoxin, bcl-2, XIAP, and Mcl-1. HDIs have also been shown to upregulate Fas and the Apo-2L/TRAIL receptors DR4 and DR5, downregulate c-FLIP, and enhance Apo-2L/TRAIL-induced death-inducing signaling complex (DISC) and apoptosis.

Treatment of leukemias with HDI alone or in combination with other agents such as ATRA has been shown to overcome the inhibition of differentiation caused by chimeric fusion oncoproteins such as PML-RARα, PLZF-RARα, or AML-ETO. HDIs have also been shown to induce the expression of gelsolin, an actin-binding protein involved in morphologic and cytostructural changes associated with differentiation. Several HDIs have been shown to induce acetylation of hsp90 and inhibit its chaperone association with important pro-survival client proteins such as AKT and c-Raf. This directs these

Table 55-5 Human Histone Deacetylases

Characteristics	Class I	Class IIa	Class IIb	Class III
Members	HDAC1, 2, 3, 8, 11	HDAC4, 5, 7, 9	HDAC6, 10	SIRT1, 2, 3, 4, 5, 6, 7

client proteins to polyubiquitylation and proteasomal degradation, thus contributing to the lowering of the threshold for apoptosis in cancer cells. Inhibition of HDAC6 results in marked accumulation of ubiquitinated proteins (inhibition of the aggresome), via acetylation of α-tubulin, which in turn results in increased cellular stress and cytotoxicity.

Histone deacetylase inhibitors may also act by exerting antiangiogenic and immune modulatory effects via downregulation of HIF-1α and epidermal growth factor (EGF). HDIs also affect cancer cell migration, invasion, and metastasis by altering expression of extracellular matrix proteins and metastasis genes in favor of reduced cell invasion.

Classes of Histone Deacetylase Inhibitors

Several structurally diverse classes of naturally occurring and synthetic compounds have been investigated for their ability to inhibit HDAC activity (Table 55-6). These include short-chain fatty acids (e.g., valproic acid), hydroxamic acid derivatives (e.g., vorinostat, panobinostat), synthetic benzamides (e.g., entinostat), and cyclic tetrapeptides (e.g., romidepsin). All of these have undergone clinical evaluation.

Short-Chain Fatty Acid Histone Deacetylase Inhibitors

Sodium butyrate (SB), a well-studied member of this class of compounds, induces in vitro growth arrest and differentiation of human leukemia cells at millimolar concentrations. Its clinical development has been hampered by its short half-life and difficulty in achieving millimolar levels in vivo. Phenylbutyrate, another derivative of butyric acid, is able to induce in vitro growth arrest and differentiation of leukemia cells at clinically achievable submillimolar concentrations. Importantly, at these levels, phenylbutyrate is able to synergize with retinoids in inducing cell cycle arrest, differentiation, and apoptosis of myeloid leukemia cells and with ara-C in myeloid leukemias. Valproic acid (VPA), a well-tolerated antiepileptic, was shown to be effective as an HDI at levels ranging between 0.5 and 2.5 mM.

Two phase I trials have examined the therapeutic effects of phenylbutyrate in patients with AML and MDS. No responses were noted in either study, with neurotoxicity being the dose-limiting toxicity. Several studies have used valproic acid as monotherapy or in combination with other agents in hematologic malignancies. As monotherapy in MDS, response rates have been as high as 16% using the IWG criteria. Neurotoxicity has been the major side effect. Other side effects of VPA include thrombocytopenia, weight gain, asthenia, and rarely hepatic failure and pancreatitis. Given the low response rate, emphasis has shifted to newer HDIs.

Vorinostat and Other Hydroxamic Acid Derivative Histone Deacetylase Inhibitors

Members of this class are some of the most potent HDIs. They contain a functional group that interacts with the critical zinc atom at the base of the catalytic pocket of the class I and II HDACs. These HDIs also possess a hydrophobic cap and an aliphatic side chain that interacts with the edge and fits into the hydrophobic catalytic pocket, respectively, of the HDACs. Members of this class inhibit both class I and II HDACs. Vorinostat (SAHA, Zolinza) is a second-generation polar–planar compound that induces in vitro growth arrest, differentiation, or apoptosis of a variety of cancer, leukemia, and multiple myeloma cells by restoring function of aberrantly silenced genes among other effects. In phase I studies, vorinostat was administered intravenously to patients with solid tumors or hematologic malignancies daily × 3 or daily × 5 for up to 3 weeks. The maximum tolerated dose of vorinostat in patients with hematologic malignancies was 300 mg/m^2 daily × 5 for 3 weeks; thrombocytopenia and leukopenia were the notable toxicities, but induced no significant responses as a single agent in refractory AML. In sequential treatments in vitro, a schedule-dependent synergy was seen with other agents used to treat AML, but in some instances, antagonistic activity was observed. In a phase II study of vorinostat combined with gemtuzumab ozogamicin as induction therapy for elderly AML patients, a complete response rate of more than 20% was observed. In a phase I trial of relapsed AML, vorinostat with idarubicin induced a 17% response rate with modification of histone acetylation patterns.

More impressive responses have been seen in patients with lymphoma. Specifically, treatment of patients with progressive, persistent, or recurrent T-cell cutaneous lymphoma showed strong evidence of significant responses, resulting in rapid FDA approval (see Chapter 84). In the pivotal study, 74 patients with stage IB and higher T-cell cutaneous lymphoma who had failed two systemic therapies were treated with vorinostat at a dose of 400 mg orally once daily.

Table 55-6 Histone Deacetylase Inhibitors*

Name	Type of Compound	Cell Culture (Activity)	Animal Tumor Models	Clinical Trial
Butyrates	Short-chain fatty acids	Yes (uM)	Yes	Phase I/II
Valproic acid	Short-chain fatty acid	Yes	Yes	Phase I/II
Trichostatin A	Hydroxamic acid	Yes (nM)	Yes	—
Pyroxamide	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
Oxamflatin	Hydroxamic acid derivative	Yes (uM)	Yes	—
Suberoylanilide hydroxamic acid (SAHA)	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I/II
TPX-HA analog (CHAP)	Hydroxamic acid derivative	Yes (nM)	Yes	—
LAQ824	Hydroxamic acid derivative	Yes (nM)	Yes	Phase I
MS-275	Benzamide derivative	Yes (uM)	Yes	—
CI-994 (N-acetyl dinaline)	Benzamide derivative	Yes	Yes	Phase I
Depsipeptide (FR901228, FK-228)	Cyclic tetrapeptides	Yes (nM)	Yes	Phase I/II
Trapoxin	Cyclic tetrapeptides	Yes (nM)	—	—
Apicidin	Cyclic tetrapeptides	Yes (nM)	Yes	—

*Activity reported as "Yes" indicates that the compound has been shown to inhibit histone deacetylase (HDAC) activity, that is, growth of transformed cells in culture and in vivo tumor growth in animal studies. (—) indicates no data reported. CI-994 is reported to inhibit histone deacetylation but does not directly inhibit HDAC.

Sixty-one patients (82%) had stage IIB or higher CTCL and 30 patients (41%) had Sézary syndrome. The objective response rate was 30% based on a standardized scoring system, and the median time to tumor progression was 202 days. In these studies, the common toxicities were diarrhea (52%), fatigue (52%), nausea (41%), and anorexia (24%). Although the definitive mechanism of action of this high degree of response is not known, a recent review outlines the current hypotheses. Furthermore, highly significant synergy has been observed in preclinical models combining vorinostat with bortezomib.

Progress with other lymphomas has been more complex. Thirty-nine patients with advanced hematologic malignancies were enrolled in a trial composed of two cohorts examining IV and PO formulations of vorinostat. Up to 70% of patients had diffuse large B-cell lymphoma. The median numbers of prior treatments were seven and five in the IV and PO cohorts, respectively. A substantial number of patients had undergone a prior stem cell transplant. Most patients tolerated vorinostat well. Responses were seen in about 15% of patients.

In patients with refractory follicular lymphoma, NHL, or mantle cell lymphoma, overall response rates of 47% were seen, and responses were observed in two of nine patients with marginal zone lymphoma. The duration of response was longer than 1 year. The largest recent study, by the Southwest Oncology Group (SWOG), in NHL, showed a very low response rate as a single agent, which resulted in combination therapy studies. A number of such studies are underway, but none to date has generated significant results showing combined agent clinical synergy.

Panobinostat is a second-generation hydroxamic acid-based hybrid polar HDI tested both in vitro and in vivo tumor models and in clinical trials. Panobinostat induces apoptosis in a dose-dependent manner on human CML blast crisis K562 cells and acute leukemia MV4-11 cells with the activating length mutation of FLT-3. Exposure to panobinostat is associated with hyperacetylation of H3, H4, and Hsp 90; increase in p21; and induction of cell cycle G1 phase accumulation.

Fifteen patients with a median age of 63 years and refractory AML, ALL, or MDS received IV panobinostat in a phase I trial at the following dose levels (mg/m^2): 4.8, 7.2, 9.0, 11.5, and 14.0. Grade III QTc prolongation was observed in four patients at the 14.0 mg/m^2 level and in one patient at the 11.5 mg/m^2 level. QTc prolongation was asymptomatic and reversible on drug discontinuation. Other toxicities included nausea, diarrhea, vomiting, hypokalemia, and thrombocytopenia. Eight of 11 patients with peripheral blasts had transient reductions in blast counts, which increased shortly after drug discontinuation. Panobinostat has also been shown to be highly effective in CTCL[26] but not more effective than vorinostat. However, unlike vorinostat, single-agent activity has been seen, with response rates of almost 40% in refractory Hodgkin lymphoma. Even more impressive have been recent results in patients relapsing after autologous transplantation, in which overall responses of greater than 70% and objective and durable responses were seen in 27% in a large cohort of 129 patents.[27] This agent also synergizes with everolimus in blocking bcl-6 and mTOR. Panobinostat is being tested as a single agent or in combination with conventional chemotherapy or novel agents in NHL, myeloma, myeloid malignancies, and solid tumors.

Synthetic Benzamide Derivative Histone Deacetylase Inhibitors

Although structurally diverse, these compounds contain a benzamide moiety. Two important members of this class of HDIs are entinostat, which exerts antiproliferative effects at micromolar levels against pancreas, breast, colorectal, lung, and ovarian cancer cell types and in Hodgkin lymphoma cell lines. It has been shown to induce TGF-β receptor, which may enhance the antitumor effects of TGF-β. DLT was reached with the starting dose of 2 mg/m^2 daily for 28 days in a 42-day cycle. Pharmacokinetic data revealed a 30- to 50-fold longer half-life in humans than that predicted from animal models.

Cyclic Tetrapeptide Histone Deacetylase Inhibitors

The principal members of this class of agents are depsipeptide (Romidepsin). Romidepsin has recently been approved by the FDA as an IV agent for the treatment of patients with relapsed or refractory CTCL. It is a potent HDI that exerts in vitro antitumor effects at nanomolar levels against several cancer cell types. It also induces apoptosis of human acute leukemia and CLL cells. It is a natural product derived from *Chromobacterium violaceum,* a bacterium isolated from Japanese soil samples. Additionally, Romidepsin was shown to exert antiangiogenic effects by modulating the expression of genes involved in angiogenesis. In the pivotal study, 130 patients with confirmed peripheral T-cell lymphoma received Romidepsin at 14 mg/m^2 as a 4-hour IV infusion weekly for 3 weeks every 28 days. Objective responses were seen in 25% and complete responses in 15%, with a duration of response of 17 months. A second study in 47 peripheral T-cell lymphoma patients had a 38% objective response rate. A phase I study of romidepsin in patients with CLL and AML at a dosage of 13 mg/m^2 IV on days 1, 8, and 15 of a 4-week cycle showed antitumor activity in several patients, although no CRs or partial responses (PRs) were observed. Response was greater in patients with CLL than AML. There were no life-threatening toxicities, but constitutional symptoms characteristic of HDAC inhibition were observed in the majority of patients.

Depsipeptide shows substantial activity against CTCL and has recently been approved by the FDA for treatment of CTCL patients who have received at least one prior line of systemic therapy at a dose of 14 mg/m^2 intravenously over 4 hours on days 1, 8, and 15 of a 28-day cycle. Another phase II study of depsipeptide as a single agent has shown an encouraging 38% response rate in PTCL. In relapsed myeloma, no objective responses have been observed.

Combinations of Histone Deacetylase Inhibitors With Other Agents

Histone Deacetylase Inhibitors With Cell Cycle and Cell-Signaling Modulators

Both vorinostat and SB have also been combined with the cell cycle–dependent kinase (CDK) inhibitor flavopiridol. The combination of HDI and flavopiridol dramatically increased apoptosis of cultured and primary AML cells, resulting in a synergistic cytotoxic response. Because treatment with flavopiridol also transcriptionally downregulates several antiapoptotic gene expressions, this may be responsible for the synergistic effect observed with the combination. Recent studies have shown that treatment with vorinostat or LAQ824 attenuates the mRNA level of *BCR-ABL* and promotes polyubiquitylation and proteasomal degradation of BCR-ABL. In addition, a combined treatment with LAQ824 and imatinib or PD180970 was shown to induce apoptosis of imatinib-sensitive or imatinib-refractory CML cells. Similarly, the combination of vorinostat and dasatinib on cultured human, primary CML, or murine pro-B BaF 3 cells expressing unmutated or mutated form of BCR-ABL showed enhanced apoptosis. The more potent TKI, nilotinib, has also been studied with the HDI, panobinostat, in cells with ectopic expression of *BCR-ABL* and mutated clones (T315I, E255K) that are imatinib resistant. Taken together, these preclinical findings support the rationale to study the safety and efficacy of the combinations of these HDIs with specific inhibitors of pro-growth and survival signaling triggered by oncoprotein tyrosine kinases.

Heat Shock Protein Inhibitors

The "heat shock response" was first described in 1962. Crucial observations were made indicating that certain regions of the chromosomes of the fruit fly *Drosophila* puffed out in response to a sudden increase in temperature. The gene products encoded on these chromosomes were later termed *heat-shock proteins* (HSPs). Contrary to most cellular proteins, HSP production increases several-fold in response to environmental stresses, including heat shock, nutrient deprivation,

oxidative stresses, heavy metals, and alcohol exposure. They form multimolecular complexes with variable cellular proteins, regulating their correct folding, repair, degradation, and function; hence the HSPs' more accurate designation is "molecular chaperones." A number of multigene families of HSPs exist, and their individual products vary in cellular expression, function, and localization. They are classified according to their molecular weight (e.g., HSP90, HSP70, HSP27). Exceptions to this rule are the chaperones identified as glucose-regulated proteins (GRP94 and GRP75).

HSP90 regulates the function and stability of many key signaling proteins that allow cancer cells to escape the inherent toxicity of their environment, to evade the effects of chemotherapy, and to protect themselves from their own genetic instability. In humans, HSP90 consists of four genes, cytosolic HSP90α and HSP90β, GRP94, and HSP75/TNF-associated protein 1 (TRAP1). The monomer HSP90 consists of conserved 25-kd N-terminal and 55-kd C-terminal domains. The N-terminus contains a highly conserved ATP-binding domain. Dimerization of these nucleotide-binding domains is essential for ATP binding and hydrolysis. Phosphorylation leads HSP90 to interact with co-chaperones such as HSP70 and p23 to form heteroprotein complexes, which are essential for various protein functions. Such proteins include several transcription factors (e.g., steroid hormone receptor, retinoid receptors, and HIF-1α) serine/threonine and tyrosine kinases (e.g., c-SRC/v-SRC, RAF-1, ERB2, EGFR, MEK, CDK4, AKT, BCR-ABL, LCK, FAK, c-MET), and other proteins with various functions (e.g., mutant p53, catalytic subunit of telomerase hTERT, TNFR1, and RB). HSP90 inhibition leads to misfolded client proteins that are involved in malignancy to be polyubiquitinated and degraded by proteosomes. Significant interest in HSP90 inhibition has led to the following compounds.

Benzoquinone Ansamycins (Herbamycin A, Geldanamycin, and Tanespimycin)

The first class of HSP90 inhibitors to be discovered was the benzoquinone ansamycins, which include herbamycin A and geldanamycin. These natural products were first isolated from the actinomycete broths in the 1970s. Hemamycin A was later shown to reverse the malignant phenotype of *v-Src*–transformed fibroblasts, with potent antitumor activity in vitro and in vivo animal models. The effects of this drug on other tyrosine kinases, including $p210^{bcr\text{-}abl}$, were also described, leading to the frequent use of herbimycin A as a general TKI. However, Whitesell and colleagues later identified HSP90 as the prominent benzoquinone ansamycin-binding protein, and they described the ability of these drugs to disrupt the complex between v-Src and HSP90, resulting in destabilization of v-Src protein and its eventual loss from treated cells. Subsequent immunoprecipitation and x-ray crystallography studies showed that geldanamycin competes at the ATP-binding site and inhibits the intrinsic ATPase activity of HSP90, preventing the formation of mature multimeric HSP90 complexes capable of chaperoning client proteins (Fig. 55-10). As a result, the client proteins are ubiquitinated and targeted for proteasomal degradation. Although clearly active in human tumor xenograft models, preclinical evaluation of geldanamycin demonstrated significant hepatotoxicity at therapeutic levels. Screening for geldanamycin analogs resulted in the discovery of 17-allylamino-17-demethoxygeldanamycin, or tanespimycin (17-AAG), a semisynthetic geldanamycin derivative in which an allylamino group replaces the methoxy in the 17 position (see Fig. 55-10). Tanespimycin has a significantly improved toxicity profile but similar to geldanamycin retains the ability to inhibit HSP90. In addition, tanespimycin has been shown to have greater affinity for binding to HSP90 from cancer versus normal host cells.

Preclinical Studies of Tanespimycin

Preclinical studies of tanespimycin exhibited significant antiproliferative and cytotoxic effects against a wide panel of transformed cell lines, inhibiting pathways that regulate cell cycle progression, apoptosis, invasion, and angiogenesis. In the NCI in vitro cancer screen, the mean GI_{50} for tanespimycin was 0.19 μM, with greater than average sensitivity in melanoma, leukemia, non–small cell lung, ovarian, breast, prostate, and renal cancer panels.

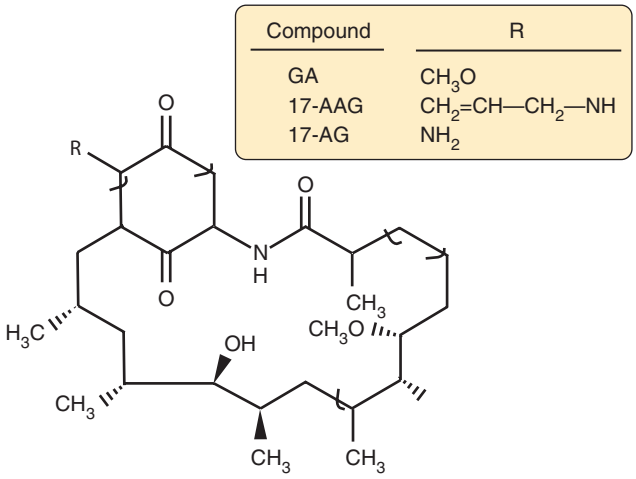

Figure 55-10 CHEMICAL STRUCTURE OF GELDANAMYCIN (GA), 17-ALLYLAMIN-17-DEMETHOXYGELDANAMYCIN (17-AAG), AND 17-AMINO-GELDANAMYCIN (17-AG).

Benzoquinone ansamycins have been reported to induce G1 as well as G2/M block. In a panel of breast cancer cell lines, 17-AAG and geldanamycin caused a G1 arrest. This G1 block resulted from downregulation of signaling pathways controlling cyclin D or CDK4/cyclin D1 activity, particularly depletion of tyrosine kinases (ERBB2, EGF receptor), and degradation of c-RAF-1 with reduced phosphorylation of ERK. A G2/M block has been reported in RB-deficient cells treated with tanespimycin; however, the requirement for RB deficiency appears to be cell dependent. A number of G2 checkpoint kinases such as WEE1 and MYT1 have also been identified as HSP90 client proteins.

HSP90 plays a crucial role in regulating apoptosis. Tanespimycin induced cytosolic accumulation of cytochrome C and cleavage and activation of caspases 9 and 3, triggering apoptosis in HL-60/Bcr-Abl with ectopic expression of p185-Bcr-Abl and K562 with endogenous p210-Bcr-Abl cells. Tanespimycin treatment leads to proteasomal degradation of Bcr-Abl along with AKT depletion. However, high ectopic expression of HSP70 inhibits 17-AAG–induced Bax conformation change, mitochondrial localization, and apoptosis. This is important because of tanespimycin and other analogs of geldanamycin (17-DMAG and IPI504) or radicicol induce HSP70 levels. Therefore, strategies leading to abrogation of HSP70 induction would further antileukemic effects of HSP90 inhibitors.

In addition to their modulation of the cell cycle and programmed cell death, geldanamycin and tanespimycin have been implicated in the regulation of invasion, metastasis, and angiogenesis. Tanespimycin treatment of H322 and H358 cells enhanced E-cadherin expression and inhibited secretion of MMP-9 and VEGF. Geldanamycins have also been shown to inhibit the HGF/SF-MET signaling pathway, resulting in decreased cell motility and invasion of c-MET transformed cells. HSP90 inhibitors also significantly reduce VEGF secretion by decreasing HIF1α expression as well as inducing degradation of all three VEGF receptors.

Combination studies incorporating tanespimycin have shown promise. In lung and colorectal cell lines, combinations of tanespimycin with cisplatin, doxorubicin, or paclitaxel have been synergistic or additive. In addition, tanespimycin is synergistic with novel agents, including imatinib, bortezomib, ERK inhibitors, and SAHA. Combined treatment of panobinostat, a histone deacetylase inhibitor, with tanespimycin exerted synergistic effects in AML and CML cells with decreased Bcr-Abl, p-AKT, AKT, and p-STAT5 levels.

Metabolism of Tanespimycin

In human and murine microsome assays, three metabolites of tanespimycin (17-AAG) were identified: 17-aminogeldanamycin (17-AG), a diol, and an epoxide. The 17-AAG diol is the major metabolite in human hepatic microsomes followed by 17-AG. Cytochrome P450 (3A4) was identified as the enzyme responsible for 17-AAG metabolism. Acrolein, a known nephrotoxin, is a byproduct of 17-AG. Also, the 17-AG metabolite has biological activity equivalent to that of the parent compound. The quinone-metabolizing enzyme DT-diaphorase has been shown to alter tanespimycin's antitumor properties. A positive correlation between DT-diaphorase expression levels and growth inhibition by tanespimycin has been established. Transfection of an active DT-diaphorase gene NQO1 into a human carcinoma cell line increased tanespimycin's growth-inhibitory activity 32-fold. Polymorphisms of the NQO1 gene, which is found in 5% to 20% of the population, as well as acting as a substrate for PGP efflux pump may limit its clinical efficacy.

Clinical Investigation With Tanespimycin

Several phase I trials in adults have explored different scheduling regimens of tanespimycin. Administration of tanespimycin daily for 3 days or for 5 days has been associated with dose-limiting toxicities, namely, hepatotoxicity, diarrhea, and thrombocytopenia at substantially lower doses (40-56 mg/m^2). Grade III GI toxicity, including nausea, vomiting, and diarrhea, is associated with the formulation of tanespimycin, which contains 4% DMSO. No objective clinical responses were reported with either schedule; however, in xenograft models, the effects of tanespimycin on HSP90 client proteins lasted up to 72 hours, suggesting that twice-weekly dosing might be more effective. Thus additional trials have evaluated twice weekly and weekly for 3 weeks out of 4. A recent study recommended phase II doses of 175 to 200 mg/m^2 given twice weekly. This schedule was associated with a persistent increase of HSP70; however, no consistent changes in PBMC phosphorylated Akt, HSP90, or Raf-1 during treatment. Combination phase I studies of tanespimycin with docetaxel, irinotecan, imatinib, trastuzumab, and bortezomib are currently ongoing.

Clinical Investigation With IPI-504

Because tanespimycin has poor aqueous solubility and must be administered with DMSO or newer Cremophor formulations, synthesis of HSP90 inhibitors with more favorable pharmaceutical properties is required. IPI-504, the highly soluble hydroquinone hydrochloride derivative of tanespimycin, has been shown to be 4000-fold more soluble than tanespimycin. In preclinical studies, single-agent IPI-504 as well as in combination with bortezomib has shown antitumor effects in xenograft models of multiple myeloma. Also, treatment with IPI-504 resulted in BCR-ABL protein degradation, decreased numbers of leukemia stem cells, and prolonged survival of leukemic mice bearing the T315I mutation. A phase I study has been initiated in relapsed myeloma patients. IPI-504 is administered over 30 minutes on days 1, 4, 8, and 11 every 21 days. Thus far, 15 patients have been treated, with doses ranging from 90 to 300 mg/m^2. No dose-limiting toxicities have been observed to date.

Clinical Investigation With Alvespimycin (KOS-1022)

Alvespimycin (KOS-1022) is a second-generation HSP90 inhibitor that has begun phase I trials with IV and PO schedules. Escalating doses of alvespimycin were given intravenously over 1 hour twice weekly every 3 weeks. Alvespimycin demonstrated antileukemic activity with tolerable toxicity at 24 mg/m^2 twice weekly. In 23 patients with AML, 3 patients experienced complete response and 1 patient demonstrated stable disease while on study for 9 cycles. Clinical trials of alvespimycin in combination with trastuzumab in solid malignancies are also ongoing.

17-DMAG

The water-soluble stable geldanamycin derivative, 17-(dimethylaminothylamino)-17-demethoxygeldanamycin (17-DMAG), has demonstrated more potent in vitro and in vivo antitumor activity than 17-AAG. In addition, 17-DMAG offers three potential advantages over 17-AAG: (1) aqueous solubility eliminates formulation problems associated with 17-AAG, (2) 17-DMAG undergoes limited metabolism, and (3) it has higher PO bioavailability. Phase I studies evaluating 17-DMAG have been recently initiated.

Other HSP90 Inhibitors

In addition to benzoquinone ansamycins and the semisynthetic analog tanespimycin, several other compounds were found to bind HSP90 and disrupt its chaperone function.

Radicicol

Radicicol, a macrocyclic antibiotic isolated from *Monosporum bonorden*, binds the N-terminal domain of HSP90, competing with its natural ligand, ATP. Although a more potent inhibitor of HSP90 ATPase compared with geldanamycin, radicicol lacks antitumoral activity in vivo owing to its unstable chemical nature. Oxime-derivative compounds, which retain the HSP90 inhibitory activity and have a more stable chemical structure, were developed.

Novobiocin

Novobiocin, a coumarin antibiotic, binds the C-terminus domain of HSP90, as opposed to N-terminus binding with geldanamycin and radicicol. However, it was shown to retain inhibitory activity against HSP90 and degrade its client-signaling proteins. Thus it appears that N- and C-terminal domains are both essential for HSP90 chaperone functions.

Bryostatin 1

Bryostatin 1 (NSC339555) is a macrocyclic lactone isolated from the marine bryozoan *Bugula neritina*. It originally attracted attention because of its activity against a wide variety of tumor types in an NCI screen. In hematopoietic cells, bryostatin 1 displays the unique capacity to inhibit the growth of human leukemia cells while stimulating the growth of their normal counterparts.

Bryostatin 1 has been shown to act like the phorbol ester phorbol myristate acetate (PMA) in that it binds to and activates the serine-threonine kinase protein kinase C. However, in contrast to PMA, it is a weak inducer of leukemic cell maturation and in fact blocks PMA-mediated differentiation. This may reflect the ability of bryostatin 1, on chronic administration, to downregulate PKC activity.

In preclinical studies, bryostatin 1 has shown activity against continuously cultured and primary human leukemia and lymphoma cells when administered at nanomolar concentrations. In addition, bryostatin lowers the threshold for leukemic and lymphoma cell apoptosis in response to conventional cytotoxic agents. The latter include ara-C, fludarabine, vincristine, paclitaxel, and chlorodeoxyadenosine. It is postulated, although not definitively established, that such actions may reflect bryostatin 1–mediated downregulation of PKC, which exerts antiapoptotic actions. More recently, bryostatin 1 has been shown to interact synergistically with more novel agents, including flavopiridol, through a process that may involve induction of TNF. In clinical studies, bryostatin 1 has been administered according to a variety of schedules. Dose-limiting toxicity consists of myalgias, which are cumulative and which do not respond well to standard analgesic therapy. Other toxicities include fatigue, hepatotoxicity, nausea and vomiting, and phlebitis.

Bryostatin 1 as a single agent has shown some, although limited, activity. For example, when administered as a 120-hour continuous

infusion every 2 weeks at a dose of 120 μg/m^2, three of 25 patients with CLL or NHL achieved a CR or objective PR. On the other hand, of nine patients with multiple myeloma, none responded to this bryostatin 1 dose and schedule.

Results have been somewhat more promising when bryostatin 1 was combined with established cytotoxic drugs. For example, administration of bryostatin 1 as a 24-hour infusion (50 μg/m^2) immediately before and after a split course of high-dose ara-C resulted in four CRs in 23 patients with highly refractory disease. Administration of escalating doses of bryostatin 1 as a 1-hour infusion immediately before or after a 5-day course of fludarabine (doses of 16-25 mg/m^2/day) resulted in 17 of 53 objective responses, including six in patients who had progressed on fludarabine previously. Neither sequence was clearly superior to the other.

Finally, in a phase I study, patients with B-cell malignancies were treated with a 24-hour continuous infusion of bryostatin 1 followed by a bolus injection of vincristine every 2 weeks. The maximally tolerated dose of bryostatin 1 was 50 μg/m^2. Of the 24 evaluable patients, five patients had durable CRs or PRs, and an additional five patients had stable disease. Collectively, these findings suggest that bryostatin 1 may have a role in hematologic malignancies when combined with established cytotoxic agents.

DRUG RESISTANCE TO CHEMOTHERAPEUTIC AGENTS OR MULTIDRUG RESISTANCE

Although many hematologic malignancies develop resistance to a specific class of chemotherapeutic agents, especially to targeted therapeutics, through the development of kinase region point mutations, emergence of resistance to multiple cytotoxic chemotherapeutic agents is also common among hematologic malignancies. The basis for resistance includes specific drug resistance mechanisms, overexpression of the ABC transports such as MDR-1 for drug efflux, and overexpression of antiapoptotic proteins. The Goldie–Coldman hypothesis predicts that drug-resistant tumor cell clones survive because of a favorable spontaneous mutation, which occurs in approximately one in a million cells. Because 1 g of tumor contains 1×10^9 cells, it becomes obvious that high tumor burden states have a tremendous number of mutations, which can contribute to drug resistance. This is the rationale for using combination chemotherapy at specific dose intervals to maximize dose intensity.

Drug resistance mechanisms have been discovered and subsequently defined at the molecular level by investigators working in vitro with tumor cell lines selected in the presence of specific antitumor agents, by analysis of primary samples of untreated and treated hematologic malignancies, and through screening of tumor banks. Classes of resistance include acquired protein deficiency, loss of sensitivity to apoptotic signals, and age-related defects in the cellular pathways that normally lead to apoptosis.

P-Glycoprotein (ABC-B1 Transporter)

Structure and Function

The ABC superfamily of membrane transporters mediates the cross membrane flux of xenobiotics, naturally occurring toxic compounds, drugs, peptides, and ions. *ABC* stands for ATP-binding cassette transporter family. They have profound impact on homeostasis and are critically important to proliferation and differentiation signals in normal progenitor cells. They also mediate drug sensitivity. The terminology remains challenging because many earlier works referred to PGP and MRP, but the more recent consensus on the ABC superfamily has created a more simple approach going forward. PGP (ABC B1 transporter) has been the subject of intense biochemical and clinical studies since it was first discovered in drug-resistant cell lines more than 20 years ago. The biochemistry of PGP has been reviewed in detail by several investigators. This phosphorylated glycoprotein has a molecular mass of approximately 170 kd and is localized to the plasma membrane, where it functions as a drug efflux pump (Table 55-7). The ATP-dependent extrusion of antineoplastic agents confers a relative level of resistance to the cell that overexpresses PGP. Recently, the family of drug-transporting proteins has been more carefully characterized, leading to the use of the terms *ATP-binding cassette transporters*. The observation of double minute chromosomes and homogeneously staining regions in several MDR cell lines suggested that gene amplification is involved in PGP-mediated MDR. The human *MDR1* gene, which codes for PGP and is involved in antitumor drug resistance, and the human *MDR2* gene (the product of which is expressed by hepatocytes) are located very near each other on human chromosome 7q21.1. The human *MDR1* gene has 28 exons and codes for a protein of 1280 amino acids. The PGP molecule has two homologous halves, each with a hydrophobic region containing six transmembrane domains and a hydrophilic region containing an ATP-binding site. The N-linked glycosylation occurs on the extracellular side (Fig. 55-11). PGP is a member of the ABC superfamily, which includes, among more than 100 others, the multidrug resistance–associated protein (MRP); the pf*mdr* pump in *Plasmodium falciparum*, which results in chloroquine resistance; STE6, the transporter of the "a" peptide mating factor in yeast; the cystic fibrosis transmembrane conductance regulator (CFTR); and the TAP-1 and TAP-2 proteins that transport antigenic peptides for association with class I molecules and surface antigen presentation. MRP has been demonstrated in several MDR mammalian cell lines and in human tumors (see later), but a recent study in human tumor cell lines has shown TAP overexpression associated with MRP as well as drug resistance resulting from transfection of the *TAP* genes.

P-glycoprotein has a broad specificity for hydrophobic compounds and can both reduce the influx of drugs into the cytosol and increase efflux from the cytosol. To accomplish the former, this "hydrophobic vacuum cleaner" must detect drugs and expel them while they are still in the plasma membrane. Drugs are thought to be effluxed from the cytosol through a single barrel of the PGP transporter, although an exact mechanism has been lacking. A recent study has used electron microscopy to generate an initial structure of PGP to 2.5-nm resolution. The structure was further refined by three-dimensional reconstructions from single particle image analysis of detergent-solubilized PGP and by Fourier projection maps of small crystalline arrays of PGP. This demonstrates that PGP is monomeric, with the shape of a cylinder 10 nm in diameter with a maximum height (in the plane of the membrane) of 8 nm (see Fig. 55-11). Approximately half of the PGP molecule is within the membrane because the lipid bilayer is approximately 4 nm in depth. When viewed from the extracellular surface of the membrane, PGP is pteroidal with a large central pore 5 nm in diameter. This large aqueous chamber in the membrane that is open to the extracellular space is closed on the cytoplasmic side presumably by the two 3-nM intracellular lobes (putative nucleotide-binding domains) and the hydrophilic cytoplasmic loops between the transmembrane domains. Thus this large pore has a "gate" on the cytoplasmic side of the membrane that can regulate the transport of different-sized substrates.

Substrates of PGP include (see Table 55-7) anthracyclines (doxorubicin, daunorubicin, epirubicin, and idarubicin), anthracenediones (mitoxantrone), aminoacridines (*m*-AMSA), taxanes (taxol and taxotere), epipodophyllotoxins (VP-16 and VM-26), vinca alkaloids (vincristine, vinblastine, and vinorelbine), bortezomib, and actinomycin D. Mitomycin C and one of the topoisomerase I inhibitors (topotecan) are both weak substrates for PGP. Several drugs reverse the resistance mediated by PGP overexpression and sensitize cells to the cytotoxic effects of antineoplastic agents. These drugs compete with antitumor agents for efflux from the cell, effectively increasing the intracellular concentration of the cytotoxic drug, and include immunosuppressants (cyclosporin A, FK 506, rapamycin, PSC 833), calcium channel blockers (verapamil, nifedipine), antiarrhythmics (quinidine), and other miscellaneous agents. Several of these MDR-modulating agents have been used in clinical trials in an effort to sensitize resistant tumor cells (see later).

Table 55-7 Characteristics of Three Mechanisms of Multidrug Resistance That Result From Overexpression of P-Glycoprotein (PGP), Multidrug Resistance-Associated Protein (MRP), or Lung Resistance-Related Protein (LRP)

	PGP	MRP	LRP
Gene on chromosome	7q21.1	16p13.1	16p11.2
		Protein	
Molecular mass	170 kd	190 kd	110 kd
Cellular location	Plasma membrane	Plasma membrane	Cytoplasm » nuclear membrane
Function	Efflux pump, chloride channel	Drug transporter	Major vault protein (nucleocytoplasmic transport?)
Energy source	ATP	ATP	
Post-translational modifications	N-glycosylation, phosphorylation	N-glycosylation, phosphorylation	*No* N- or O-glycosylation
Analogs	Member ABC superfamily	Member ABC superfamily; GS-X pump, MOAT, LTC_4 transport	
		Drug Resistance Phenotype	
Antitumor agents	Act-D, AMSA, dauno, dox, epi, ida, mito-C	Act-D, chlor, CDDP-GSH, dauno, dox, epi, mel, tax (low), vbl (low), vcr, VM-26, VP-16	Carbo, CDDP, dox, mel, vcr, VP-16
	(Low), mtz, nav, tax, txtr, tpt (low), vbl, vcr, VM-26, VP-16	As, Cd, colch (low), GSH	
Other drugs	Colch, rhod	Conjugates, GSSG, LT_4, Sb	
Reversing agents	CSA, FK506, nifed, PSC833, quin, rap, verap	CSA, gnstn, indo, nicard, prbn, PSC833, verap, VX-710	
Normal hematopoietic tissues with increased expression	NK ($CD56^+$) T cells, suppressor T cells ($CD8^+$), B cells, $CD34^+$ stem cells	PBMNs (especially T cells), rbc membranes; liver and spleen low level	Macrophages
Prognostic significance	AML, MM, NHL	AML (inv 16)	AML, ALL

ABC, ATP-binding cassette; *act-D,* actinomycin D; *ALL,* acute lymphoblastic leukemia; *AML,* acute myeloid leukemia; *As,* arsenicals; *ATP,* adenosine triphosphate; *carbo,* carboplatin; *Cd,* cadmium; *CDDP-GSH;* cisplatin glutathione conjugate; *chlor,* chlorambucil; *colch,* colchicine; *CSA,* cyclosporin A; *dauno,* daunomycin; *dox,* doxorubicin; *epi,* epirubicin; *gnstn,* genistein; *GS-X,* glutathione conjugate; *GSSG,* oxidized glutathione; *ida,* idarubicin; *indo,* indomethacin; LTC_4, cysteinyl leukotriene; *mel,* melphalan; *mito-C,* mitomycin C; *MM,* multiple myeloma; *MOAT,* multispecific organic anion transporter; *mtz,* mitoxantrone; *nav,* navelbine; *NHL,* non-Hodgkin lymphoma; *nicard,* nicardipine; *NK,* natural killer; *nifed,* nifedipine; *prbn,* probenecid; *quin,* quinidine; *rap,* rapamycin; *rhod,* rhodamine; *Sb,* antimonials; *tax,* taxol; *tpt,* topotecan; *txtr,* taxotere; *vbl,* vinblastine; *vcr,* vincristine; *verap,* verapamil; *VM-26,* teniposide; *VP-16,* etoposide.

Methods of Detection

Several monoclonal antibodies that recognize PGP and are commercially available for routine analyses have been described. Monoclonal antibodies C219 and JSB-1 recognize internal epitopes of PGP, whereas antibodies MRK16 and UIC2 detect external antigens and are more suited for FACS analysis.

P-Glycoprotein Expression in Normal Human Tissue

High levels of expression of *MDR1*/PGP have been found in the epithelium of several human tissues with excretory function, suggesting that PGP is normally involved in transporting both exogenous toxic compounds and endogenous metabolites. These tissues include the adrenal cortex, renal proximal tubule epithelium, biliary hepatocytes, small and large intestinal mucosa, pancreas, and endothelial cells of the brain and testis. Normal human hematopoietic tissues with high levels of *MDR1*/PGP include $CD34^+$ progenitor cells, $CD56^+$ (NK) cells, and $CD8^+$ (T-suppressor) cells. Lower levels of expression have also been observed in $CD4^+$ (T-helper) cells, $CD19^+$ B cells, and $CD14^+$ cells (monocytes).

P-Glycoprotein Expression in Human Malignancies

Increased expression of PGP has been observed in several human tumors, especially those malignancies that arise in tissues that normally have high levels of PGP expression. An analysis of 61 human tumor cell lines (from leukemia, CNS tumors, melanoma, breast cancer, ovarian cancer, colon cancer, lung cancer, and kidney cancer), which were not selected for resistance to antitumor agents, demonstrated coexpression of two or three of the MDR proteins (PGP, LRP, or MRP) in 64% of the cell lines. PGP and LRP were overexpressed in 3% of the tumors; MRP and LRP in 43%; and PGP, LRP, and MRP in 18%. The cell lines with the highest levels of drug resistance were found to overexpress all three proteins. Whether this is true in primary human tumors awaits further investigations.

Acute Myeloid Leukemia

An earlier meta-analysis of studies that examined the expression of *MDR1*/PGP in blasts of patients with AML found that 40% (105 of 261 patients) who were PGP positive achieved a CR, but 81% (192 of 238) of PGP-negative patients obtained a CR. An analysis of 96 untreated patients with AML showed that PGP expression predicted induction failure ($P<.0001$) and decreased OS ($P<.001$), as did unfavorable cytogenetics. PGP expression was not detected in patients with favorable cytogenetic abnormalities [t(15;17), inv(16), t(8;21)], was found in 29% of those samples with a normal karyotype, and expressed in 62% of patients with an unfavorable cytogenetic abnormality. PGP was also detected in 63% of those with secondary AML compared with 25% of those with de novo disease. PGP analysis with the MRK16 antibody in 211 elderly patients (older than 55 years) with untreated AML again showed that PGP expression is significantly associated with a decreased CR rate and

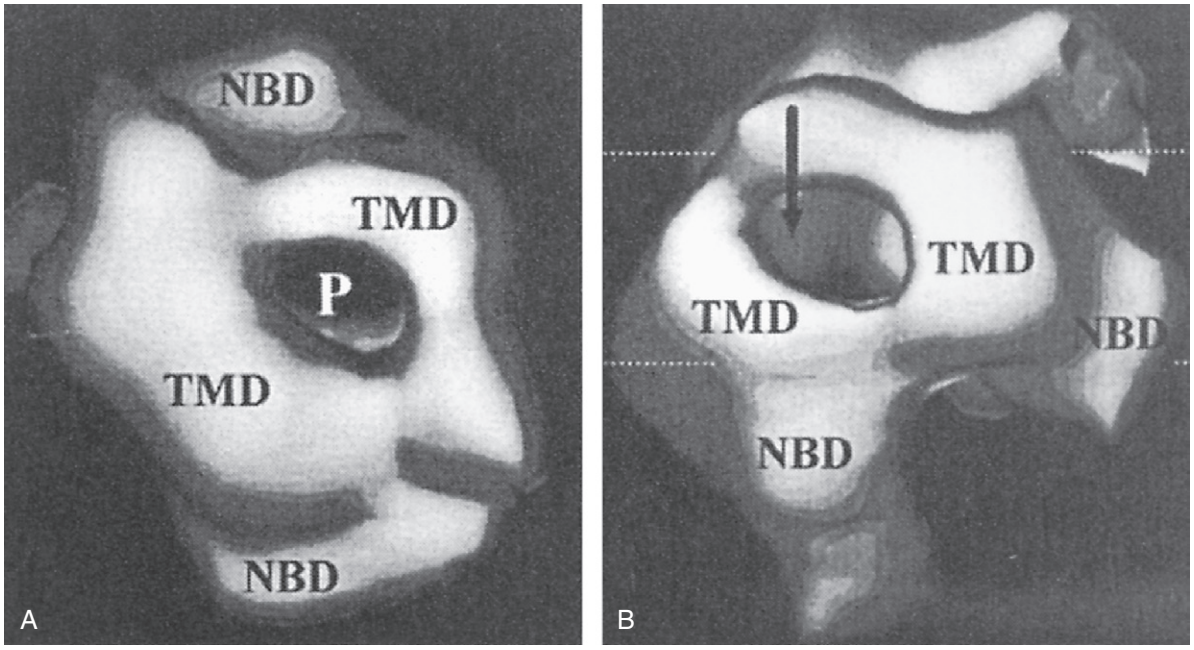

Figure 55-11 STRUCTURE OF P-GLYCOPROTEIN (PGP) DETERMINED BY ELECTRON MICROSCOPY; A COMPUTER GRAPHIC REPRESENTATION OF THE THREE-DIMENSIONAL RECONSTRUCTION IS SHOWN AS A SHADED SURFACE REPRESENTATION OF THE STRUCTURE. The straight arrow shows the putative adenosine triphosphate (ATP)–binding domains. P represents the aqueous pore open at the extracellular face of the membrane. TMD, two thumbs, each of which probably corresponds to one of the two transmembrane domains. NBD, 3-nm lobes projecting from the structure at the cytoplasmic face of the membrane, probably corresponding to the two nucleotide-binding domains. **A,** View perpendicular to the extracellular surface of the lipid bilayer; **B,** side view of PGP in which the approximate position of the lipid bilayer is indicated by the two horizontal *dashed lines*. *Arrow* indicates asymmetric opening providing access from the lipid phase to the aqueous core of the protein. *(Reproduced with permission from Rosenberg MF, Callaghan R, Ford RC, et al: Structure of the multidrug resistance P-glycoprotein to 2.5 nm resolution determined by electron microscopy and image analysis.* J Biol Chem *272:10685, 1997.)*

resistant disease. Patients in this report with de novo PGP-negative AML with favorable cytogenetics have a CR rate of 81% compared with 12% for those with secondary AML, which is PGP positive and has unfavorable cytogenetics. Clinical trials using the PGP substrate PSC833 acting as a competitive inhibitor did not show the dramatic benefit expected, especially in older patients with acute leukemias.

Impact of P-Glycoprotein in Other Hematologic Malignancies

The role of PGP in the drug resistance of NHL, myeloma, and ALL is ill-defined. CLL is another chronic leukemia in which few PGP-related antineoplastic agents are used. However, a single study has shown a correlation between *MDR1* expression and survival, in which the 10 B-CLL patients who were *MDR1* positive had a median survival of 19 months compared with 46 months for the 17 patients who were *MDR1* negative (P <.01). Nonetheless, a recent study identified bortezomib as a substrate for PGP, raising the possibility that myeloma PGP levels affect clinical response. There have not been recent studies of the role of PGP in drug resistance in NHL in the past 5 years. With the newer kinase inhibitors, it has recently been noted that Nilotinib and dasatinib are high-affinity substrates of ABCG2. These agents appear to inhibit the function of this transporter, but whether this will translate into clinical impact has not received prospective attention.

Clinical Studies With Modulators of P-Glycoprotein

The clinical trials that have used various modulators of PGP have been reviewed by several investigators. An early study in VAD-refractory multiple myeloma resulted in short-lived partial responses to VAD plus racemic verapamil in five of 22 patients. Four of the five responders overexpressed PGP; however, cardiac side effects precluded further dose escalation of IV *R,S*-verapamil. Continuous IV infusion of cyclosporin A (CSA) with VAD in VAD-resistant myeloma patients resulted in seven of 15 responses, which were more common in those who overexpressed PGP. A randomized SWOG phase III study of VAD and PO verapamil in 120 patients with refractory myeloma demonstrated a 41% and 36% response in the VAD and VAD/verapamil arms, respectively, with median survival times of 10 and 13 months. Continuous-infusion CSA has been dose escalated in combination with daunorubicin and ara-C. A transient hyperbilirubinemia was seen in 62% of the patients; these same patients had increased serum daunorubicin levels and a higher response rate. A complete response was seen in 26 of 42 patients; however, the MDR phenotype was not found to influence the response. A study of PSC833 in patients with acute leukemia treated with cytarabine, daunorubicin, and etoposide showed a modest benefit in patients younger than 45 years of age, raising the potential of developing an effective strategy in patients older than 60 years of age in whom PGP expression in leukemic cells is more common. Zosuquidar, a PGP inhibitor, was tested for efficacy in a phase 3 trial through ECOG in 449 patients older than the age of 60 years. No benefit in response rate or survival was noted. Likewise, in a CALGB study, in adults with untreated leukemia younger than the age of 60 years, PSC-833 also did not improve survival or response rates. Thus the future role of modulation of PGP in leukemia management remains ill defined.

Multidrug Resistance–Associated Protein (ABC G2 Transporter)

Structure and Function

The MRP was first described in 1992 in the doxorubicin-selected small cell lung cancer cell line, and its biochemical characteristics and

biologic properties have been reviewed. It has now been classified within the larger context of ABC transporters, termed *ABC G2 transporters*. Because much of the literature uses the MRP nomenclature, we refer to this herein except for the studies using the ABC terminology. This N-glycosylated plasma membrane phosphoprotein has a molecular mass of 190 kd (1531 amino acids) and is a member of the ABC transporter superfamily (see Table 55-7 and Fig. 55-12). This transporter has 18 transmembrane domains (12 in the amino end and six in the carboxyl end) and is coded on human chromosome 16p13.1.

The overexpression of MRP has been shown in vitro to result in different levels of drug resistance to several classes of antineoplastic agents, represented by actinomycin D, chlorambucil, melphalan, CDDP, daunomycin, doxorubicin, epirubicin, VM-26, VP-16, and vincristine. Low levels of resistance have also been reported to taxol, vinblastine, and colchicine. In addition to antitumoral agents, MRP (and its isoforms) are capable of transporting heavy metals (arsenicals, cadmium, and antimonials) as well as glutathione conjugates and cysteinyl leukotriene. Compounds reported to modulate MRP-mediated drug resistance in vitro include the calcium channel blocker verapamil nocardipine; the protein kinase C inhibitor GF109203X; the cyclosporin analog PSC 833; the TKI genistein; the gyrase-inhibiting antibiotic difloxacin; and amiodarone VX-710 Amiodarone VX-710, a nonmacrocyclic ligand of the FK506-binding protein FKBP12 and a potent modulator of PGP-mediated MDR, has been found to restore sensitivity of MRP-expressing HL60/ADR cells to the cytotoxic action of doxorubicin, VP-16, and vincristine. Other investigational agents include Danusertib, a potent pan-aurora and ABL kinase inhibitor being developed for CML. The nonsteroidal antiinflammatory drug indomethacin has also been shown to significantly increase the sensitivity of HL60/ADR cells to doxorubicin and vincristine and may be a specific inhibitor of MRP.[29]

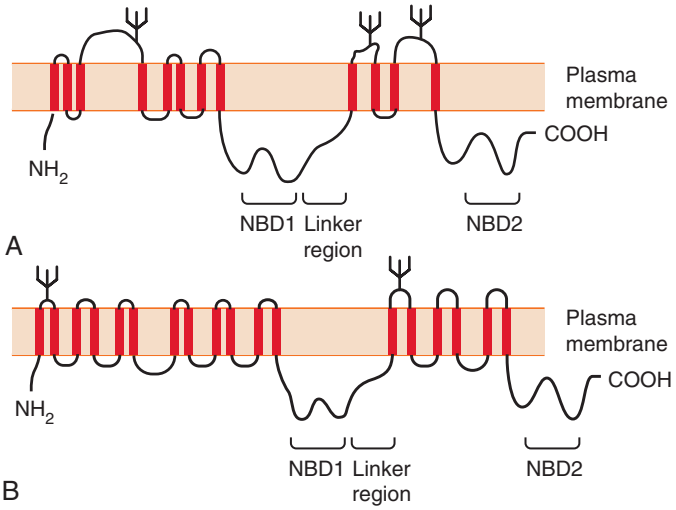

Figure 55-12 MODELS OF MULTIDRUG RESISTANCE PROTEIN (MRP) MEMBRANE TOPOLOGY. MRP possesses features common to all members of the adenosine triphosphate (ATP)–binding cassette transporter superfamily in that each half of the protein is predicted to consist of several transmembrane domains followed by a cytosolic nucleotide-binding domain (MBD). The first model **(A)** is based on computer-assisted hydropathy analyses of the human MRP amino acid sequence and predicts that MRP is composed of 12 transmembrane domains *(solid bars),* eight of which are within the NH-2 proximal half of the protein. The second model **(B),** based on a comparison of human and murine MRP with other ATP-binding cassette transporters, suggests that there are up to four additional transmembrane domains in the NH2-proximal half of the protein. *(Adapted from Loe DW, Deley RG, Cole SPC: Biology of the multidrug resistance-associated protein, MRP.* Eur J Cancer *32A:945, 1996.)*

Multidrug Resistance Protein Expression in Hematologic Malignancies

The expression of MRP mRNA or the level of MRP protein has been assessed in 148 patients with hematopoietic malignancies. MRP mRNA expression was found to be significantly increased in 84% of patients with CLL and in 30% of those with AML. The vast majority of patients with ALL, CML, multiple myeloma, hairy cell leukemia, and NHL were found to have low levels of MRP mRNA expression. MRP protein was assayed using monoclonal antibody MRPr1, and the results were generally similar with increased expression in most patients with CLL. A study of 40 patients with refractory lymphoma and 16 with newly diagnosed lymphoma suggests a limited role for MRP mRNA expression in drug resistance in NHL because 15 paired samples in the refractory group showed no difference in MRP expression pre- and post-EPOCH treatment. In addition, the untreated patients had MRP mRNA levels that were no different from the pre- or post-EPOCH patient levels. A study of 49 patients with AML and 29 with ALL demonstrated significantly higher expression of MRP in ALL (P <.007) and in secondary AML (P <.016) but not in de novo AML. Combining overexpression of ABC G2 and FLT3-ITD, an Italian group identified that in adult AML, overexpression of ABC G2 was detected in 83 (50%) and of FLT3-ITD in 47 (28%) patients. Although the response rate was not affected, the duration of remission was much shorter when these proteins were overexpressed. In a small study of 14 patients with relapsed AML, relapse was associated with a twofold increase in blast MRP mRNA relative to 29 patients with newly diagnosed AML (P <.01). Paired blast samples (obtained at diagnosis and at relapse) from 13 AML and four ALL patients showed a twofold increase in 80% of the patients at relapse, suggesting that the expression of the MRP transporter at relapse may be involved in drug resistance. Because purine nucleoside antimetabolites may be exported by ABC G2, as noted earlier, it is of note that the recently released antileukemia agent clofarabine is also a substrate but its function is mediated inversely by levels of deoxycytidine kinase. Also of note is the recent finding that drug treatment can demethylate and thus activate the ABC G2 exporter, thereby increasing its protective tumor impact.

The larger family of transporters, the ABC group that includes ABC G2 and ABC B1, are overexpressed in leukemic cells and in many malignant stem cells. In fact, in addition to CD44, high levels of ABC transporters assist in the characterization and isolation of the transplantable subpopulation of malignant stem cells. Brendel and coworkers found that both imatinib and nilotinib used to block the abl kinase in CML were effectively blocking the ABC transporter in CML cells. This suggested both that these agents might function in part by blocking expression of an important leukemic stem cell protein and that they would sensitize CML cells to other agents transported by the ABC system.

DNA Repair Pathway Mechanisms of Drug Resistance

O6-Alkylguanine-DNA Alkyltransferase (MGMT)

As noted previously, the nitrosoureas and methylating agents are cytotoxic largely because of formation of DNA adducts at the O^6 position of guanine. The most efficient means of protection from the cytotoxicity of adducts at the O^6 position of guanine is rapid repair by the O^6-alkylguanine-DNA alkyltransferase (AGT or MGMT). This protein serves as the stoichiometric acceptor protein for O^6-alkylguanine DNA monoadducts, transferring the alkyl group from DNA to the active site of the protein, inactivating the protein, and restoring DNA to normal. However, the N^1G-N^3C DNA cross-link that follows chloroethylation is not a substrate for AGT. There is a striking correlation between drug resistance and alkyltransferase activity. Of interest, high levels of AGT are found in many leukemias, but low AGT is observed in normal human CD34 cells, perhaps

explaining why nitrosoureas are not used in leukemia management and why nitrosoureas are effective myeloablative agents used in high-dose chemotherapy regimens. A novel inhibitor of AGT, O^6-benzylguanine (BG) has been used to sensitize human tumors to BCNU. Studies indicate activity of the combination of BG and BCNU in myeloma and in cutaneous lymphomas. Therapeutic benefit from the methylating and alkylating agent cloretazine appears to be related to lower levels of AGT. Likewise, temozolomide has some therapeutic efficacy in leukemia in a manner inversely related to AGT levels in the tumor cells. A study in five pediatric patients pointed out that response to temozolomide was greater in those with MGMT promoter methylation and no evidence of mismatch repair. This has been tested in a prospective phase 2 trial of older patients with leukemia. Temozolomide was given in a dosing schedule dependent on MGMT promoter methylation status, with a shorter course of therapy in those with low MGMT expression in the leukemic cells. The overall response rate in elderly leukemia patients who would otherwise not be candidates for treatment was about 40%, with a median duration of about 29 to 35 weeks.

Mismatch Repair

The spectrum of drug resistance and sensitivity to methylating agents does not end with AGT. Evidence suggests that methylating agent–induced cell death involves an aborted effort at mismatch repair. Karran and others, in mammalian systems, have shown that the replicative DNA polymerase and the repair polymerase pauses at O^6-mG and preferentially inserts a thymine (T) at the site. The O^6-mG:T base pair is recognized by the mismatch repair (MMR) system, which initiates base excision repair (BER; see later). In human cells, the MMR complex consists of at least six proteins involved in the recognition and repair of mismatch lesions: HMLH1, hMSH2, hMSH3, hPMS1, hPMS2, and GTBP (GT-binding protein, also called MSH6), all of which appear to be homologs of MMR proteins found in *Escherichia coli* and in yeast. After binding recognition, an endonuclease removes a patch of approximately 100 to 1000 bp containing the T mismatch, DNA polymerase δ or γ fills in the patch, with reinsertion of a T opposite the O^6-mG, and a DNA ligase closes the strand break. Because the O^6-mG:T is re-formed, cytotoxicity ensues as a result of repetitive efforts at DNA repair and induction of chromosomal breakage, rearrangements, energy depletion, and apoptosis. Drug resistance based on mutation or loss of expression of an MMR protein, owing to mutation within one of the gene coding regions, or promoter methylation leading to loss of gene expression, has been noted in solid tumors and in leukemias and lymphomas. The mutator phenotype was originally described in cells with acquired resistance to methylnitrosourea, methylmethanesulfonate, or *N*-methyl-*N*-nitroso-*N*-nitrosoguanidine, which were tolerant to G→A point mutations according to the inability to repair O^6-mG and are cross-resistant to 6-thioguanine (6-TG) used in childhood leukemia maintenance regimens, which form the 6-TG:T mismatch.

Major Molecular Response Mutations and Methylating Agent Resistance

Mismatch repair defects in humans were initially described in hereditary nonpolyposis colon cancer, which comprises approximately 15% of all colon cancer, lymphomas, and relapsing acute leukemias. The genetic defect results in a high rate of spontaneous mutations within microsatellite DNA, resulting in the RER phenotype arising as the expansion or contraction of mono-, di-, or tri-nucleotide repeats within the microsatellites. Tumor cells defective in MMR are remarkably resistant to temozolomide regardless of AGT activity or its inhibition by BG, confirming the importance of MMR in sensitivity to methylating agents. Of interest, MMR mutant cells are also two- to threefold resistant to cisplatin, perhaps because the cisplatin DNA adduct is bound by the MMR complex, slowing its recognition and repair by the nucleotide repair pathway and increasing its cytotoxicity. Such MMR-deficient cells also exhibit microsatellite instability, a measure of genomic instability and the propensity to develop further mutations during therapy leading to subclones of resistant cells. Loss of PMS2 has been identified in a family of childhood lymphomas. Microsatellite instability is seen in acute leukemias and in T-cell leukemias, suggesting both that these malignancies have lost MMR function and that they are more prone to drug resistance and acquisition of additional mutations that give rise to further drug resistance. Evidence of microsatellite instability and loss of MMR is present in some leukemias but is much more common in treatment-related leukemias, again providing a mechanism of drug resistance.

Base Excision Repair

Methylating agents such as procarbazine and temozolomide form large numbers of N^3-A and N^7-G adducts in addition to O^6-mG (with TMZ, the relative amounts are 72 N^7mG : 8 O^6mG : 5 N^3mA). Thus, under normal circumstances, cells process many more N^7mG and N^3mA lesions than O^6mG lesions even though the latter appear much more cytotoxic except in MMR-defective cells. Repair of N^3-A and N^7-G adducts through BER is efficient and normally leads to cell survival rather than cell death. Adducts are recognized by the methylpurine glycosylase (MPG) with removal of the base, generating an abasic (or AP) site. The AP site is then cleaved by the class II hydrolytic endonuclease (or AP endonuclease) generating a single strand break with a 5′ PO_4, which becomes the substrate for DNA polymerase-β, and to a lesser extent, polymerases δ and γ, followed by DNA ligase (reviewed by Sancar). Other compounds induce nucleotide pool imbalance leading to misincorporation of bases that become substrates for BER. These compounds include folate antagonists such as methotrexate, 5-ourouracil (5-FU), and to a lesser extent, nucleoside analogs such as fludarabine. Misincorporation of uracil after 5-FU inhibition of thymidilate synthase also leads to BER. Compounds to disrupt BER, such as methoxyamine, are now being developed and may lead to combination therapy for hematologic malignancies. An initial phase 1 trial with methoxyamine has been completed with pemetrexed, and a second trial with temozolomide continues. A third trial using the combination of fludarabine and methoxyamine (TRC-102) in patients with CLL has found remarkable efficacy in the first cohorts after relapsing from fludarabine (unpublished).

DRUG RESISTANCE TO ANTIMETABOLITES

Although overlap exists, antimetabolites can be classified into nucleoside analogs that are incorporated into RNA or DNA (or both) and agents that inhibit de novo purine and pyrimidine biosynthetic pathways. Mechanisms of resistance to these agents fall into several broad categories. For example, many antimetabolites are prodrugs in that they must be converted intracellularly into active nucleotide forms to exert their cytotoxic actions. Consequently, events that interfere with cellular accumulation of drug or nucleotide formation will reduce activity. Examples include decreased transport of methotrexate or decreased nucleotide formation of Ara-C and 6-thioguanine by reductions in activity of deoxycytidine kinase or HGPRT, respectively. Alternatively, enhanced drug catabolism reduces cytotoxicity. Examples include the deamination of Ara-C (to inactive Ara-U) by cytidine deaminase or catabolism of 6-TG by thiopurine methyltransferase. A third mechanism of resistance stems from the presence of increased intracellular levels of a competing metabolite (e.g., dCTP in the case of Ara-C, or hypoxanthine or guanine in the case of 6-TG). Fourth, alterations in the level of activity of a target enzyme or the presence of a mutant form that is a poor target of inhibition will also confer resistance. Examples include increased activity or a mutant form of DHFR (in the case of methotrexate), an altered DNA polymerase α (in the case of Ara-C), or increased activity of ribonucleotide reductase (through overexpression of either subunit). Finally, cytokinetic factors represent a common theme in the case of most (but not all) antimetabolites in that a

reduction in the S-phase fraction generally leads to reduced drug sensitivity. Note that these resistance mechanisms are agent specific and are distinct from the more general modes of resistance (e.g., increased expression of BCL2) associated with defects in the distal cell death pathway.

FUTURE DIRECTIONS

Future treatment strategies for hematologic malignancies are directed against cellular targets that are responsible for the altered biology and transformed phenotype of cancer versus normal cells. This altered biology results from the accumulation of genetic mutations and alterations secondary to the unique genomic instability of cancer cells. A major advance has occurred with the targeting of protein kinases, fusion proteins, promoter demethylation and histone deacetylation, immunomodulatory proteins such as lenazolid, and inhibitors of cytokines such as IL-6 that are overexpressed in hematologic malignancies. Defects in the DNA repair pathway and in cell cycle checkpoints that cause inappropriate progression through the cell cycle facilitate the genomic instability of cancer cells. These are also critical for transformation, and agents that overcome these abnormalities are potential targets for drug development.

Because dysregulated cell cycle progression is a common feature of neoplastic cells, several strategies are being developed and tested to exploit this therapeutic strategy. These approaches include the use of drugs that inhibit the function of the mitotic kinase $p34^{cdc\text{-}2}$ (CDK1), for example, flavopiridol or inhibitors of the dual-specific phosphatase cdc25, which dephosphorylates and activates $p34^{cdc\text{-}2}$. Flavopiridol also inhibits CDK2 and CDK4 by binding to the hydrophobic, adenine-binding pocket of the ATP site of these G_1-S kinases, thereby inducing G_1 arrest. An additional strategy is to inhibit mitogenic signaling mediated by oncogene products such as activated Ras, Raf, and BCR-ABL. Antisense oligonucleotides to RAF, BCR-ABL, MYB, RAS, and BCL2 are being tested for their antitumoral effects alone or in combination with other cytotoxic drugs. Inhibitors of Ras farnesylation exert their antitumoral effects by, as yet, unclear mechanisms.

The growth of tumors and leukemia also requires the delivery of nutrients and growth factors through new blood microvessels (angiogenesis). Inhibitors of angiogenesis have potential use in treating patients with cancer and leukemia. Such agents target the vascular endothelial growth factors (e.g., VEGF, bFGF, and PDGF) or their receptor-mediated signaling (e.g., SU 5416).

APPENDIX 55-1

CLINICAL PHARMACOLOGY OF ALKYLATING AGENTS

MECHLORETHAMINE (MUSTARGEN)

Chemistry: Mechlorethamine, also called nitrogen mustard, is a water-soluble and alcohol-soluble analog of sulfur mustard gas. It is a bifunctional chloroethylating agent that alkylates DNA, RNA, and protein.

Absorption, Fate, and Excretion: The parent compound is highly reactive and has a biologic half-life of approximately 15 minutes. The principal route of degradation is spontaneous hydrolysis, but some enzymatic demethylation also occurs.

Preparation and Administration: Mechlorethamine is supplied in vials of 10 mg with 100 mg of sodium chloride and is reconstituted with 10 mL of sterile water to yield a 1-mg/mL solution, ideally prepared immediately before use. However, the manufacturer considers the drug expired 1 hour after reconstitution. The drug is injected over a few minutes through a tubing as a freely running IV infusion. For topical application (e.g., in mycosis fungoides), 10 mg of drug is dissolved in 60 mL of tap water. Alternatively, a 10 mg% ointment has been used by dissolving the drug in 95% ethyl alcohol and petrolatum (Aquaphor). Mechlorethamine is a powerful vesicant. In the event of extravasation, vigorous irrigation followed by 0.25% sodium thiosulfate injection at the site of extravasation should be attempted. Ice packs may be placed for 6 to 12 hours to minimize the local reaction.

Toxic Effects: Myelosuppression is the dose-limiting systemic side effect. This worsens with each additive cycle. Severe nausea and vomiting, infertility, alopecia, and pain at the site of injection, which can sometimes spread to involve the venous system (tracking), are also common. Occasionally, a macular papular rash is observed, but this does not appear to be allergic in nature and does not contraindicate continuation of therapy. Infertility is common but may be reversible. Infrequent adverse effects include alopecia, anorexia, weakness, and diarrhea. The drug has also been shown to induce chromosomal abnormalities and may contribute to the development of secondary leukemias, as seen in patients treated with this agent as part of the MOPP (mechlorethamine, vincristine, procarbazine, prednisone) regimen.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Mechlorethamine is incorporated in many chemotherapy combinations used in the treatment of Hodgkin disease (MOPP and MOPP/ABV [Adriamycin, bleomycin, and vinblastine] hybrid) and in some NHLs (prednisone, etoposide, methotrexate, doxorubicin [Adriamycin], cyclophosphamide, Leucovorin [PROMACE]/MOPP). However, its use has largely been supplanted by other agents.

CYCLOPHOSPHAMIDE (CYTOXAN)

Chemistry: Cyclophosphamide is a cyclic phosphamide ester of mechlorethamine. After being metabolically activated, it alkylates DNA, forming cross-links.

Absorption, Fate, and Excretion: The drug is relatively well absorbed orally, with approximately 75% oral bioavailability. The parent compound is not active. The drug is metabolized by the hepatic CYP system, which ultimately generates at least two active compounds, phosphoramide mustard and acrolein. The latter appears to be responsible for cyclophosphamide's bladder toxicities. The plasma half-life of cyclophosphamide varies from 4 to 6.5 hours. Approximately 15% of the drug is excreted unchanged in the urine. Dose reduction should be considered in patients with severe renal failure.

Preparation and Administration: Cyclophosphamide is supplied as 25- and 50-mg tablets and as a powder for parenteral administration in 100-, 200-, and 500-mg and 1- and 2-g vials. It is dissolved by adding 5 mL of preservative-free sterile water for every 100 mg of drug. Cyclophosphamide is chemically stable for 24 hours at room temperature and for 6 days if refrigerated.

Toxic Effects: Bone marrow suppression is the major side effect. The myeloid series is primarily affected, although thrombocytopenia also occurs at high doses and alopecia is common. Nausea and vomiting can be severe and are usually delayed, occurring 6 to 8 hours after administration. Hemorrhagic cystitis occurs in 10% of patients receiving nontransplant doses and is apparently caused by the formation of the urotoxin acrolein. Because of this potential side effect, patients should be well hydrated. Mesna disulfide (sodium 2-mercaptoethanesulfonate disulfide) has also been used on a weight-equivalent basis to ameliorate cyclophosphamide-induced bladder toxicity. Other potential toxic effects include stomatitis, skin and nail hyperpigmentation, interstitial pulmonary fibrosis, and the syndrome of inappropriate secretion of antidiuretic hormone. Rare episodes of acute congestive heart failure have been reported. After bone marrow transplant doses, hemorrhagic cystitis is common, and cardiac toxicity (cardiomyopathy) may be seen. Late sequelae include bladder fibrosis (more common with daily [oral] therapy), bladder cancer, leukemogenesis, and infertility.

Potential Drug Interactions: Corticosteroids may increase P450 enzyme–induced metabolism and is often avoided in high-dose therapy. When combined with doxorubicin, it may increase cardiac toxicity. This may be prevented by amifostine. In animal studies, conflicting results were reported when the P450 enzyme inducer phenobarbital was given with cyclophosphamide. Most investigators, however, have observed a reduction in the amounts of active metabolites. Conversely, when cimetidine (but not ranitidine) was administered in leukemia-bearing mice before treatment with cyclophosphamide, a significant prolongation of their survival and higher plasma concentrations of alkylating metabolites were observed. Although one should remain alert for these potential drug interactions, none has been demonstrated in humans. Cyclophosphamide reduces serum pseudocholinesterase levels, which may prolong the neuromuscular blocking effects if given simultaneously. Caution must be exercised when administering high doses of these two drugs to critically ill patients. Life-threatening hyponatremia may develop when used in conjunction with indomethacin, although the precise incidence is unknown.

Therapeutic Indications in Hematology: Cyclophosphamide is a key drug in the treatment of lymphomas and myeloma. It is incorporated in many chemotherapy regimens, including CHOP, MACOP-B, PROMACE/CYTABOM, CVP, and VMCP (see Chapters 81 and 85 for details). In addition, cyclophosphamide is the drug

most commonly used in preparatory regimens for bone marrow transplantation. It is also used in solid tumors and as an immunosuppressant in nonmalignant conditions such as glomerulonephritis and systemic lupus erythematosus.

IFOSFAMIDE (IFEX)

Chemistry: Ifosfamide is an oxazaphosphine nitrogen mustard that differs from cyclophosphamide by the placement of chloroethyl groups.

Absorption, Fate, and Excretion: As in the case of cyclophosphamide, the parent compound is inactive and is metabolized by the cytochrome P450 system in the liver. The metabolism of ifosfamide is influenced by the dose and schedule of administration. When administered as a single bolus, 60% is eliminated into the urine, 53% as unchanged inactive drug. When administered daily for 5 consecutive days, 56% is excreted into the urine, 15% as the inactive parent compound. The half-life is 7 hours when administered daily for 5 consecutive days and 15 hours when given as a single bolus dose. There is poor penetration across the blood–brain barrier. Its longer half-life and slower metabolic activation allow higher doses to be given.

Preparation and Administration: The drug is provided in 1-g vials and should be reconstituted in sterile water or bacteriostatic water to a final concentration of 50 mg/mL. Ifosfamide can be diluted further in 5% dextrose, normal saline, or Ringer solution for injection to achieve concentrations of between 0.6 and 20 mg/mL. The solution should be infused over 30 minutes. To prevent hemorrhagic cystitis, patients must receive Mesna disulfide for protection against urotoxicity and must be kept well hydrated (2 L/day). Mesna is a thiol compound that is rapidly oxidized to dimesna in vivo. Mesna and dimesna are filtered by the glomeruli, reabsorbed in the proximal tubule, and finally secreted back into the tubular lumen of the kidney. In the tubules, approximately one-third of the filtered dimesna is readily converted back to Mesna. The free sulfhydryl group of this compound reacts with the urotoxic metabolite acrolein produced by both ifosfamide and cyclophosphamide (see Fig. 55-6). This reaction creates a nontoxic acrolein–Mesna thioether that is safely eliminated in the urine. Mesna has also been shown to inhibit the degradation of ifosfamide or cyclophosphamide to acrolein.

Mesna has been given in combination with ifosfamide in different doses and schedules. One recommended schedule uses IV bolus injection in a dosage equal to 20% of the ifosfamide dose (on a milligram-to-milligram basis) at the time of ifosfamide administration and 4 and 8 hours after each dose of ifosfamide. Mesna has also been given by continuous infusion with excellent results. The two agents may be mixed together in the same IV solution; however, Mesna is not compatible with cisplatin.

Toxic Effects: With the use of Mesna to protect against urotoxicity, myelosuppression—especially leukopenia and, to a lesser extent, thrombocytopenia—is the dose-limiting side effect. Renal tubular acidosis can occur. Central nervous system effects, observed in approximately 10% of patients treated, include somnolence, confusion, depressive psychosis, and hallucinations. Less commonly, dizziness, disorientation, and cranial nerve dysfunction occur. Nausea and vomiting are common. Low serum albumin and elevated serum creatinine may enhance central nervous system toxicity. As with cyclophosphamide, such side effects as alopecia, leukemogenesis, and infertility also occur. Cardiac toxicity is rare.

Potential Drug Interactions: Because ifosfamide is also metabolized by the P450 system, physicians should remain alert for the same type of potential drug interactions that have been reported with cyclophosphamide. A recent report advises close monitoring of warfarin anticoagulant control in patients receiving ifosfamide/Mesna.

Therapeutic Indications in Hematology: Ifosfamide was recently approved for treatment of patients with refractory testicular cancer. In hematologic malignancies, its major indication is in the treatment of refractory lymphomas.

MELPHALAN (MELPHALAN)

Chemistry: Melphalan is synthesized from nitrogen mustard and phenylalanine. It is a bifunctional chloroethylating agent that forms DNA cross-links.

Absorption, Fate, and Excretion: The oral bioavailability of melphalan is quite variable, 20% to 50% of the drug being excreted in the stool. Some patients show virtually no oral absorption. This fact is particularly pertinent in the treatment of myeloma patients, in whom a lack of response to melphalan may simply be caused by poor oral absorption. Melphalan has a half-life of approximately 90 minutes. It is extensively metabolized, with only approximately 10% to 15% of an administered dose excreted unchanged in the urine.

Preparation and Administration: Melphalan is commercially available in 2-mg tablets and in IV formulation for high-dose therapy.

Toxic Effects: The dose-limiting toxicity is myelosuppression, manifested by leukopenia and thrombocytopenia and generally occurring 2 to 3 weeks after therapy. Recovery may take 6 weeks, however, in patients who have been heavily pretreated with chemotherapy drugs, radiotherapy, or both. Nausea, vomiting, and alopecia are uncommon side effects and are usually mild. Occasionally, amenorrhea and azoospermia, pulmonary fibrosis, dermatitis, and secondary malignancies (e.g., leukemia) occur, especially in patients receiving the drug over the long term. At cumulative doses of less than 600 mg, the incidence of second hematologic malignancy is probably less than 2% but may be greater than 15% at higher doses. Higher doses used in transplant patients result in gastrointestinal toxicity that is dose limiting. At these doses, the syndrome of inappropriate secretion of antidiuretic hormone, pneumonitis, and hepatic venoocclusive disease have been observed.

Potential Drug Interactions: Administration of high-dose IV melphalan with cyclosporine increases the risk of cyclosporine nephrotoxicity.

Therapeutic Indications: The major use of melphalan is for the treatment of multiple myeloma, either as a single agent or in combination with other alkylating agents and prednisone (e.g., the MP and VMCP regimens). The IV formulation has been approved for isolated limb perfusion in melanoma. It is used in high-dose protocols for myeloma and solid tumors at doses of 140 to 200 mg/m^2.

CHLORAMBUCIL (CHLORAMBUCIL)

Chemistry: Chlorambucil is an aromatic derivative of mechlorethamine.

Absorption, Fate, and Excretion: Chlorambucil is well absorbed after oral administration. It is extensively metabolized in the liver to its major metabolite, phenylacetic acid mustard (PAAM), which also has bifunctional alkylating activity. The half-lives of chlorambucil and PAAM are 1.5 and 2.5 hours, respectively; less than 1% of either chlorambucil or PAAM is excreted in the urine.

Preparation and Administration: Chlorambucil is commercially available as 2-mg tablets.

Toxic Effects: Treatment is usually well tolerated, with myelosuppression the dose-limiting toxic effect. Patients on a daily oral

schedule should have biweekly complete blood counts (CBCs). Nausea and vomiting are uncommon, but mild alopecia and skin rashes occasionally occur. As with the other alkylating agents, azoospermia (especially above a cumulative dose of 400 mg), amenorrhea, and secondary leukemia are potential risks of prolonged therapy. Rare cases of pulmonary fibrosis have also been reported.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: The major uses are in the treatment of Waldenström macroglobulinemia, low-grade lymphomas, chronic lymphocytic leukemia (CLL), and Hodgkin disease. Except for CLL, chlorambucil has been supplanted by newer agents.

BUSULFAN (MYLERAN)

Chemistry: Busulfan is an alkylsulfonate bifunctional alkylating agent not chemically related to mechlorethamine. It forms DNA intrastrand and interstrand cross-links.

Absorption, Fate, and Excretion: Busulfan is well absorbed after oral administration. When given by the IV route, greater than 90% is cleared from the plasma after 3 minutes. The drug is extensively metabolized to inactive compounds that are excreted renally. The major metabolite is methane sulfonic acid, although more than 10 other not fully identified metabolites exist. Virtually no intact busulfan is found in the urine. The biologic half-life of busulfan is approximately 2.5 hours.

Preparation and Administration: The drug is commercially available as 2-mg tablets.

Toxic Effects: Although at low doses the major effect of busulfan is on the granulocytic series, at high doses, all three hematologic series are affected. Compared with the other alkylating agents, its nadir of myelosuppression may be relatively late, in a range of 11 to 30 days. Hematologic recovery is also prolonged and may take approximately 54 days. A relatively common side effect is an Addisonian-like syndrome characterized by skin hyperpigmentation and weakness but without abnormalities in adrenal function. Cumulative pulmonary toxicity has been well described and consists of a mixed alveolar and interstitial pneumonitis. As with the other alkylating agents, infertility and leukemogenesis can occur. Nausea and vomiting are rare. At high doses, it is associated with hepatic venoocclusive disease in up to 19% of patients. Seizures may also occur and are controlled by diphenylhydration.

Potential Drug Interactions: A metabolic interaction may take place between busulfan and various anticonvulsant medications; however, further description of the specific effects is awaited.

Therapeutic Indications in Hematology: Busulfan is used mainly in the treatment of chronic myeloid leukemia. More recently, high-dose busulfan has been incorporated into preparatory regimens for bone marrow transplantation. Blood level monitoring with adjustment for higher dose levels improved therapeutic outcome and reduced toxicity.

CARMUSTINE (BCNU)

Chemistry: Carmustine, also called BCNU (1,3[bis]-2-chloroethyl-nitrosourea), decomposes spontaneously into a chloroethyl hydroxide that can alkylate the DNA and into an isocyanide molecule, which may produce carbamylation of proteins. Cytotoxicity is caused by DNA cross-links.

Absorption, Fate, and Excretion: Intravenously administered carmustine is rapidly metabolized, with a half-life of 70 minutes. Approximately 30% to 80% of metabolites are eliminated in the urine within 24 hours. The drug, its metabolites, or both readily cross the blood–brain barrier, resulting in cerebrospinal fluid concentrations within the range of 15% to 70% of plasma levels. Peak serum levels vary widely in patients treated at 200 to 600 mg IMF.

Preparation and Administration: Carmustine is commercially available in 100-mg vials as a white lyophilized powder. The drug is reconstituted with 3 mL of absolute alcohol provided by the manufacturer and 27 mL of sterile water and can be further diluted with normal saline or 5% dextrose in water. It should be used immediately after reconstitution and can be infused over 1 to 2 hours.

Carmustine is chemically stable for 3 hours at room temperature and for 24 hours when refrigerated.

Toxic Effects: Myelosuppression is the dose-limiting toxic effect and tends to increase with successive cycles of therapy. Leukopenia and thrombocytopenia are characteristically delayed and reach their maximum between the third and sixth weeks after drug administration. Nausea and vomiting can be severe. Abnormal liver function test results may be found, but the abnormalities are usually mild and reversible. Two rare but serious toxic effects include cumulative pulmonary or interstitial pneumonitis progressing to fibrosis and progressive renal damage, which are dose related. Secondary leukemias can also occur 5 to 10 years after treatment. Patients who receive greater than 1100 mg/m^2 are at increased risk of pulmonary fibrosis. Carmustine is not a vesicant, but rapid infusion often produces a burning sensation at the injection site.

Potential Drug Interactions: Cimetidine may enhance the myelosuppressive effect of carmustine. Carmustine may decrease the pharmacologic effects of phenytoin. In rats with intracerebrally implanted tumors, pretreatment with phenobarbital eliminated the antitumor activity of carmustine. The reduction in carmustine antitumor activity correlated with increased carmustine metabolism, which is apparently the result of hepatic microsomal enzyme induction.

Therapeutic Indications in Hematology: Carmustine in combination with other cytotoxic agents may be used in the initial treatment of Hodgkin disease (BCVPP regimen) and multiple myeloma (VBAP regimen). In high-dose therapy, it appears in BEP for relapsed lymphomas.

LOMUSTINE (CCNU)

Chemistry: Lomustine, also called CCNU, is a nitrosourea derivative with choloroethyl and cyclohexyl side chains.

Absorption, Fate, and Excretion: The drug is rapidly absorbed from the gastrointestinal tract and is rapidly and completely metabolized. Its active metabolites have prolonged plasma half-lives, within a range of 16 to 48 hours. Approximately 50% of an administered dose is detectable (as metabolites) in the urine within 24 hours, and 75% is detectable within 4 days. Active metabolites cross the blood–brain barrier and can be detected in significant concentrations in the cerebrospinal fluid.

Preparation and Administration: The drug is commercially available in 10-, 40-, and 100-mg capsules.

Toxic Effects: The toxicity profile of lomustine is similar to that of carmustine. Because lomustine can produce vomiting and the drug is given orally, special attention should be directed to emesis control. If the patient vomits soon after ingestion, the vomitus should be inspected for the presence of intact capsules. The drug should be given again if capsules are identified with certainty. Secondary leukemias are reported 3 to 10 years after use.

Potential Drug Interactions: These are similar to those of carmustine.

Therapeutic Indications in Hematology: Lomustine is occasionally used as second-line treatment for patients with Hodgkin disease and non-Hodgkin lymphoma (NHL) and for childhood gliomas.

STREPTOZOCIN (ZANOSAR)

Chemistry: Streptozocin is a naturally occurring nitrosourea derived from *Streptomyces acromogenes*. The drug is a glucosamine-1-methyl-nitrosourea, which, unlike the other nitrosoureas, methylates DNA and is cytotoxic owing to induced mismatch repair.

Absorption, Fate, and Excretion: After IV administration, the drug is rapidly metabolized, with no intact drug detectable in the plasma after 3 hours. Its half-life is 40 hours. Within the first 24 hours after administration, approximately 10% of the parent compound is excreted in the urine.

Preparation and Administration: The drug is commercially available in 1-g vials and is reconstituted with either 9.5 mL of normal saline or 5% dextrose in water for injection to form a 100-mg/mL solution. IV infusion of the drug over 30 to 45 minutes usually prevents discomfort at the injection site. Patients should be kept well hydrated to preclude renal tubular toxicity.

Toxic Effects: Although nausea and vomiting have been considered by some investigators to be the limiting toxic effects, in most phase I trials, nephrotoxicity was the principal dose-limiting effect. Nausea and vomiting are severe and require aggressive antiemetic support. Streptozocin may also aggravate duodenal ulcers. Renal toxicity frequently occurs and includes mild proteinuria, glycosuria, hypophosphatemia, renal tubular acidosis, and occasionally irreversible azotemia. Although the myelosuppressive effect of streptozocin is mild, it can potentiate the bone marrow suppression of other cytotoxic drugs. Slight increases in hepatic enzymes can also occur. Occasionally, patients (primarily those with insulinomas) may experience transient alterations in glucose metabolism.

Potential Drug Interactions: Streptozocin can potentiate the hyperglycemic effect of glucocorticosteroids. Phenytoin therapy decreases the cytotoxic effect of streptozocin on the pancreatic β cells, leading to potential interference with its therapeutic effect in patients with pancreatic islet cell tumors. Streptozocin is a potent renal toxin, and every effort should be made to avoid concomitant administration of other nephrotoxins.

Therapeutic Indications in Hematology: Streptozocin has been used in the initial treatment of Hodgkin disease and, less commonly, in NHLs.

DACARBAZINE (DTIC)

Chemistry: Dacarbazine is also called DTIC [5-(3,3-dimethyl-1-triazeno)imidazole-4-carboxamide]. After undergoing metabolic activation by microsomal enzymes in the liver, it acts primarily as an alkylating agent.

Absorption, Fate, and Excretion: After IV administration, the drug is extensively metabolized. Activated DTIC has an elimination half-life of 5 to 7 hours. Approximately 40% to 50% of the parent drug is found in the urine within the first 24 hours after administration.

Preparation and Administration: DTIC is commercially available in 100- and 200-mg vials, which must be protected from light and stored at a temperature of 2° to 8° C. The drug is reconstituted with normal saline or sterile water to produce a 10-mg/mL solution. It can be administered as a slow IV push or by infusion over 15 to 30 minutes.

Toxic Effects: Myelosuppression, primarily represented by leukopenia, is the dose-limiting toxic effect. Use of the drug leads to considerable problems with emesis and requires aggressive antiemetic support. A flulike syndrome consisting of fever, malaise, and myalgias may occur. Direct sunlight during the first 2 days after drug administration may result in facial flushing, facial paresthesias, and lightheadedness. Hepatotoxicity and diarrhea have also been reported. Pain along the injection site can occur if the drug is rapidly infused but can usually be lessened by prolonging the infusion rate. Secondary leukemias are reported between 3 and 10 years after use.

Potential Drug Interactions: DTIC activation may be enhanced by phenytoin or phenobarbital, although the clinical significance of this potential interaction remains uncertain. There may be a potential (as yet poorly characterized) drug interaction with levodopa, whereby the response to levodopa is diminished.

Therapeutic Indications in Hematology: DTIC is used primarily in the treatment of Hodgkin disease as part of the ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and DTIC) regimen and for melanoma.

PROCARBAZINE

Chemistry and Mechanism of Action: Procarbazine is a substituted hydrazine derivative with a chemical structure similar to that of the monoamine oxidase inhibitors (MAOIs). Accordingly, procarbazine exhibits weak MAOI effects. Procarbazine itself is inert and must undergo metabolic activation to generate cytotoxic reactants, the mode of action of which is not clear. They may inhibit transmethylation of methyl groups of methionine into tRNA or may also directly damage DNA. Hydrogen peroxide, formed during the autooxidation of procarbazine, may attack protein sulfhydryl groups contained in residual proteins tightly bound to DNA.

Absorption, Fate, and Excretion: Procarbazine is rapidly and completely absorbed by the oral route, with peak plasma levels occurring within 60 minutes. It penetrates well into the cerebrospinal fluid. The drug is readily metabolized in the liver and has a plasma half-life of 10 minutes after IV injection. The major sites of elimination are the kidneys, where approximately 70% of the drug is excreted as *N*-isopropylterephthalamic acid and less than 5% is excreted unchanged.

Preparation and Administration: Procarbazine is commercially available as 50-mg capsules.

Toxic Effects: The usual dose-limiting toxic effect is myelosuppression. Occasionally, nausea and vomiting may be dose limiting, although tolerance to those effects may develop during continued administration. Other less common side effects include paresthesias, headache, dizziness, depression, apprehension, insomnia, nightmares, hallucinations, drowsiness, ataxia, foot drop, decreased reflexes, tremors, coma, confusion, convulsions, skin rash, alopecia, myalgia, and arthralgia. Procarbazine may possibly be leukemogenic.

Potential Drug Interactions: Combination chemotherapy that includes procarbazine may result in a decrease in digoxin plasma levels. Because procarbazine is a weak MAOI, hypertensive reactions could theoretically occur after concurrent ingestion of sympathomimetics, levodopa, tricyclic antidepressants, or foods with high tyramine content (e.g., dark beer, yogurt, cheeses, and red wines). However, such reactions have not been reported. Concomitant use of narcotics or other strong sedatives may result in exaggerated depressant effects, leading to coma and possibly death. Procarbazine also interacts with alcohol, causing a disulfiram-like reaction.

Therapeutic Indications in Hematology: Procarbazine is often used in combination with other cytotoxic agents in the treatment of Hodgkin disease (MOPP and MOPP derivatives) and to a lesser extent in the treatment of non-Hodgkin lymphoma (PROMACE-MOPP).

TEMOZOLOMIDE

Chemistry and Mechanism of Action: Temozolomide is not active but undergoes rapid nonenzymatic conversion at physiologic pH to the reactive compound monomethyl 5-triazino imidazole carboxamide (MTIC), which is also the active methyl group–donating metabolite of dacarbazine. Unlike dacarbazine, formation of MTIC from temozolomide does not require metabolic activation (liver); thus there is much more consistent conversion from temozolomide to the methyl-donating MTIC. The cytotoxicity of MTIC is thought to be primarily caused by alkylation of DNA. Alkylation (methylation) occurs mainly at the O6 and N7 positions of guanine. Cytotoxicity results from processing of these lesions by methylguanine methyltransferase, mismatch repair, and base excision repair.

Absorption, Fate, and Excretion: Temozolomide is rapidly and completely absorbed after oral administration; peak plasma concentrations occur in 1 hour. Food reduces the rate and extent of temozolomide absorption.

Temozolomide exhibits a mean elimination half-life of 1.8 hours and exhibits linear kinetics over the therapeutic dosing range. Temozolomide is spontaneously hydrolyzed at physiologic pH to the active species, 3-methyl-(triazen-1-yl)imidazole-4-carboxamide (MTIC) and to temozolomide acid metabolite. MTIC is further hydrolyzed to 5-amino-imidazole-4-carboxamide (AIC), which is known to be an intermediate in purine and nucleic acid biosynthesis and to methylhydrazine, which is believed to be the active alkylating species. Approximately 38% of the administered temozolomide total radioactive dose is recovered over 7 days, 37.7% in urine and 0.8% in feces. The majority of the recovery of radioactivity in urine is as unchanged temozolomide (5.6%), AIC (12%), temozolomide acid metabolite (2.3%), and unidentified polar metabolite(s) (17%). Overall clearance of temozolomide is approximately 5.5 L/hr/min.

Preparation and Administration: Temozolomide is given orally with each capsule containing either 5, 20, 100, 140, 180, or 250 mg of temozolomide. The inactive ingredients for TEMODAR capsules are lactose anhydrous, colloidal silicon dioxide, sodium starch glycolate, tartaric acid, and stearic acid.

Toxic Effects: Bone marrow depression, including neutropenia, lymphopenia, anemia, and thrombocytopenia, occurs frequently with temozolomide. Mild transaminase elevations of up to 40% of patients and hyperbilirubinemia of up to 19% are seen. Mild to moderate headache is among the most commonly reported adverse effects along with moderate nausea and vomiting, although these may be secondary to the use of antiemetics.

Drug Interactions: None described.

Therapeutic Indications in Hematology: Temozolomide may have some activity in both acute myeloid leukemia and acute lymphocytic leukemia, but the correct dose is presently unknown. Temozolomide has no activity in non-Hodgkin lymphoma.

BENDAMUSTINE

Chemistry and Mechanism of Action: Bendamustine is a bifunctional alkylating agent (mechlorethamine analogue) Its structure is characterized by a nitrogen mustard group linked to a benzimidazole nucleus, which forms covalent bonds with electron-rich nucleophilic moieties, resulting in interstrand DNA crosslinks. Bendamustine is active against both quiescent and dividing cells.

Absorption, Fate, and Excretion: Although absorbed well orally, bendamustine is only administered intravenously. It is highly protein bound, averaging approximately 95%. The half-life of bendamustine is approximately 40 minutes. Bendamustine is primarily metabolized in the liver via hydrolysis, and little is excreted in urine unchanged, but the pharmacokinetics in patients with significant renal failure are unknown.

Preparation and Administration: Bendamustine is available for IV use in single-use vials containing either 25 mg or 100 mg of bendamustine HCl. Sterile water for injection is added to each vial to obtain a 5-mg/mL solution. The lyophilized powder should completely dissolve in 5 minutes. After being diluted with either 0.9% sodium chloride injection, USP, or 2.5% dextrose/0.45% sodium chloride injection, USP, the final admixture is stable for 24 hours when stored refrigerated or for 3 hours when stored at room temperature.

Toxic Effects: Bendamustine frequently causes anemia, severe neutropenia, and thrombocytopenia. Infusion reactions presenting as fever, chills, pruritus, and rash have been seen. Antihistamines, antipyretics, and corticosteroids have been effective in preventing these reactions. Tumor lysis syndrome has been seen with the first dose of bendamustine, so appropriate precautions should be taken. Local reactions are seen with extravasation, and care should be taken when administering the drug in a peripheral site. Headache, nausea, and vomiting as well as skin reactions, including rash, toxic skin reactions, and bullous exanthema, have occurred with bendamustine. Acute myeloid leukemia has been reported in patients after use of bendamustine hydrochloride.

Drug Interactions: Although their clinical significance is unknown, ciprofloxacin, fluvoxamine, and omeprazole may increase bendamustine levels and decrease levels of active minor metabolites.

Therapeutic Indications in Hematology: Bendamustine has been effective in treating chronic lymphoid leukemia, multiple myeloma, Hodgkin disease, non-Hodgkin lymphoma, and indolent B cell lymphomas.

APPENDIX 55-2

CLINICAL PHARMACOLOGY OF ANTIMICROTUBULE AGENTS

VINCRISTINE (ONCOVIN) AND VINBLASTINE (VELBAN)

Chemistry and Mechanism of Action: Both vincristine and vinblastine are asymmetric dimeric compounds that bind to the protein tubulin at a site distinct from that for the taxanes. At low concentrations, vincristine and vinblastine inhibit microtubule dynamics. At higher concentrations, they disrupt microtubules that constitute the mitotic spindle, resulting in metaphase arrest. They are relatively M-phase specific. Owing to their lipophilicity, vinca alkaloids are rapidly taken into cells and achieve several-hundred-fold higher intracellular than extracellular concentrations. Whereas overexpression of the multidrug resistance transporters P-glycoprotein or multidrug resistance protein can reduce the intracellular accumulation, alterations in the α or β tubulins can affect drug–target interaction for vinca alkaloids.

Absorption, Fate, and Excretion: After IV injection, both drugs are rapidly distributed to the body tissues, especially the red blood cells and platelets. Their elimination follows a triphasic pattern. The elimination half-lives are as follows: α, less than 5 minutes; β, 50 to 155 minutes; and γ, 20 to 85 hours. Both vinca alkaloids are primarily eliminated through the liver into the bile and feces, making patients with obstructive liver disease more susceptible to toxic effects. A 50% reduction in the dose is recommended for serum bilirubin concentrations of 1.5 to 3.5 mg/dL. Dose modification for renal dysfunction is not indicated. After brief IV bolus administration, peak plasma vincristine concentrations of 100 to 400 mM are achieved, which decline to less than 10 mM in 2 to 4 hours. Continuous infusion doses of 1.0 mg/m^2/day produce vincristine plasma concentrations ranging from 1 to 10 nM.

Preparation and Administration: Vincristine is commercially available in 1-, 2-, and 5-mg vials. Each milliliter contains 1 mg of vincristine sulfate, 100 mg of mannitol, 1.3 mg of methylparaben, and 0.2 mg of propylparaben. Vincristine is a powerful vesicant that should be administered only intravenously into a freely running infusion of normal saline or dextrose solution. If the drug is given by continuous infusion, it must be infused through a central IV line. In case of extravasation, infusion should be discontinued and any residual drug aspirated through the line. The manufacturer also recommends infiltrating the area with 1 to 2 mL of hyaluronidase, 150 U/mL, and then applying warm compresses for 72 hours to facilitate dispersion of the drug. Vinblastine is commercially available as a lyophilized powder and a 1-mg/mL solution in 10-mg vials. The lyophilized drug is reconstituted by adding sodium chloride for injection (which may be preserved with either phenol or benzyl alcohol) to the 10-mg vial. Administration of vinblastine should follow the same guidelines described for vincristine.

Toxic Effects: Vincristine's dose-limiting toxic effect is neurotoxicity, which appears to be related to its relative polarity. Peripheral neurotoxicity usually manifests as sensory impairment, decreased deep tendon reflexes, and paresthesias. Less commonly, severe painful dysesthesias, ataxia, foot drop, and cranial nerve palsy (e.g., affecting the extraocular and laryngeal muscles) can occur. Autonomic neurotoxicities include constipation, abdominal cramps, and ileus, which may be prevented by use of mild laxatives. Alopecia occurs frequently, but myelosuppressive effects are minimal. Rare side effects include inappropriate secretion of antidiuretic hormone and ischemic cardiac toxicity. Vinblastine's dose-limiting toxic effect is myelosuppression, with leukopenia more pronounced than thrombocytopenia. Anemia is uncommon. Neurotoxicity can also occur but is significantly less common than with vincristine. Vinblastine is also a vesicant.

Potential Drug Interactions: Both vinca alkaloids have been reported to increase the accumulation of methotrexate and etoposide in tumor cells. Acute shortness of breath and bronchospasm can occur when vincristine or vinblastine is given in conjunction with mitomycin C. Because asparaginase may impair the hepatic clearance of vincristine, it is preferable to administer the vincristine 12 to 24 hours before L-asparaginase. Vincristine may decrease the absorption and plasma levels of orally administered drugs such as digoxin. Dilantin may increase the cytotoxicity of vincristine in multidrug-resistant tumor cells; however, this remains to be demonstrated in the clinic. When concurrently administered, erythromycin may increase the toxicity of vinca alkaloids, especially vinblastine.

Therapeutic Indications in Hematology: The vinca alkaloids are among the most important drugs in the treatment of hematologic malignancies. They have a broad spectrum of activity and are often incorporated into many chemotherapy regimens used in the treatment of ALL, Hodgkin disease, non-Hodgkin lymphoma, chronic lymphocytic leukemia, and multiple myeloma.

VINORELBINE (NAVELBINE)

Chemistry and Mechanism of Action: Vinorelbine is a semisynthetic derivative of vinblastine (5′-nor-hydrovinblastine) with an eight-member catharanthine ring. Similar to other vinca alkaloids, it also binds to tubulin, inhibits microtubule assembly, and produces a mitotic arrest of cells. These occur at concentrations that relatively spare axonal microtubules, which may reduce neurotoxicity.

Absorption, Fate, and Excretion: Short (6-10 minutes) IV infusions of 30 mg/m^2 produce peak plasma concentrations approximately 1.0 μg/mL with a triphase decay. Rapid α (<5 minutes) and β (49-168 minutes) half-lives result in a rapid decline in the plasma concentration in the first hour posttreatment followed by a prolonged terminal half-life of 18 to 49 hours, reflecting slow efflux from the peripheral compartment. The volume of distribution at steady state is 20 to 75.6 L/kg. The drug is extensively bound to platelets, lymphocytes, and plasma proteins. The major site of metabolism is the liver, with 33% to 80% of the drug excretion in feces and approximately 20% in urine.

Preparation and Administration: Vinorelbine is available for injection in single use as 10 mg/mL in 1- or 5-mL vials without preservatives. The calculated dose is diluted to 1.5 to 3.5 mg/mL for a slow injection (6-10 minutes) by a syringe with 5% dextrose or

0.9% saline or between 0.5 or 2.0 mg/mL in an IV bag. Because vinorelbine is a strong vesicant, it should be administered through a freely flowing IV access avoiding all extravasation.

Toxic Effects: Vinorelbine shares many of the principal toxicities of vinblastine. Myelosuppression is dose limiting but not cumulative, with nadirs occurring 7 to 10 days after administration.

Anemia and thrombocytopenia occur infrequently. Because of lower affinity for axonal versus spindle microtubules, neurotoxicity is less prominent with vinorelbine. Mild to moderate peripheral neuropathy and constipation occur in approximately 30% of patients, and the incidence of neuropathy increases with the duration of treatment. Mild to moderate nausea and vomiting is seen in 33% of patients. Stomatitis and diarrhea are less frequent. Transient elevations of transaminases have been reported. Among the miscellaneous side effects noted are chest pain with or without electrocardiographic changes (6%, most with underlying cardiac disease), as well as bronchospasm and dyspnea (5%). Alopecia is seen in 10% of patients.

Therapeutic Indications in Hematology: Objective responses have been observed in approximately 33% of patients with Hodgkin disease or non-Hodgkin lymphoma.

PACLITAXEL (TAXOL) AND DOCETAXEL (TAXOTERE)

Chemistry and Mechanism of Action: Both paclitaxel and docetaxel are complex diterpene alkaloid esters consisting of a taxane system linked to an oxetane ring and a C-13 side chain that is necessary for their cytotoxic effects in mammalian cells. After binding to the N-terminal 31 amino acids of the β-tubulin subunit in the tubulin oligomers or polymers, these taxanes kinetically stabilize microtubule dynamics at plus ends. They also decrease the lag time and shift the equilibrium toward tubulin polymerization into microtubule bundles. The disequilibrium of tubulin–microtubule polymerization results in mitotic arrest and apoptosis of cells. Taxane-induced mitotic arrest is associated with phosphorylation of BCL2 protein and increased intracellular levels of free BAX protein, which promote apoptosis. Compared with paclitaxel, docetaxel demonstrates 1.9-fold greater affinity for tubulin-binding sites and greater potency in mediating BCL2 phosphorylation.

Absorption, Fate, and Excretion: Taxanes generally are administered by IV infusion lasting over 3, 24, or 96 hours (paclitaxel) or 1 hour (docetaxel). Depending on the dose and schedule, peak plasma concentrations of paclitaxel range between 0.05 and 15.0 mM. Its steady-state volume of distribution ranges between 48 and 182 L/m^2, with rapid uptake in almost all tissues except the central nervous system and 98% plasma protein binding. Plasma decay for paclitaxel is biphasic, with α and β half-lives of 0.34 and 5.8 hours, respectively. Saturable distribution and elimination appear to be responsible for paclitaxel's nonlinear pharmacokinetics. This means that paclitaxel dose escalation in shorter schedules may result in disproportionate increases in area under the concentration–time curve and peak plasma concentration. It is metabolized to 6 hydroxy paclitaxel by the CYP3A isoform of the PU_{50} mixed-function oxidases in the hepatic microsomes. Total fecal and urinary excretion of paclitaxel and its metabolites is approximately 70% and 10%, respectively. Although dose modification is not necessary for renal insufficiency, a 50% reduction in dose is recommended even for moderate hyperbilirubinemia or significant elevations in hepatocellular enzymes. When administered as a 1-hour IV infusion, docetaxel has linear pharmacokinetics that fit a three-compartment model. Similar to paclitaxel, docetaxel also has a high clearance rate (0.36 L/hr), steady-state volume of distribution (67.3 L/m^2), and terminal half-life of 12 hours. Docetaxel also has high protein binding (97%) and extensive tissue distribution. The drug or its metabolites also have high fecal (80%) and low urinary elimination (5%). Metabolism of docetaxel also primarily occurs in hepatic microsomal P450 mixed-function oxidases, CYP3A, CYP2B, and CYP1A.

Preparation and Administration: Paclitaxel is available as a 30-mg/5 mL single-dose vial in polyoxyethylated castor oil (Cremophor EL) 50% and dehydrated alcohol, USP 50%. The contents of the vial must be diluted before use. Docetaxel for injection is available as a concentrate in polysorbate 80 in two vial contents (23.6 mg/0.59 mL or 94.4 mg/2.36 mL) along with the appropriate diluent (1.83 or 7.33 mL) in separate vials. Adding diluent that is 13% (w/w) ethanol in water for injection to the concentrate produces a final premix concentration of 10 mg docetaxel/mL. The required amount of premix is transferred by a calibrated syringe into 0.9% saline or 5% dextrose to produce a final concentration of 0.3 or 0.9 mg/mL. The IV infusion is administered over 1 hour.

Toxic Effects: Hypersensitivity reaction (HSR) was noted in up to 30% of patients in the early phase I studies. HSR occurs early in the first or second infusion and may be caused by vehicle Cremophor EL or paclitaxel itself. HSR consists of dyspnea, bronchospasm, urticaria, and hypotension. Most HSRs regress completely after stopping the infusion and treatment with antihistamines, fluids, and vasopressors. Prolonged infusions (>3 hours) and premedication (dexamethasone 20 mg orally, 12 and 6 hours before treatment, diphenhydramine 50 mg, and ranitidine 150 mg IV 30 minutes before treatment) have reduced the incidence of major HSRs to less than 3%. Patients with a history of HSR may be rechallenged with paclitaxel at a markedly slower infusion rate, 20 mg dexamethasone IV every 6 hours for four doses before treatment. Although not formulated in Cremophor EL, HSRs can occur in up to 25% of patients receiving docetaxel. Most HSRs are minor, consisting of flushing, chest tightness, and low back pain. Premedication with dexamethasone 8 mg orally twice daily for 3 days starting 1 day before treatment with docetaxel considerably reduces the incidence of HSRs and fluid retention. Neutropenia is the main toxicity of paclitaxel and docetaxel, but it is not cumulative. With higher doses of paclitaxel (250 mg/m^2 over 24 hours), this can be ameliorated with subsequent administration of granulocyte colony-stimulating factor. Severe thrombocytopenia and anemia are rare. Symmetric, distal, peripheral sensory neuropathy is usually seen with higher doses or multiple doses of paclitaxel. This often limits chronic use of paclitaxel. Diffuse areflexia and neuronopathy are less commonly seen. Higher doses can also cause motor and autonomic neuropathy as well as myalgias, especially in patients with preexisting neuropathy or when paclitaxel is used with cisplatin. Severe peripheral neuropathy or myalgias are less common after repetitive docetaxel at 100 mg/m^2. Cardiac rhythm abnormalities, especially bradyarrhythmias and (rarely) heart blocks, have been reported secondary to paclitaxel treatment. A direct causal link between paclitaxel and myocardial ischemic episodes and tachyarrhythmias has not been established. Although noted, a direct link has also not been established between the occurrence of cardiac conductance abnormalities or ischemia and docetaxel treatment. Nausea, vomiting, diarrhea, and stomatitis are uncommon and generally mild to moderate. Alopecia is universal with both drugs. Skin toxicity is more severe and common with docetaxel. It is characterized by an erythematous pruritic maculopapular rash affecting the forearms and hands. Onychodystrophy with discoloration, ridging, and brittleness of fingernails also occurs. Docetaxel can cause cumulative fluid retention, resulting in peripheral edema, third-space fluid collection, and weight gain, which usually resolves slowly after stopping docetaxel. Concurrent treatment with dexamethasone, as noted earlier, delays the onset and decreases the incidence of these side effects.

Potential Drug Interaction: When paclitaxel infusion (24 hours) is administered after cisplatin, there is a 33% reduction in the clearance rate of paclitaxel. This produces suboptimal antitumor cytotoxicity and more profound neutropenia. Hence, the sequence of paclitaxel followed by cisplatin is commonly recommended. The use of carboplatin after paclitaxel has been reported to cause less thrombocytopenia than carboplatin alone. Mucositis is more pronounced when paclitaxel is used before doxorubicin, a sequence that reduces the clearance of doxorubicin. Hematologic toxicity is more prominent with the sequence of cyclophosphamide followed by paclitaxel

compared with the reverse sequence of administration. Anticonvulsants such as phenytoin and phenobarbital induce the metabolism of paclitaxel and docetaxel by the P450 mixed-function oxidases. Conversely, in vitro studies have shown that inhibitors of the P450 system can interfere with the metabolism of both drugs. These inhibitors include erythromycin, testosterone, ketoconazole, and fluconazole.

Therapeutic Indications in Hematology: Both paclitaxel and docetaxel have significant activity against previously treated patients with non-Hodgkin lymphoma. Paclitaxel is also very active against HIV-associated Kaposi sarcoma.

APPENDIX 55-3

CLINICAL PHARMACOLOGY OF ANTIMETABOLITES

CYTOSINE ARABINOSIDE

Chemistry and Mechanism of Action: Cytosine arabinoside (1′-β-D-arabinofuranosylcytosine; ara-C) is a nucleoside analog that differs from its naturally occurring counterpart (2′-deoxycytidine) by virtue of the presence of a hydroxyl group in the 2′-β configuration. The altered reactivity of the resulting arabinosyl sugar moiety confers on ara-C its cytotoxic activity. Ara-C enters the cell by a facilitated nucleoside diffusion mechanism and is converted to its nucleoside monophosphate form, ara-CMP, by the pyrimidine salvage pathway enzyme, deoxycytidine kinase. This represents the rate-limiting step in ra-C metabolism. Ara-C may also be catabolized intracellularly to an inactive form, ara-U, by the enzyme cytidine deaminase. Ara-C is ultimately converted to its lethal triphosphate derivative, ara-CTP, by a mono- and diphosphate kinase. Ara-CTP is an inhibitor of DNA polymerases α, β, and γ and is also incorporated into replicating DNA strands, leading to inhibition of chain initiation and elongation and premature chain termination. The extent of incorporation of ara-C into DNA closely correlates with lethality in leukemic cells. Although ara-C is generally thought of as a prototypical S phase–specific agent, its ability to interfere with DNA repair polymerases (e.g., β and γ) as well as lipid biosynthetic enzymes may account for lethal effects in noncycling cells.

Absorption, Fate, and Excretion: After IV administration, ara-C is rapidly deaminated to an inactive form, ara-U, by cytidine deaminase. This enzyme is present in the plasma, liver, and kidney but is present at very low levels in the central nervous system (CNS). The initial plasma half-life of ara-C has been estimated to be 10 to 12 minutes. Approximately 90% of the administered ara-C dose is excreted by the kidneys as ara-U or other inactive metabolites. The terminal half-life of ara-C is approximately 2 to 3 hours. CNS ara-C levels after a 2-hour infusion approximate 50% of plasma concentrations. Steady-state plasma concentrations after standard-dose therapy (e.g., 100-200 mg/m^2/day as a continuous infusion) approximate between 10^{-7} and 10^{-6} M. When ara-C is given as a high-dose bolus infusion (e.g., 1-3 g/m^2 over 1-3 hours), plasma levels as high as 100 μM can be achieved.

Preparation and Administration: Ara-C is provided as a sterile, lyophilized powder for reconstitution in vials containing 100 mg, 200 mg, 1 g, or 2 g of material. The powder is reconstituted with sterile bacteriostatic water for injection with benzyl alcohol (0.945%) added as a preservative. When reconstituted in this way, solutions are stable for up to 48 hours under controlled temperatures (e.g., between 15° C and 30° C or 60°-86° F). Material reconstituted without preservative should be used immediately. For intrathecal injection, ara-C should be reconstituted in a diluent that does not contain preservative (e.g., preservative-free 0.9% sodium chloride, USP) and used immediately.

Toxic Effects: Ara-C is primarily toxic to rapidly dividing tissues; consequently, myelosuppression and gastrointestinal toxicity represent the major side effects of this agent. Patients receiving ara-C regularly experience leukopenia, anemia, and thrombocytopenia, with nadirs appearing 7 to 14 days after drug administration. Gastrointestinal toxicity includes nausea and vomiting, abdominal pain, mucositis, and a chemical hepatitis characterized by elevation of liver function enzymes. The latter is generally reversible. Patients receiving ara-C as a high-dose infusion (e.g., 1-3 g/m^2 repeated every 12 hours for a total of 6-12 doses) experience standard toxicities and several unique ones. These include alopecia, an exfoliative dermatitis, a chemical conjunctivitis (generally ameliorated by the prophylactic administration of a steroid or saline ophthalmic solution), a respiratory distress–like syndrome (characterized by the appearance of rales, abnormal radiography findings, and pulmonary insufficiency), and cerebellar toxicity. The latter, which is characterized by nystagmus, ataxia, and other cerebellar signs, may be irreversible, and its appearance mandates discontinuation of therapy. Intrathecal administration of ara-C has been rarely associated with toxicities described below for methotrexate.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: Ara-C represents a mainstay in the treatment of AML (e.g., as part of the "7 and 3" regimen in which it is given in conjunction with daunorubicin). It is also incorporated into some induction regimens for ALL. High-dose ara-C (HIDAC), either alone or in combination with anthracycline antibiotics, is frequently used in the treatment of refractory or relapsed acute myeloid leukemia or acute lymphoblastic leukemia. HIDAC has also been used in some salvage regimens for non-Hodgkin lymphoma (e.g., ESHAP). Chronic low-dose ara-C has been used in the treatment of patients with the myelodysplastic syndrome.

METHOTREXATE

Chemistry and Mechanism of Action: Methotrexate (*N*-4-[[(2,4-diamino-6-pteridinyl)methyl]methylamino]benzoyl]-L-glutamic acid) represents a member of a class of compounds referred to as antifolates. Methotrexate is a potent inhibitor of dihydrofolate reductase, an enzyme responsible for the reduction of dihydrofolates to tetrahydrofolates. The latter are required in 1-carbon transfer reactions involved in de novo purine and pyrimidine biosynthesis, including conversion of deoxyuridylate (dUMP) to thymidylate (dTMP) by thymidylate synthase. As in the case of most antimetabolites, methotrexate is primarily active against S-phase cells. Methotrexate is transported across cell membranes by an energy-dependent, temperature-sensitive, concentrative process involving folate-binding proteins, after which it is polyglutamylated by the enzyme folylpolyglutamyl synthetase. Polyglutamylation of methotrexate enhances its intracellular retention and in some studies has been shown to correlate with the sensitivity of leukemic cells to this agent. The mechanism by which methotrexate kills cells may stem from interference with DNA synthesis (leading to a "thymine-less death") secondary to DHFR inhibition, disruption of purine biosynthesis, or a combination of these actions. The lethal actions of methotrexate may be reversed by reduced folates such as 5-formyltetrahydrofolate (leucovorin). The possibility that tumor cells may exhibit impaired transport of such reduced folates serves as the basis for strategies involving administration of high-dose methotrexate in conjunction with leucovorin rescue.

Absorption, Fate, and Excretion: In adults, oral absorption is dose dependent, with mean bioavailability approximating 60% at doses of 30 mg/m^2 or less. At higher doses (e.g., ≥80 mg/m^2), bioavailability is less. Peak plasma concentrations occur 1 to 2 hours after oral administration. Methotrexate bioavailability approximates 100% for parenteral routes of administration; with these routes, peak plasma methotrexate levels are achieved within 30 to 60 minutes after

administration. For each route, the steady-state volume of distribution ranges from 40% to 80% of body weight. Methotrexate tends to accumulate in third-space fluids (e.g., ascites or pleural effusions) and can result in prolonged release and accompanying toxicity. Consequently, it is generally not advisable for patients with fluid accumulations to receive methotrexate. Methotrexate competes with reduced folates for transport across cell membranes; however, at high doses (e.g., ≥100 mg/m^2), passive diffusion is the primary mechanism through which intracellular accumulation occurs. Methotrexate is approximately 50% protein bound and does not penetrate the CNS barrier when administered orally or parenterally at conventional doses. However, when given by the intrathecal route, high CNS levels are achieved. Administration of high-dose methotrexate with leucovorin rescue can also result in therapeutic CNS levels.

The primary route of excretion is renal, with 80% to 90% of the drug appearing unchanged in the urine within 24 hours after IV administration. The terminal half-life of methotrexate is 4 to 10 hours for patients receiving low-dose therapy and 8 to 15 hours for those receiving high-dose therapy. Because of the primary renal rate of excretion and the possibility of nephrotoxicity, methotrexate should be withheld or administered at reduced doses in patients with impaired renal function. Patients receiving high-dose methotrexate therapy should be hydrated and their urine alkalinized before administration to reduce the risks of toxicity.

Preparation and Administration: Methotrexate is available in multiple formulations: (1) tablets, containing 2.5 mg methotrexate and inactive ingredients (lactose, magnesium stearate, and pregelatinized starch; (2) methotrexate sodium injection, available in vials of 25, 50, and 250 mg, containing benzyl alcohol as a preservative, sodium chloride, and water for injection (preservative-containing solutions should not be used for intrathecal or high-dose administration); (3) methotrexate sodium injection without preservative, which can be used for intravenous, intraarteriolar, intrathecal, and high-dose administration; and (4) lyophilized powder, which is provided in 20-mg vials and is reconstituted with preservative-free sodium chloride or 5% dextrose in water to a final concentration not exceeding 25 mg/mL.

For intrathecal administration, solutions of 1 to 1.5 mg/mL should be prepared using preservative-free 0.9% sodium chloride as the diluent. For high-dose therapy, leucovorin rescue is required to prevent significant toxicity. Leucovorin is administered 12 to 24 hours after methotrexate at a dose of between 15 and 25 mg intravenously, intramuscularly, or orally every 6 hours until the methotrexate dose declines to levels of less than 5×10^{-7} M.

For patients receiving intermediate or high-dose methotrexate (e.g., ≥500 mg/m^2), serum methotrexate and creatinine levels should be monitored at 24-hour intervals. If, after 48 hours, serum methotrexate levels are greater than 5×10^{-7} M but less than 1×10^{-6} M, leucovorin is continued at a dose of 25 mg/m^2 every 6 hours for eight doses until methotrexate levels decline to below 5×10^{-7} M. If levels are greater than 1×10^{-6} M but less than 2×10^{-6} M at 48 hours, the dose of leucovorin is increased to 100 mg/m^2 every 6 hours for eight doses. For methotrexate levels ≥2×10^{-6} M at 48 hours, the dose of leucovorin is 200 mg/m^2 every 6 hours for eight doses.

Toxic Effects: Methotrexate primarily exhibits its toxic effects toward proliferating tissues. Consequently, dose-limiting toxicities include bone marrow suppression (leukopenia, thrombocytopenia, anemia), mucositis, and diarrhea. High-dose therapy is occasionally accompanied by transient elevations in liver function test results, but chronic low-dose therapy is more often associated with hepatic fibrosis. Standard-dose therapy is rarely associated with nephrotoxicity, but acute renal failure can be seen with high-dose therapy secondary deposition of 7-*OH*-methotrexate in the renal tubules. The risk of methotrexate nephrotoxicity is significantly reduced by ensuring adequate hydration and alkalinization of the urine. Other reported toxicities include a maculopapular rash and an idiosyncratic pulmonary toxicity characterized by cough, fever, dyspnea, hypoxia, and interstitial infiltrates.

A necrotizing leukoencephalopathy has been reported in patients receiving methotrexate who have had prior cranial irradiation. Intrathecal methotrexate has been associated with several toxicities, including (1) chemical arachnoiditis; (2) motor paralysis accompanied by cranial nerve dysfunction, seizures, and coma; and (3) chronic demyelinating syndrome. Each of these may be exacerbated by prior craniospinal irradiation.

Potential Drug Interactions: Methotrexate exhibits many potential drug interactions that are related to plasma protein binding. For example, many compounds are known to displace methotrexate from serum albumin, potentially increasing its bioavailability. These agents include sulfonamides, salicylates, tetracyclines, chloramphenicol, and phenytoin. However, the clinical implications of such interactions are not clear. Nonsteroidal antiinflammatory drugs should not be administered in conjunction with methotrexate when the latter is given at intermediate or high doses owing to the potential for elevation and prolongation of methotrexate plasma concentrations. Penicillins can reduce renal clearance of methotrexate and should be used with caution in this setting. Probenecid may also reduce renal transport of methotrexate. Administration of methotrexate can also reduce the clearance of theophyllines, and concomitant use of these agents requires careful monitoring. Increases in methotrexate toxicity have been observed in some patients receiving trimethoprim–sulfamethoxazole, possibly as a consequence of enhanced antifolate effects. Administration of folates in vitamin preparations may reduce the efficacy of methotrexate by bypassing dihydrofolate reductase inhibition. Methotrexate may increase the toxicity (and potentially the activity) of various antineoplastic agents in a schedule-dependent manner (e.g., when given before 5-fluroracil).

Therapeutic Indications in Hematology: Methotrexate is widely used in the treatment of acute lymphoblastic leukemia (ALL), particularly in the maintenance phase. Methotrexate is frequently administered intrathecally in patients with CNS leukemia and prophylactically in certain patients with ALL. It also represents a component of various multidrug regimens used in the treatment of non-Hodgkin lymphoma (e.g., M-BACOD, PROMACE-CYTABOM).

HYDROXYUREA

Chemistry and Mechanism of Action: Hydroxyurea is an inhibitor of the ribonucleotide reductase system that catalyzes the rate-limiting step in the de novo biosynthesis of purine and pyrimidine deoxyribonucleotides, that is, the conversion of ribonucleotide diphosphates to their deoxyribonucleoside diphosphate derivatives. Ribonucleotide reductase consists of two subunits: a binding and allosteric effector component and an iron-binding catalytic component. Hydroxyurea binds to and inactivates the catalytic subunit of the enzyme. Similar to most antimetabolites, hydroxyurea is an S phase–specific agent and blocks cells in the G_1S phase of the cell cycle. Exposure of cells to hydroxyurea leads to a depletion of deoxyribonucleotide triphosphate (dNTP) pools, the extent of which correlates with DNA synthesis inhibition and cell death. Two consequences of hydroxyurea administration include potentiation of the metabolism or cytotoxicity of nucleoside analogs (e.g., ara-C) as a result of dNTP pool depletion and elimination of amplified genes present extrasomally in double minute chromosomes.

Absorption, Fate, and Excretion: Hydroxyurea is generally administered orally, although IV regimens are currently being investigated. The drug is readily absorbed from the gastrointestinal tract, with peak plasma levels as high as 2.0 mM occurring approximately 2 hours after oral administration. Serum concentrations decline to undetectable levels after 24 hours. The drug is primarily excreted via the renal route, with 75% to 80% of the drug appearing in the urine 12 hours later. The drug penetrates the cerebrospinal fluid, although it has not been established that therapeutic levels are achieved after standard oral administration.

Preparation and Administration: Hydroxyurea is provided as 500-mg capsules. The drug is stored at room temperature in tightly capped containers and protected from heat.

Toxic Effects: The most common adverse reactions include myelosuppression (leukopenia, thrombocytopenia, anemia), gastrointestinal symptoms (e.g., nausea and vomiting, stomatitis, anorexia, appetite disturbances), and dermatologic toxicity (e.g., rashes, skin ulcerations, facial erythema). Rarer toxicities, generally seen at high doses include neurologic disturbances, such as drowsiness, dizziness, headache, and convulsions; altered renal function; and alopecia. The mutagenic potential of hydroxyurea is unknown, and the drug should be avoided when possible in pregnant women.

Potential Drug Interactions: As noted earlier, hydroxyurea may increase the toxicity of certain nucleoside analogs. Hydroxyurea may also serve as a radiosensitizing agent; consequently, patients receiving concurrent radiation therapy may experience enhanced toxicity.

Therapeutic Indications in Hematology: Hydroxyurea has become, along with interferon-α, the mainstay of therapy in patients with chronic or accelerated phase chronic myeloid leukemia (CML). It is currently recommended for initial therapy of CML over busulfan and may prolong the chronic phase of this disease compared with the latter agent. Hydroxyurea has also been successfully used in the treatment of other myeloproliferative disorders, including myeloid metaplasia and myelofibrosis, polycythemia vera, and essential thrombocytosis. Its leukemogenic potential is uncertain, however, and it should be used with caution, particularly in younger patients. Hydroxyurea has also been shown to reduce the incidence of painful crises in individuals with sickle cell anemia in a subset of patients, a phenomenon that may result from increases in red blood cell fetal hemoglobin levels.

FLUDARABINE

Chemistry and Mechanism of Action: Fludarabine phosphate is a fluorinated derivative of the nucleotide analog 9′-β-D-arabinofuranosyladenine (ara-A) that is resistant to deamination by the degradative enzyme cytidine deaminase. It is converted intracellularly to its triphosphate derivative, which inhibits ribonucleotide reductase, as well as DNA polymerase α and DNA primase. Fluoro-ara-ATP is also incorporated into DNA, a process that appears to be essential for the induction of apoptosis in leukemic cells. Fludarabine is toxic to S-phase cells, but its ability to interfere with DNA repair may contribute to lethality in their noncycling counterparts.

Absorption, Fate, and Excretion: After IV injection, fludarabine phosphate is rapidly deaminated (i.e., within minutes) in the plasma to its nucleoside derivative, 2′-fluoro-ara-A, which is then converted intracellularly to its nucleotide form, 2′-fluoro-ara-AMP by the pyrimidine salvage pathway enzyme, deoxycytidine kinase. The half-life of 2′-fluoro-ara-A is approximately 10 hours; the primary mode of elimination is renal, with 25% of the total dose appearing in the urine as unchanged 2-fluoro-ara-A. Total body clearance of fludarabine is inversely correlated with serum creatinine.

Preparation and Administration: Fludarabine is supplied as a sterile powder in 50-mg vials containing 50 mg of mannitol and sodium hydroxide to adjust the pH to 7.7. Material is reconstituted in 2 mL of sterile water to yield a 25 mg/mL solution for injection. The material may be stored at 4° C (40° F); because the reconstituted solution contains no antimicrobial preservative, the drug should be administered within 8 hours of formulation.

Toxic Effects: The most common dose-limiting toxicity is myelosuppression (neutropenia, thrombocytopenia, and anemia). Other toxicities include fever, chills, infection, nausea, and vomiting. Rarer toxicities include malaise, fatigue, anorexia, and weakness. Patients with chronic lymphocytic leukemia (CLL) receiving fludarabine have experienced serious opportunistic infections and tumor lysis syndrome. The most serious toxicity of fludarabine when administered at high doses (>40 mg/m^2/day for 5 days) is irreversible neurotoxicity, including cortical blindness, necrotizing leukoencephalopathy, and death. This phenomenon has rarely, if ever, been seen in patients receiving conventional doses (e.g., 25 mg/m^2/day for 5 days). Rare reports of interstitial pneumonitis have appeared.

Potential Drug Interactions: Fludarabine has been shown to potentiate the intracellular metabolism and activity of ara-C, although the toxicity of this combination may also be enhanced. No other interactions have been reported.

Therapeutic Indications in Hematology: Fludarabine has shown marked activity in both untreated CLL and in disease refractory to standard alkylating agent therapy. Fludarabine has also shown activity as a single agent, and particularly in combination with others (e.g., mitoxantrone, Cytoxan) in indolent non-Hodgkin lymphoma.

2′-CHLORODEOXYADENOSINE

Chemistry and Mechanism of Action: 2′-Chlorodeoxyadenosine (CdA; cladribine) is a derivative of deoxyadenosine that differs from its parent compound by the presence of a chlorine moiety at the 2′-position of the purine ring. It is transported intracellularly by facilitated nucleoside diffusion and phosphorylated by the pyrimidine salvage pathway enzyme deoxycytidine kinase. CdA is relatively resistant to deamination by cytidine deaminase. CdA is readily converted to its triphosphate derivative, 2′-chlorodeoxyadenosine-5′-triphosphate, particularly in cells of lymphoid origin, and is incorporated into tumor cell DNA by DNA polymerase α. CdATP is also an effective inhibitor of ribonucleotide reductase, which may contribute to lethal effects. CdA induces cell death (apoptosis) in both cycling and noncycling cells, possibly by promoting DNA fragmentation and by depleting cells of adenosine triphosphate or NAD, or both.

Absorption, Fate, and Excretion: Relatively little pharmacokinetic information concerning CdA is available. The drug is most commonly administered as a 7-day continuous infusion or as a 2-hour infusion over 5 days. The bioavailability of CdA after subcutaneous administration approximates that of the IV route but is less than that after oral administration. Renal excretion appears to be the major route of elimination. When given as a 2-hour infusion, CdA has a relatively long terminal half-life (e.g., ≈6 hours), and plasma concentrations after such a schedule may approximate those associated with the continuous infusion. Cerebrospinal fluid levels are approximately 25% of plasma concentrations.

Preparation and Administration: For daily infusions, CdA is diluted under sterile conditions in bags containing 500 mL of 0.9% sodium chloride injection, USP. The use of 5% dextrose solutions is not recommended because of enhanced degradation of the drug. For preparation of longer infusions (e.g., 7 days) the use of bacteriostatic sodium chloride injection, USP, is recommended. After being prepared, solutions of CdA should be refrigerated at a temperature between 4° C (40° F) and 8° C (47° F) for no more than 8 hours before administration.

Toxic Effects: The major toxicity of CdA is myelosuppression, which is primarily observed after intermittent rather than continuous infusion. Other toxicities include fever, generally beginning several days after initiation of therapy, and increased susceptibility to opportunistic infections. Rare side effects include nausea and hepatic and renal toxicity.

Potential Drug Interactions: None reported.

Therapeutic Indications in Hematology: CdA has shown significant activity in CLL and hairy cell leukemia. However, response rates in the former disorder appear to be somewhat less than those obtained with fludarabine; moreover, patients who have progressed on fludarabine therapy infrequently respond to CdA. Other diseases in which CdA has shown activity include non-Hodgkin lymphoma and Waldenström macroglobulinemia.

2′DEOXYCOFORMYCIN (PENTOSTATIN; DCF)

Chemistry and Mechanism of Action: 2′-Deoxycoformycin is an adenosine analog that is a highly effective inhibitor of the purine biosynthetic enzyme adenosine deaminase (ADA). It is transported across cell membranes by facilitated nucleoside diffusion, where it binds tightly to ADA. Inhibition of ADA results in accumulation of deoxyadenosine metabolites, most notably dATP. dATP exerts its toxic effects through inhibition of ribonucleotide reductase and induction of global imbalances in deoxyribonucleotide triphosphate pools. These result in interference with DNA synthesis and repair. 2′-Deoxycoformycin is particularly toxic to certain lymphoid cells with low levels of ADA activity. It is also toxic to both cycling and resting cells; the mechanism underlying its cytotoxicity toward quiescent cells is unknown.

Absorption, Fate, and Excretion: After IV injection of 2′-deoxycoformycin, the plasma clearance follows a biphasic pattern, with a terminal elimination half-life of 3 to 15 hours. Protein binding is limited. The drug is only partially metabolized, with approximately 60% to 80% of the drug appearing unchanged in the urine after 24 hours. The total body clearance of 2′-deoxycoformycin correlates well with creatinine clearance. Patients with impaired renal function may require reductions in the 2′-deoxycoformycin dose.

Preparation and Administration: 2′-Deoxycoformycin is unstable when reconstituted in solutions of pH less than 5.0. Consequently, it is customarily reconstituted in normal saline. 2′-Deoxycoformycin is provided in vials containing 10 mg of drug, 50 mg of mannitol, and sodium hydroxide to adjust the pH to less than 7.0. It is administered as an IV infusion over 20 to 30 minutes. Hydration is recommended before and after 2′-deoxycoformycin administration.

Toxic Effects: The major toxicities of 2′-deoxycoformycin include myelosuppression, nausea and vomiting, immunosuppression, acute renal failure, keratoconjunctivitis, fever, and elevations of liver function enzymes. At high doses, neurologic toxicity, including somnolence, seizures, and coma, have been reported, although these are seen infrequently in patients receiving standard dose therapy. When administered at such doses (e.g., 4 mg/m^2 biweekly), side effects are relatively minor.

Potential Drug Interactions: 2′-Deoxycoformycin may augment the toxicity of ara-A (vidarabine) as a consequence of inhibition of ADA.

Therapeutic Indications in Hematology: 2′-Deoxycoformycin is primarily used in the treatment of hairy cell leukemia, in which response rates of up to 90% have been reported, even in patients refractory to other therapy, including α-interferon. Activity has also been reported in other lymphoid malignancies, such as T-cell lymphoma, chronic lymphocytic leukemia, prolymphocytic leukemia, and Waldenström macroglobulinemia, although its precise role in the treatment of these disorders remains to be fully evaluated.

6-THIOGUANINE

Chemistry and Mechanism of Action: Thioguanine (6-TG) is a guanine analog in which the 6′-hydroxyl group is replaced by a sulfhydryl group. It interferes with de novo purine biosynthesis at multiple levels. After transport across the cell membrane by facilitated diffusion, 6-TG competes with hypoxanthine and guanine for phosphorylation by hypoxanthine–guanine phosphoribosyltransferase (HGPRT) and is converted to its nucleotide form, 6-thioguanylic acid (TGMP), which accumulates within cells. TGMP inhibits several purine biosynthetic enzymes, including glutamine-5-phosphoribosylpyrophosphate aminotransferase and IMP dehydrogenase. 6-TG nucleotides are also incorporated in DNA and RNA, where they function as fraudulent bases. It is presently unknown which of these actions (interference with purine interconversions, blockade of de novo purine biosynthesis, or nucleic acid incorporation) is primarily responsible for 6-TG cytotoxicity, although DNA incorporation appears to play a significant role. 6-TG is considered to be an S phase–specific agent.

Absorption, Fate, and Excretion: After oral administration, the bioavailability of 6-TG is variable, ranging from 14% to 46% of the administered dose (mean, 30%). Peak plasma levels are achieved 8 hours after administration and decline slowly thereafter. The average plasma disappearance of 6-TG is approximately 80 minutes, with a range of 25 to 240 minutes. Relatively little unchanged material appears in the urine; the major excreted product is the methylated derivative 2-amino-6-methyl thiopurine. Central nervous system penetrance after parenteral administration is minimal.

Preparation and Administration: 6-TG is available in tablet form for oral administration. Each tablet contains 40 mg of 6-TG and inactive ingredients, including gum acacia, lactose, magnesium stearate, potato starch, and stearic acid. IV preparations are available only in experimental settings.

Toxic Effects: The major dose-limiting toxicity of 6-TG is myelosuppression. Other less common toxicities include gastrointestinal disturbances (nausea and vomiting, anorexia, diarrhea), jaundice, and elevated liver function test results.

Potential Drug Interactions: In contrast to 6-MP, the metabolism of 6-TG is not modified by allopurinol; consequently, dose adjustments do not have to be made when these agents are administered concurrently.

Therapeutic Indications in Hematology: The primary indication for 6-TG is in the treatment of acute myeloid leukemia, generally in conjunction with other agents (e.g., daunorubicin and ara-C). However, it has not been firmly established that addition of 6-TG to such regimens improves therapeutic efficacy. 6-TG also has activity in chronic myeloid leukemia, although it has been supplanted by other agents (e.g., hydroxyurea, interferon-α) in this disorder.

6-MERCAPTOPURINE

Chemistry and Mechanism of Action: 6-Mercaptopurine (1,7-dihydro-6*H*-purine 6-thione monohydrate; 6-MP; purinethol) is an analog of the purine bases adenine and hypoxanthine. It is both an antineoplastic and immunosuppressive agent. Similar to 6-TG, 6-MP and its metabolites act at multiple levels to interfere with purine biosynthesis and interconversions. It competes with hypoxanthine and guanine for HGPRTase, and after conversion to thioinosinic acid (TIMP), blocks conversion of IMP to xanthylic acid and IMP to AMP. Both TIMP and another metabolite, 6-methylthioinosinate (MTIMP) inhibit glutamine-5-phosphoribosylpyrophosphate aminotransferase. 6-MP is also incorporated into RNA and DNA, thereby functioning as a fraudulent base. It is unknown which of these actions is primarily responsible for the lethal actions of 6-MP, although available evidence points to DNA incorporation as a prime determinant of cytotoxicity.

Fate, Absorption, and Excretion: After oral administration, the bioavailability of 6-MP is highly variable, presumably because of interpatient differences in gastrointestinal absorption, which averages 50% of the administered dose. Extensive catabolism by hepatic xanthine oxidase also contributes to drug elimination. Approximately 50% of the administered 6-MP or its metabolites are recovered in the urine. The volume of distribution generally exceeds the total body water. After IV administration, the plasma disappearance half-life was 47 minutes in adults. Plasma protein binding is modest (≡19%), and central nervous system penetrance is minimal.

Preparation and Administration: 6-MP is supplied as tablets for oral administration. Each tablet contains 50 mg of 6-MP and the inactive ingredients corn and potato starch, lactose, magnesium stearate, and stearic acid. An IV preparation containing 500 mg of 6-MP per vial is available for investigational use.

Toxic Effects: The major dose-limiting toxicity of 6-MP is myelosuppression. This is dose related and is manifested by leukopenia, thrombocytopenia, and anemia. The hematologic effects of 6-MP may be delayed, so it is important to withdraw the medication temporarily at the first sign of unusual hematologic toxicity. Individuals with an inherited disorder of thiopurine methyltransferase deficiency may be particularly susceptible to 6-MP–mediated hematopoietic suppression. Other toxicities include hepatotoxicity (elevated liver function test results, cholestasis, hepatic necrosis, ascites), nausea, vomiting, mucositis, fever, rash, and diarrhea. The hepatotoxicity, which occurs in 10% to 40% of patients, requires close monitoring and discontinuation of therapy until recovery occurs. Patients receiving 6-MP uniformly experience immunosuppression.

Potential Drug Interactions: Allopurinol, an inhibitor of xanthine oxidase, significantly reduces the catabolism of 6-MP when the latter is given orally, leading to major increases in plasma concentrations. Allopurinol does not alter the pharmacokinetics of IV 6-MP, presumably because of the absence of first-pass metabolism of 6-MP when administered by this route. When administered in conjunction with allopurinol, the dose of 6-MP should be reduced by one-third to one-fourth. Increased toxicity has been reported in patients receiving concurrent 6-MP and trimethoprim–sulfamethoxazole. 6-MP may also modify the effects of warfarin.

Therapeutic Indications in Hematology: The major use for 6-MP is in the maintenance phase of treatment for acute lymphoblastic leukemia. 6-MP has also been used in the treatment of patients with immune thrombocytopenia purpura or autoimmune hemolytic anemia refractory to all other forms of therapy.

5-AZACITIDINE

Chemistry and Mechanism of Action: 5′-Azacitidine is an analog of the nucleoside cytidine, differing from the parent compound by virtue of the presence of nitrogen at the 5′ position of the heterocyclic ring. 5′-Azacytidine is transported across the cell membrane by facilitated nucleoside diffusion and is converted to its nucleotide monophosphate form, 5′-aza-CMP, by the pyrimidine salvage pathway enzyme uridine–cytidine kinase. 5′-Azacytidine is also a substrate for the degradative enzyme cytidine deaminase. It is ultimately converted to its lethal derivative, 5′-aza-CTP, which is incorporated into RNA, and to a lesser extent, DNA. The lethal actions of 5′-azacytidine are believed to result from its ability to interfere with protein synthesis through disruption of RNA processing. The chemical instability of the 5′-azacitidine ring structure is also believed to contribute to the cytotoxicity of this compound.

Absorption, Fate, and Excretion: The drug distributes into a volume corresponding to the total body water after IV administration and is also well absorbed after subcutaneous injection.

It is extensively deaminated in the plasma and liver and displays minimal plasma binding. Peak plasma concentrations after IV injection approximate 1.0 mM. The initial half-life of 5′-azacitidine (or its metabolites) is approximately 4 hours, although the drug is rapidly converted to various derivatives within minutes of administration. There is minimal cerebrospinal fluid penetrance.

Preparation and Administration: Azacitidine is available in 100-mg vials and can be administered both intravenously and subcutaneously When given subcutaneously, it should be reconstituted with 4 mL of sterile water for injection. The diluents should be injected slowly into the vial. Vigorously shake or roll the vial until a uniform suspension is achieved. The suspension will be cloudy. The resulting suspension will contain azacitidine 25 mg/mL. Do not filter the suspension after reconstitution. Doing so could remove the active substance. Azacitidine reconstituted for subcutaneous administration may be stored for up to 1 hour at 25° C (77° F) or for up to 8 hours between 2° C and 8° C (36° F and 46° F).To provide a homogeneous suspension, the contents of the dosing syringe must be resuspended immediately before administration. To resuspend, vigorously roll the syringe between the palms until a uniform, cloudy suspension is achieved. When given intravenously, reconstitute each vial with 10 mL of sterile water for injection. Vigorously shake or roll the vial until all solids are dissolved. Withdraw the required amount of solution to deliver the desired dose and inject into a 50- to 100-mL infusion bag of either 0.9% sodium chloride injection or lactated Ringer solution.

Toxic Effects: The major toxicity of 5′-azacitidine has been leukopenia and, to a lesser extent, thrombocytopenia. Nausea and vomiting, which are often refractory to standard antiemetic therapy, have also been encountered, most frequently in patients receiving bolus infusions. Gastrointestinal toxicity is ameliorated by administering 5′-azacitidine as a continuous infusion. Other potential side effects include diarrhea, fever, hepatotoxicity (most frequently in patients with preexisting hepatic disease), neuromuscular toxicity, rash, and hypotension.

Drug Interactions: None reported.

Therapeutic Indications in Hematology: 5′-Azacitidine is primarily used in the treatment of refractory acute myeloid leukemia, with response rates ranging from 17% to 30% when used as a single agent. 5′-Azacitidine has also yielded clinical responses in a subset of patients with the myelodysplastic syndrome when administered as a low-dose continuous infusion. In early trials, low-dose 5′azacytidine has increased fetal hemoglobin levels in some patients with sickle cell anemia and thalassemia; however, its mutagenic potential has limited the use of this agent in nonmalignant conditions.

DECITABINE

Chemistry and Mechanism of Action: Decitabine is a synthetic nucleoside analog of 2′-deoxycytidine, a cytotoxic S-phase pyrimidine analogue that induces hypomethylation of DNA at concentrations that do not cause major suppression of DNA synthesis. It also causes cellular differentiation or apoptosis. This is accomplished by intracellular phosphorylation of decitabine to its triphosphate form, which is incorporated into DNA and blocks methylation of newly synthesized DNA by binding to DNA methyltransferase. Nonproliferating cells seem relatively insensitive to decitabine.

Absorption, Fate, and Excretion: Decitabine is widely distributed with less than 1% protein binding and is tolerated after subcutaneous injection. There is some central nervous system penetration after subcuaneous injection with cerebrospinal fluid concentrations in patients with meningeal leukemia that were approximately 20% of corresponding steady-state plasma levels. The mean half-life is 0.5

to 0.6 hours. The route of metabolism appears to be deamination by cytidine deaminase, principally found in the liver but also in granulocytes, intestinal epithelium, and whole blood.

Preparation and Administration: Decitabine is available in 50-mg vials, which are reconstituted with 10 mL of sterile water for injection (USP); upon reconstitution, each milliliter contains approximately 5.0 mg of decitabine at a pH of 6.7 to 7.3. Immediately after reconstitution, the solution should be further diluted with 0.9% sodium chloride injection, 5% dextrose injection, or lactated Ringer solution injection to a final drug concentration of 0.1 to 1.0 mg/mL. Unless used within 15 minutes of reconstitution, the diluted solution must be prepared using cold (2°-8°C) infusion fluids and stored at 2° to 8°C (36°-46°F) for up to a maximum of 7 hours until administration.

Toxic Effects: The major toxicity of decitabine has been bone marrow suppression, including leukopenia, thrombocytopenia and anemia. Nausea and vomiting are mild. Other potential side effects include diarrhea; fever; and hepatotoxicity, including hyperbilirubinemia, transamination elevations, and electrolyte abnormalities.

Drug Interactions: None reported.

Therapeutic Indications in Hematology: Decitabine is indicated for treatment of patients with myelodysplastic syndromes (MDS) including previously treated and untreated, de novo, and secondary MDS. It has also been used as salvage therapy both alone and in combination for acute myeloid leukemia, chronic myeloid leukemia, and acute lymphoid leukemia.

GEMCITABINE
